
added to the resonance stabilization of the free base structure. In the case of the corresponding Homolka bases of the triphenylmethane dyes the normal steric repulsion of the ortho hydrogens is not released, nor does the possibility of intramolecular chelation exist. A consideration of the geometry of the resonating ions, therefore, gives us two factors which account for the ready formation of free bases in the pyrrole series and the relative instability of the Homolka bases of the triphenylmethane dyes.

The authors are indebted to the Rockefeller Foundation for a research grant which has made this investigation possible.

Experimental Section

Preparation of 3,5,3′,5′-Tetramethyl-4,4′-dicarbethoxydipyrrylmethene Hydrobromide (V).—A solution of 0.350 g. of 3,5,3′,5′-tetramethyl-4,4′-dicarbethoxydipyrrylmethane (II) in 500 cc. of dry carbon tetrachloride was prepared by refluxing the finely divided methane in the solvent for several hours. After the solution had been brought to room temperature 0.16 g. of bromine in 2 cc. of carbon tetrachloride was run in quickly while the flask was twirled. The solution was allowed to stand in the ice box overnight, after which time 0.390 mg. of fine red needles (92% of the theoretical) was filtered from the solution. The free base (VI) was obtained by shaking a chloroform solution of the hydrobromide salt with calcium hydroxide. The long red needles were recrystallized from benzene–hexane; m. p. (dec.) 189–190°.

3,3′-Dicarbethoxy-4,5,4′,5′-tetramethyldipyrrylmethene Hydrobromide (VII).—A solution of 1 g. of the corresponding dipyrrylmethane[20,21] in 100 cc. of dry carbon tetrachloride was placed in a 200-cc. Erlenmeyer flask; 0.51 g. of bromine in 5.1 cc. of carbon tetrachloride was run in quickly while the flask was twirled and the solution was allowed to stand several hours in the ice box; 0.910 g. of deep red crystals was obtained on filtration. Addition of petroleum ether to the mother liquors gave an additional 0.150 g. of the methene salt; total yield, 87%. The free base VIII was prepared by shaking a chloroform solution of the hydrobromide salt with calcium hydroxide.[22,23] Recrystallization from benzene–hexane gave beautiful orange-red crystals; m. p. (dec.) 164–165°.

3,4,3′,4′-Tetramethyl-5,5′-dicarbethoxydipyrrylmethene Hydrobromide (IX).—The corresponding dipyrrylmethane[24,25] (5 g.) was dissolved in one liter of dry carbon tetrachloride. After the solution had been brought to room temperature, 2.55 g. of bromine in 25.5 cc. of carbon tetrachloride was added rapidly with stirring. A rich crop of brilliantly colored crystals appeared in a few minutes. After cooling in an ice box 5.9 g. of fine red needles was filtered off; yield, 96%. The dipyrrylmethene salt decomposed at 160–165°. *Anal.* Calcd. for $C_{19}H_{25}N_2O_4Br$: C, 53.65; H, 5.93. Found: C, 53.64; H, 5.94. All attempts to prepare the free base yielded the dipyrrylcarbinol (X).

3,4,3′,4′-Tetramethyl-5,5′-dicarbethoxydipyrrylcarbinol (X).—The corresponding dipyrrylmethene salt (1 g.) was suspended in about 50 cc. of water, the mixture shaken thoroughly and allowed to stand overnight. The brilliant red color of the suspended crystals faded slowly until after six hours only a faint pink remained. The easily filtrable precipitate weighed 0.830 g. Recrystallization from benzene yielded a beautiful white compound melting with decomposition at 185–186°. *Anal.* Calcd. for $C_{19}H_{26}N_2O_5$: C, 62.97; H, 7.23. Found: C, 63.25; H, 7.18.

3,4,3′,4′-Tetramethyl-5,5′-dicarbethoxydipyrrylcarbinol Methyl Ether (XI).—The corresponding dipyrrylmethene salt (IX) (200 mg.) was dissolved in boiling anhydrous methanol. The red color of the methene disappeared rapidly and on cooling, 150 mg. of pearly crystals precipitated; yield, 85%. The material melts sharply with decomposition at 169–170°. *Anal.* Calcd. for $C_{20}H_{28}N_2O_5$: C, 63.81; H, 7.50. Found: C, 63.93; H, 7.46.

Both the dipyrrylmethyl carbinol (X) and the dipyrrylmethyl methyl ether (XI) described above may be converted back to the corresponding dipyrrylmethene hydrobromide (IX) by dissolving them in dry carbon tetrachloride and saturating the solution with dry gaseous hydrogen bromide. The identity of the methene salt was checked by analysis.

3,5,4′-Trimethyl-4,3′,5′-tricarbethoxydipyrrylmethene Hydrobromide (XII).—The corresponding dipyrrylmethane[26,27] (500 mg.) was dissolved in 500 cc. of dry carbon tetrachloride; 0.2 g. of bromine in 5 cc. of carbon tetrachloride was added quickly with stirring at room temperature. After standing several hours in the cold 500 mg. of fine orange red needles was filtered from the solution; yield, 83%. Conversion of the methene salt to the base (XIII) by the method described above gave a compound identical with the methene base prepared by several independent methods; m. p. (dec.) 125–126°.

3,5,4′-Trimethyl-4,3′,5′-tricarbethoxydipyrrylcarbinol Methyl Ether (XIV).—This compound was prepared by the method described by Corwin and Andrews.[28]

3,3′,5,5′-Tetracarbethoxy-4,4′-dimethyldipyrrylmethyl Bromide (XV).—A solution of 10 g. of the corresponding dipyrrylmethane[26,29,30] (thoroughly desiccated) in one liter of dry carbon tetrachloride was prepared in a 1.5 liter filter flask equipped with a one-holed rubber stopper containing a calcium chloride drying tube. The sidearm of the filter flask was tightly sealed with a piece of rubber tubing and a screw clamp; 3.5 g. of bromine in 35 cc. of dry carbon tetrachloride was run in rapidly with stirring and the flask quickly stoppered. The addition of the bromine caused no cloudiness and the color of the solution was simply that of the added bromine. Even after six hours an appreciable amount of bromine remained unreacted. After standing twenty-four hours the stopper was replaced by a rubber stopper containing a capillary with a drying tube attached to the end. The flask was then hooked up to a water pump by means of an intervening drying tube, and the carbon tetrachloride removed at room temperature. The slightly colored crystalline residue was recrystallized from dry benzene–hexane (purified); yield, 10.6 g. or 90%. Repeated recrystallization from benzene–hexane gave 8.0 g. of analytically pure compound; m. p. (dec.) 132–133°. The compound turns pink at 128–130°. *Anal.* Calcd. for $C_{23}H_{29}N_2O_8Br$: C, 51.02; H, 5.40; Br, 14.26. Found: C, 51.09; H, 5.42; Br, 15.45 (± 1%).

In the process of purification it was observed that benzene solutions of the dipyrrylmethyl bromide (XV) became highly colored when heated to the boiling point of benzene; on cooling, this color disappears. The same phenomenon was reported by Gomberg for the tritolylmethyl halides in benzonitrile.[31] It was also observed that cold colorless solutions of the dipyrrylmethyl bromide were capable of imparting a definite orange-red color to filter paper and to textiles in general. The color imparted to wool was the most intense.

When the dipyrrylmethyl bromide was dissolved in concentrated sulfuric acid only a weak coloration occurred. Chloroform solutions on the other hand became intensely colored when anhydrous stannic chloride was added. This color vanished immediately when water was added to the solution. The assumed dipyrrylmethene hexachlorostannate salt (XVII) was not isolated.

1,3,5,1′,4′-Pentamethyl-4,3′,5′-tricarbethoxydipyrrylmethyl Bromide (XVIII).—A solution of 3.9 g. of the corresponding dipyrrylmethane[27] (thoroughly desiccated) was prepared in a 500-cc. Erlenmeyer flask. 1.47 g. of bromine in 14.7 cc. of carbon tetrachloride was run in rapidly while the flask was twirled. After the addition the flask was stoppered immediately, and then placed in a desiccator and allowed to stand overnight. After this time a small amount of red oil had collected on the sides of the flask; the solution itself was clear. The following operations were then carried out in a dry air chamber. A nitrogen tank with a glass top and arm holes served as a dry air chamber. Compressed air, conducted through a tall column of calcium chloride, was passed through the chamber for one-half hour before operations were begun and continued until completed. The solution was transferred to a one-liter flask equipped with a one-holed rubber stopper containing a capillary with a drying tube attached to the end. The filter flask was then hooked up to a water pump by means of an intervening drying tube and the carbon tetrachloride pumped off at room temperature. The pink colored crystalline residue, weighing 3.5 g., was placed in an Erlenmeyer flask equipped with a tight fitting rubber stopper. The crystals were then covered with dry benzene–hexane in the ratio of ten to one, the flask well stoppered, and removed from the dry air chamber. After replacing the stopper with an air reflux condenser equipped with a drying tube, the mixture was gently refluxed until solution was complete. The flask was once again stoppered with a drying tube, returned to the dry air chamber and allowed to stand until crystallization was complete. Soft almost colorless crystals were then painfully collected on a Büchner funnel in the dry air chamber. The material melted, turning blood red at 135–136°.

Anal. Calcd. for $C_{23}H_{31}N_2O_6Br$: C, 54.01; H, 6.11; Br, 15.63. Found: C, 54.28; H, 6.11; Br, 16.11 (± 1%). It is absolutely necessary to follow the above precautions for the exclusion of water vapor in order to obtain analytical material. By merely suspending the compound in water and filtering over fifty per cent. of the bromine is lost.

The dipyrrylmethyl bromide readily dissolves in concentrated sulfuric and perchloric acid to yield brilliantly colored solutions. Likewise, the same intense color is obtained when a chloroform solution of the bromide is treated with anhydrous stannic chloride. Dilution of the acid solutions and addition of water to the stannic chloride solution discharges the color.

1,3,5,1′,4′-Pentamethyl-4,3′,5′-tricarbethoxydipyrrylcarbinol Methyl Ether (XIX).—This derivative was obtained by simply dissolving the corresponding dipyrrylmethyl bromide in hot methanol and allowing the solution to cool. The compound was recrystallized several times from the same solvent; m. p. 93–94°. *Anal.* Calcd. for $C_{24}H_{34}N_2O_7$: C, 62.32; H, 7.41. Found: C, 62.48; H, 7.42.

Summary

1. The effect of substituents on the structure of the dipyrrylmethenes has been studied by comparing the properties of a variety of these pigments.

2. It has been shown that the ionic character of the dipyrrylmethene halides is strongly dependent on the nature and position of the substituents on the pyrrole rings.

3. Several new dipyrryl carbinols have been prepared.

4. Two colorless dipyrrylmethyl bromides have been synthesized. These compounds, which are analogous in structure and behavior to triphenylmethyl bromide, have not been observed heretofore in the pyrrole series.

5. It has been shown that steric interference of hydrogens or substituents ortho to the bridge carbon atom exerts a strong influence on the structure of both the triphenyl and dipyrrylmethane dyes.

6. The present observations on the dipyrrylmethenes and previously established data on the triphenylmethane series have been correlated on the basis of a common electronic interpretation. A comparison of the structural geometry of the two dye systems completes the relationship.

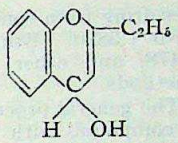
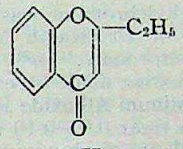
The Reduction of Ester Vinylogs[1]

BY ROBERT H. BAKER AND PATTY CAMPBELL WEISS

In an attempt to prepare 2-ethylchromen-4-ol, I, by methods more suitable than the one developed by Mozingo and Adkins,[2] it was observed that aluminum isopropoxide does not reduce 2-ethylchromone, II.[3] The failure of this reaction



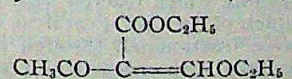
I



II

may be attributed to the fact that the ketone is a vinylog of an ester and hence has an oxidation potential which is numerically too far below that of acetone to allow it to oxidize isopropyl alcohol.[4]

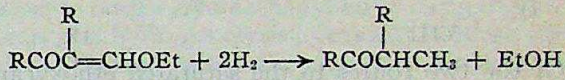
It appeared that open chain vinylogs might approach more nearly the properties of esters, and hence might exhibit alkoxyl exchange in the presence of aluminum alkoxides,[5] but no reaction of this type has been unequivocally demonstrated. Both 2-ethylchromone, II, and O-ethylbenzoylacetone, IV, were recovered unchanged after refluxing with isopropyl alcohol in the presence of aluminum isopropoxide. The latter compound was also unaffected by heating to 100° in the presence of pure aluminum *s*-butoxide. Ethyl α-ethoxymethyleneacetoacetate, III, was changed



III

by similar treatment but the only identifiable product was a small amount of a dimer and much tar was produced. This is not surprising in light of the ease of dimerization of methyl ketones[6] and the great instability of this compound when kept at room temperature.

The catalytic reduction of these compounds demonstrates the extraordinary lability of the alkoxyl group. Over palladium catalysts Kötz and Schaeffer[7] found that those which are easily hydrolyzed are hydrogenated according to the equation



In this reaction hydrogenolysis of the ethoxyl must precede the reduction of the ethylenic linkage, for there is no precedent for the reverse order which would require the hydrogenolysis of a saturated ether under mild conditions. It appeared that the hydrogenolysis reaction might be minimized and hydrogenation favored by use of catalysts less active than palladium which allow of greater selectivity. Some typical results of these experiments are shown in Table I.

TABLE I

SELECTIVE HYDROGENATION OF ESTER VINYLOGS

Compound	Temp., °C.	Time, min.	Cat.	Moles H_2 per mole cmpd.	% Product
Ethyl α-ethoxymethylene-acetoacetate	23	48[a]	Ni(R)	1.6	50 Ethyl α-methylaceto-acetate
Same	150	40[a]	CuCrO	0.8	Non-distillable tar

Same	120	120[a]	Ni(R)	1.0	64% Mixture of VI and β-ethoxybutyrophenone
Same	180	330	CuCrO	2.0	58 Butyrophenone, IX
Ethyl β-ethoxycrotonate	130	70	Ni(R)	0.9	86 Ethyl β-ethoxybutyrate
Same	170	120	CuCrO	0.6	45 Ethyl β-ethoxybutyrate

[a] Glass liner used.

Ethoxymethyleneacetoacetic ester, III, presents a very labile ethoxyl group, it being vinylogous to two carbonyl groups. Over nickel it underwent hydrogenolysis followed by hydrogenation of the carbon-to-carbon double bond under very mild conditions. Over copper–chromium oxide it is apparently polymerized before hydrogenation takes place.

In O-ethylbenzoylacetone, IV, the alkoxyl is vinylogous to only one carbonyl group, and it was possible to avoid hydrogenolysis with nickel or to make it the predominating reaction over copper–chromium oxide. Of the several ways that hydrogen might attack this molecule, the more plausible are shown below.

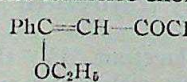
Of the two routes to the saturated ethoxycarbinol, VI, evidence that the preferred one is through the ethoxyketone, V, was obtained from experiments in which the hydrogen adding was limited to one mole. The boiling point of the ketone, V, is so near that of the alcohol, VI, that only the mixture was isolated; however, its presence was demonstrated in the mixture by polarographic and Grignard machine analysis. Evidence for the formation of the ethoxyvinyl carbinol, VII, was less conclusive, but its presence can hardly be discounted on the basis of the fact that nickel generally shows little preference for an ethylenic over a carbonyl linkage. Its presence was indicated by tests for unsaturation applied to some of the low boiling fractions resulting from various hydrogenations over nickel.

The third mode of hydrogenation leads to butyrophenone, IX, and this is brought about over copper–chromium oxide. No evidence for the formation of crotonophenone, VIII, was obtained, the runs with limited quantities of hydrogen seemingly resulting only in the production of butyrophenone.

Ethyl β-ethoxycrotonate presents a still less powerful group to activate the vinylogous ethoxyl and is hydrogenated entirely to β-ethoxybutyric ester over either of the two catalysts.

The structures of the products of hydrogenation of O-ethylbenzoylacetone, IV, confirm the structure originally claimed for this enol ether by Claisen,[8] and dispute the contention of Weygand[9] that regardless of the method of preparation the compound is the isomeric enol ether, X.



(X)

Experimental Part

Preparation of Compounds.—Ethyl α-ethoxymethyleneacetoacetate was prepared from one mole each of ethyl acetoacetate and acetic anhydride and two moles of ethyl orthoformate according to Claisen.[10] It was found to be desirable to distil the product rapidly from hydroquinone without the aid of a column. The product distilling at 149–151° (16 mm.) amounts to 76 g., 41%, and has $n^{20}D$ 1.4715–1.4720. It may be kept for a few weeks only if protected by hydroquinone at 0° and in the dark, one-half of it being destroyed by keeping under ordinary conditions at room temperature for one month.

O-Ethylbenzoylacetone was prepared by the method of Claisen.[8] A number of preparations indicated that seven minutes of refluxing of benzoylacetone and ethyl orthoformate with strictly dry ethyl alcohol and ferric chloride gives the best yield, 53% of product $n^{20}D$ 1.5610–1.5615, b. p. 119% (1 mm.), when distilled through a 16-plate column.

2-Ethylchromone was a sample resulting from some research of Dr. Ralph Mozingo,[2] $n^{25}D$ 1.5820. Ethyl β-ethoxycrotonate,[11] $n^{30}D$ 1.4471–1.4478, and other compounds were made by established methods.

Aluminum Alkoxide Reactions.—The general procedure was to treat 0.05–0.10 mole of the compound with three equivalents of aluminum alkoxide dissolved in its corresponding alcohol. Aliquots were taken at the beginning and after various periods of heating and analyzed polarographically. The height of the 2-ethylchromone wave[2,12] was not diminished after sixty hours of refluxing. The remainder of the solution after hydrolysis, isolation, and distillation through a 3-plate column yielded the major portion of unchanged 2-ethylchromone, $n^{25}D$ 1.5806.

The heights of the O-ethylbenzoylacetone wave[13] also showed that no reduction of this compound had occurred. After treatment with water and fractionation, the compound corresponded in boiling point and refractive index to starting material. As a further test to see if alkoxyl exchange is possible, this compound was heated with pure aluminum *s*-butoxide for two hours at 100°. Then just sufficient water was added to hydrolyze the alkoxide and the oil was isolated. This was distilled through a 3-plate micro column yielding fractions which appeared to be unchanged material. A small tail fraction was analyzed as follows:[14] Calcd. for O-ethylbenzoylacetone, $C_{12}H_{14}O_2$: C, 75.76; H, 7.41. Calcd. for O-*s*-butylbenzoylacetone, $C_{14}H_{18}O_2$: C, 77.03; H, 8.31. Found: C, 76.05; H, 7.67. Since the tail fraction represented 15% of the starting weight and the carbon analysis cannot admit of more than 25% of *s*-butyl derivative, the exchange in the whole fraction cannot have been greater than 4%, if any.

Ethyl α-ethoxymethyleneacetoacetate, when thus treated with aluminum isopropoxide in isopropyl alcohol, turned quite yellow after ten minutes at 60°. There was a sharp drop in the height of the polarographic wave which remained approximately equivalent to one-half of the original concentration after three hours. After treatment with water and isolation, there was obtained a viscous yellow oil 50% of which was distillable at 200–218° (1 mm.). This was an amber colored plastic mass which did not crystallize after standing a year. Its molecular weight, Rast, was 370, while that calculated for the starting material is 186.

Hydrogenations.—The catalysts, apparatus and procedures were similar to those which are particularly adapted to selective hydrogenations.[15,16] No solvents were used, and glass liners for the bombs appeared to be of no benefit except possibly in the case of ethyl α-ethoxymethyleneacetoacetate which reacted with metals to such an extent that much of the nickel catalyst was destroyed. The products were fractionated through either a 10- or 16-plate column and the recorded boiling points are subject to the usual errors attending slow fractionation through electrically heated, total condensation apparatus.

Identification of Hydrogenation Products.—Ethyl α-methylacetoacetate, $n^{21}D$ 1.5215, was converted into the

2,4-dinitrophenylhydrazone, m. p. 59°, and into ethyl methyl ketone the semicarbazone of which melted at 136°.[17]

β-Ethoxypropylphenylcarbinol has not been previously described. It has the following constants: b. p., 82.5° (1 mm.); $n^{21}D$ 1.4995; d^{20}_4 0.994; M_D, found, 56.8; M_D, calcd., 52.0; mol. wt., cryoscopic in benzene 202, cryoscopic in camphor 198; mol. wt. calcd., 194; % hydroxyl, found, 8.76, 8.75[18]; calcd., 8.76. The Baeyer and iodoform tests are negative. We are unable to explain the anomaly in molecular refractivity except on the basis that this product is in all probability a mixture of two racemic forms.

β-Ethoxybutyrophenone was thought to be present in the reaction mixture resulting from limited hydrogenation of O-ethylbenzoylacetone over nickel. Nine fractions boiling 94–110° (1 mm.) were collected from a 3-plate distillation. The first six of these, 94–100°, showed a gradual drop in refractive index, $n^{20}D$ 1.5137–1.5075 and represented 64% of the weight of starting material. The last two fractions $n^{20}D$ 1.5645 represented 11% recovery of crude starting material. Fraction number three gave negative tests with bromine and with permanganate, and the presence of an aryl ketone in approximately 50% concentration was demonstrated by the polarograph, $\pi = -1.68$. Assuming the mixture to be pure alcohol and ketone the Grignard machine analysis indicated 56% of alcohol of molecular weight 195 and 44% ketone of molecular weight 194. The calculated molecular weights of the expected ketone and alcohol, V and VI, are 194 and 196, respectively.

Butyrophenone, $n^{20}D$ 1.5127, showed a polarographic wave in lithium chloride solution at −1.68 volts (empirical). It gave a semicarbazone, m. p. 189–190°, and a 2,4-dinitrophenylhydrazone, m. p. 190°, in agreement with the literature.[17]

Ethyl β-ethoxybutyrate, $n^{20}D$ 1.4076; d^{20}_4 0.925; M_D found, 42.6, calcd., 42.4; had the correct boiling point at 745 mm., 173°.[19]

(18) Adkins, Frank and Bloom, THIS JOURNAL, **63**, 554 (1941).

Summary

1. Compounds which are open-chain vinylogs of esters are too much like esters to be reduced by aluminum alkoxides. They, however, are not sufficiently ester-like to undergo alkoxyl exchange with these reagents.

2. When the alkoxyl group is in a vinylogous position to both a keto-carbonyl and a carbethoxyl, it undergoes hydrogenolysis over nickel under very mild conditions. When the alkoxyl is vinylogous to only a keto-carbonyl it is more resistant to hydrogenolysis and the nature of the hydrogenation products may be controlled by selection of catalysts. The carbethoxyl group does not labilize such groups sufficiently to allow of hydrogenolysis prior to hydrogenation of the ethylenic linkage.

EVANSTON, ILL. RECEIVED OCTOBER 28, 1943

[CONTRIBUTION FROM THE DEPARTMENT OF CHEMISTRY, DUKE UNIVERSITY]

The Acetylation of Certain Unsymmetrical Aliphatic Ketones with Acetic Anhydride in the Presence of Boron Trifluoride[1,2]

BY CHARLES R. HAUSER AND JOE T. ADAMS

The acetylation of ketones with acetic anhydride in the presence of boron trifluoride to form 1,3-diketones has been carried out previously apparently only with ketones such as acetone,[3,4] diethyl ketone[3] or acetophenone,[3,5] each of which can yield but a single monoacetyl derivative. The purpose of this investigation has been to determine the products of acetylation, in the presence of boron trifluoride, of certain unsymmetrical aliphatic ketones each of which might form two different monoacetyl derivatives. Three types of unsymmetrical ketones have been studied, types I, II and III, represented below, with which it is possible to form, respectively, the methyl and methylene derivatives, the methyl and methinyl derivatives, and the methylene and methinyl derivatives, thus

$$\underset{\text{Type I}}{CH_3COCH_2R} \xrightarrow[BF_3]{Ac_2O} \underset{\text{Methyl deriv.}}{CH_3COCH_2COCH_2R} + \underset{\text{Methylene deriv.}}{CH_3COCHRCOCH_3}$$

$$\underset{\text{Type II}}{CH_3COCHR_2} \xrightarrow[BF_3]{Ac_2O} \underset{\text{Methyl deriv.}}{CH_3COCH_2COCHR_2} + \underset{\text{Methinyl deriv.}}{CH_3COCR_2COCH_3}$$

$$\underset{\text{Type III}}{RCH_2COCHR_2} \xrightarrow[BF_3]{Ac_2O} \underset{\text{Methylene deriv.}}{CH_3COCHRCOCHR_2} + \underset{\text{Methinyl deriv.}}{CH_3COCR_2COCH_2R}$$

Seven ketones have been acetylated, five of type I, methyl ethyl, methyl *n*-propyl, methyl isobutyl, methyl *n*-amyl and methyl *n*-hexyl ketones, and one each of types II and III, methyl isopropyl ketone and 2-methylcyclohexanone,[6] respectively. The yields of acetylation products isolated from these ketones were 28–59%, the

highest yields being obtained from methyl *n*-amyl and methyl *n*-hexyl ketones. Considerable amounts (15–25%) of the ketones were generally recovered and relatively little high boiling material was obtained. The only other product found was acetylacetone resulting from the self-condensation of the acetic anhydride as described previously.[3]

The acetylation products obtained from each of the ketones (except methyl ethyl ketone) were found to consist of a mixture of the two possible acetyl derivatives shown in the general equations represented above. A reasonably good separation of the isomeric 1,3-diketones has been realized by extracting ether solutions of the acetylation products with alkali, in which the methyl derivatives are relatively much more soluble than are the methylene derivatives, while the methinyl derivatives are insoluble in alkali. Essentially complete extraction of the methyl derivatives was indicated when the alkaline extracts no longer gave the red enol test (characteristic of the methyl derivatives),[7] but instead gave the purple enol test (characteristic of the methylene derivatives),[7] or gave no enol test (characteristic of isopropylacetylacetone[8] and the methinyl derivatives). Complete extraction of the methylene derivative of 2-methylcyclohexanone was indicated when the alkaline extract no longer gave the purple enol test. The methyl and methylene derivatives of ketones of type I were recovered with relatively little loss so that a fairly reliable estimate of the proportions in which these derivatives were present in the original acetylation products could be made. Alkali extractions of acetylation products from the ketones of types II and III, however, produced some cleavage apparently involving mainly the methinyl derivative. The proportions of the acetyl derivatives of methyl isopropyl ketone (type II) has been obtained by treating the original acetylation product with copper acetate, only the methyl derivative yielding a copper salt. This method has not been applicable to the acetylation product from 2-methylcyclohexanone (type III), since the copper salt of the methylene derivative could not be crystallized.

In Table I are given the relative percentages of the two isomeric acetyl derivatives comprising the original acetylation products. These values are probably reproducible within ±3% for the derivatives of the methyl *n*-alkyl ketones, within ±5% for the derivatives of methyl isobutyl ketone, and within ±10% for the derivatives of methyl isopropyl ketone and 2-methylcyclohexanone. Since the first alkaline extract of the acetylation product from methyl ethyl ketone gave the purple enol test we have concluded that this product consists essentially only of the methylene derivative.

The proportions of the two isomeric acyl derivatives produced from at least the ketones of type I are evidently independent of the anhydride used, since, in an investigation now in progress on the acylation of ketones with higher anhydrides, it has been found that methyl ethyl, methyl isobutyl and methyl *n*-amyl ketones with propionic and butyric anhydrides yield essentially the same proportions of the corresponding methyl and methylene derivatives as those given in Table I for the acetylation products.

TABLE I

THE RELATIVE PERCENTAGES OF THE TWO ISOMERIC ACETYL DERIVATIVES COMPRISING THE ACETYLATION PRODUCTS OF KETONES

Ketone acetylated	% Methyl derivative	% Methylene derivative	% Methiny derivative
Methyl ethyl	0	100	
Methyl *n*-propyl	10	90	
Methyl isobutyl	55[a]	45	
Methyl *n*-amyl	10	90	
Methyl *n*-hexyl	10	90	
Methyl isopropyl	32[b]		68
2-Methylcyclohexanone		50	50

[a] This is the average of the values found by the alkali extraction method and by the preparation of the copper salt directly from the original acetylation product. [b] This is the value obtained by the preparation of the copper salt directly from the original acetylation product.

It can be seen from Table I that the methyl *n*-alkyl ketones of type I yield largely the methylene derivatives with only small amounts (or none) of the methyl derivatives, whereas methyl isobutyl ketone, which has a branched chain, yields a little more of the methyl than methylene derivative. Methyl isopropyl ketone (type II) yields mainly the methinyl derivative, but also a considerable amount of the methyl derivative, while 2-methylcyclohexanone (type III) yields the methylene and methinyl derivatives apparently in about equal amounts. Thus, in the presence of boron trifluoride, ketones are capable of being acylated at the α-methyl, α-methylene or α-methinyl groups at which the α-carbon atom holds, respectively, three, two and one hydrogen atoms.

Although the α-hydrogen of a ketone is involved in the acylation, it would appear that the number of hydrogens present on the β-carbon atom in the ketones of type I, $CH_3CO-\underset{\alpha}{CH_2}-\underset{\beta}{C}\lessgtr$, determines the relative proportions of the methyl and methylene derivatives that result, the proportion of the methylene derivative decreasing and that of the methyl derivative increasing as the number of β-hydrogens is decreased.[9] Thus, methyl ethyl ketone, which has three β-hydrogens yields apparently only the methylene derivative; methyl *n*-propyl, methyl *n*-amyl or methyl *n*-hexyl ke-

(7) See Morgan, Drew and Porter, *Brr.*, **58**, 333 (1925).

(8) Morgan and Thomason, *J. Chem. Soc.*, **125**, 754 (1924).

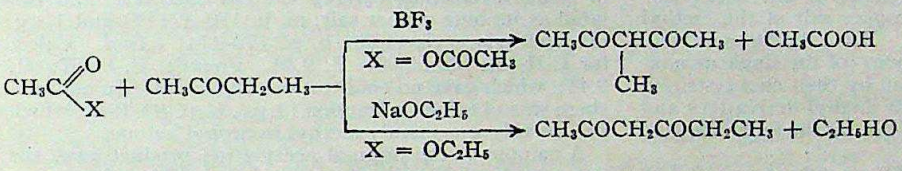
(9) On the basis that these acylations are dependent on the conversion of the ketone into its enol form by the acidic mechanism (which may be regarded as a special case of the elimination reaction), these results may be explained by the application of the theory of Baker and Nathan that CH-bond electrons may participate in tautomeric electron displacements. For the application of this theory to the elimination reaction see Hughes and Ingold, *Trans. Faraday Soc.*, **37**, 675 (1941).

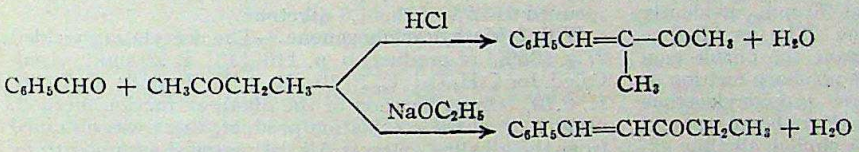
CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

tone, which has two β-hydrogens yields 90% of the methylene and 10% of the methyl derivative; while methyl isobutyl ketone, which has only one β-hydrogen, yields 45% of the methylene and 55% of the methyl derivative. An attempt to acetylate methyl neopentyl ketone, which has no β-hydrogens, failed.

The fact that the methylene derivative is the main product with methyl *n*-alkyl ketones and acetic anhydride in the presence of the acidic reagent, boron trifluoride, is in contrast to the formation of only[10] the methyl derivative with these ketones and ethyl acetate in the presence of a base, which has been the more common method of acylation of ketones. A similar relationship exists for the aldol reaction between at least methyl ethyl ketone and benzaldehyde,[11] which yields chiefly the methylene derivative in the presence of hydrogen chloride, but the methyl derivative in the presence of sodium hydroxide.





The fact that the methinyl derivative is the main product with methyl isopropyl ketone and acetic anhydride in the presence of boron trifluoride is also in contrast to the formation of only the methyl derivative with this ketone and ethyl acetate in the presence of a base.[12] The contrast is not as great with methyl isobutyl ketone,[13] however, which yields a little more of the methyl than methylene derivative in the presence of boron trifluoride and only the methyl derivative in the presence of a base.[12]

The two different courses of the acylation or aldol reaction with methyl ethyl ketone in the presence of acidic and basic reagents are paralleled by the halogenations of this ketone, which, in the presence of chlorine and hydrochloric acid, yields mainly the methylene chloro derivative,[14] 3-chloro-2-butanone, but which, in the presence of alkali, undergoes the well-known haloform reaction involving the halogenation of the methyl hydrogens. Since the formation of the enol of the ketone is generally considered to be prerequisite for the halogenation,[15] it would appear that the formation of the enol form of the ketone is also prerequisite for the acylation and aldol reactions.

Thus, these carbon–carbon condensations effected by acidic reagents may involve the activation not only of the electron-accepting component,[16] the anhydride or aldehyde, but also of the electron-donating component,[16] the ketone. The activation of the anhydride or aldehyde consists in the coördination of the acidic reagent with the carbonyl oxygen thereby making the carbonyl carbon a stronger electron-acceptor. The activation of the ketone (which, in most cases, is probably the more weakly activated of the two) consists in the coördination of the acidic reagent with its carbonyl oxygen thereby facilitating the conversion of the ketone into the enol form, which presumably is a stronger electron donor. A base, however, can activate only the ketone; of course the base used as condensing agent may attack the carbonyl carbon of the anhydride or aldehyde but this should consist in a deactivation, rather than an activation, since the electron-accepting capacity of the carbonyl carbon would thereby be destroyed. It should be pointed out also, that although the Friedel–Crafts type of acylation of benzene with an anhydride is somewhat analogous to the acylation of a ketone in the presence of an acidic reagent, probably only the anhydride is activated in the former reaction.

Certain of the acetylations described in this paper are of value for the synthesis of 1,3-diketones. The use of these and other acylations in syntheses will be discussed in a later paper.

Experimental[17]

Acetylation.—One mole of acetic anhydride and one-half mole of the ketone were placed in a three-neck flask equipped with an inlet tube (1 cm. above the surface of the liquid), a mercury-sealed stirrer and a calcium chloride tube. The mixture was cooled in an ice-bath and stirred. Boron trifluoride was passed in at such a rate that the mixture was saturated (as indicated by the copious evolution of white fumes) within two to three hours. After the mixture was saturated, the boron trifluoride was passed in for fifteen to twenty minutes longer, and the reaction mixture

(13) A study is in progress in this Laboratory to determine the products of reaction of benzaldehyde with such ketones as methyl isobutyl and methyl neopentyl ketones in the presence of an acidic reagent.

(14) Kling [*Bull. soc. chim.*, [3] **33**, 325 (1905)] found that on monochlorination in slightly acid medium, methyl ethyl ketone yields about 80% of the methylene chloro derivative and 20% of the methyl chloro derivative, 1-chloro-2-butanone. In this Laboratory Mr. R. Levine has found that in strong acid medium, the percentage of the methylene chloro derivative is even greater. Also, a preliminary experiment by Levine has indicated that, similar to the acylation in the presence of boron trifluoride, methyl isobutyl ketone yields on chlorination in strongly acid medium at least as much of the methyl chloro derivative as the methylene chloro derivative.

then poured into a solution of 130 g. of sodium acetate in one liter of water. The mixture was steam distilled[18] until the distillate no longer gave an enol test with ferric chloride. The steam distillate was cooled and practically all of the acetic acid present was neutralized by adding dilute sodium hydroxide solution until the mixture just turned litmus red. The slightly acidic mixture was extracted with ether and, after drying over sodium sulfate, the solvent distilled. The residue was fractioned *in vacuo* and the acetylation products of the ketones were collected. The forerun generally contained acetylacetone.

Alkali Extraction Method.—The two isomeric acetyl derivatives of the ketones comprising the acetylation products were separated in the following manner. Samples (10–20 g.) of the acetylation products were dissolved in 100 cc. of ether and the solutions were extracted with 100-cc. portions of cold 1% aqueous sodium hydroxide until two successive alkaline extracts (after acidification) gave, respectively, the red and the purple enol tests, the red and no enol test, or the purple and no enol test. Generally several extractions were required. The ether solutions were then distilled, while the combined alkaline extracts were acidified, extracted with ether and the solvent distilled. The methylene and methinyl derivatives were recovered essentially pure but the recovered methyl derivatives generally contained a little of the methylene derivative; however, the pure copper salt of the methyl derivative was readily obtained. The 1,3-diketones were identified by boiling points, analyses (of the single or mixture of isomeric 1,3-diketones) and by their enol tests and copper salts (which are blue with methyl derivatives and gray with methylene derivatives)[7] or by the failure to give enol tests or copper salts.

With Methyl Ethyl Ketone.—The acetylation yielded 18 g. (32%) of product, b. p. 77–79° at 30 mm., evidently consisting of only methyl acetylacetone. The first alkaline extract (using 1% or 0.5% alkali) gave the purple enol test and gray copper salt, which gave no sharp melting or decomposition point. The isomeric propionylacetone (which is more soluble in alkali) gives the red enol test and blue copper salt, m. p. 197–198.[19] A similar alkaline extraction of the forerun (6 g., b. p. 73–76° at 30 mm.), obtained on fractionation of the acetylation product, gave only acetylacetone, isolated as its blue copper salt, which decomposes above 230°.[20]

With Methyl *n*-Propyl Ketone.—The acetylation yielded 22 g. (34%) of product, b. p. 78–81° at 20 mm. *Anal.* Calcd. for $C_7H_{12}O_2$: C, 65.59; H, 9.44. Found: C, 65.58; H, 9.27. The alkali extraction method showed that this acetylation product consisted of 10% *n*-butyrylacetone (giving the red enol test, isolated as its blue copper salt, m. p. 164–165°[21]) and 90% (by difference) of ethyl acetylacetone, b. p. 80–81° at 20 mm., which gave the purple enol test and gray copper salt, m. p. 209–211°.[22]

With Methyl Isobutyl Ketone.—The acetylation yielded 29 g. (41%) of product, b. p. 79–81° at 20 mm. *Anal.* Calcd. for $C_8H_{14}O_2$: C, 67.57; H, 9.92. Found: C, 67.41; H, 9.50. The alkali extraction method showed that this product consisted of 60% of isovalerylacetone (b. p. 78–79° at 20 mm., giving the red enol test and blue copper salt, m. p. 154–155°[21]) and 40% of isopropyl acetylacetone (b. p. 183–185° at 750 mm. *Anal.* Calcd. for $C_8H_{14}O_2$: C, 67.57; H, 9.92. Found: C, 67.92; H, 10.07), which gave no enol test or copper salt.

A sample of the original acetylation product gave the copper salt of isovalerylacetone in a yield which corresponded to 50% of the 1,3-diketone.

With Methyl *n*-Amyl Ketone.—The acetylation yielded 46 g. (59%) of product, b. p. 104–106° at 20 mm. This product was not extracted with alkali; instead, the experiment was repeated and the total ether extract was subjected directly to the alkali extraction method. In this manner, the acetylation product was found to consist of 10% of *n*-hexoylacetone (b. p. 102–103° at 20 mm., giving the red enol test and blue copper salt, m. p. 137–138°[23]) and 90% of *n*-butyl acetylacetone (b. p. 105–106° at 20 mm.) which gave the purple enol test and gray copper salt, m. p. 185–186°.

With Methyl *n*-Hexyl Ketone.—The acetylation yielded 45 g. (53%) of product, b. p. 112–113° at 15 mm. *Anal.* Calcd. for $C_{10}H_{18}O_2$: C, 70.55; H, 10.66. Found: C, 70.12; H, 10.29. The alkali extraction method showed that this product consisted of 10% of *n*-heptoylacetone (giving the red enol test, isolated as its blue copper salt, m. p. 122–123°[24]) and 90% (by difference) of *n*-amyl acetylacetone (b. p. 112–113° at 15 mm.) which gave the purple enol test and gray copper salt, m. p. 177–178°.

With Methyl Isopropyl Ketone.—The acetylation yielded 18 g. (28%) of product, b. p. 73–76° at 20 mm. *Anal.* Calcd. for $C_7H_{12}O_2$: C, 65.59; H, 9.44. Found: C, 65.39; H, 9.18. On application of the alkali extraction method, using 5 g. of acetylation product, there was obtained 1 g. of isobutyrylacetone (giving the red enol test, and isolated as its blue copper salt, m. p. 170–171°[25]) and 1.4 g. of dimethylacetylacetone, b. p. 172–174° (*Anal.* Calcd. for $C_7H_{12}O_2$: C, 65.59; H, 9.44. Found: C, 65.57; H, 9.41), which gave no enol test or copper salt. In addition there was obtained a fraction (1 g.), b. p. 80–100°, which presumably was mainly methyl isopropyl ketone.

A sample of the original acetylation product gave the copper salt of isobutyrylacetone in a yield which corresponded to 32% of this 1,3-diketone.

With 2-Methylcyclohexanone.—The acetylation yielded 27 g. (35%) of product, b. p. 116–118° at 20 mm. *Anal.* Calcd. for $C_9H_{14}O_2$: C, 70.10; H, 9.15. Found: C, 70.36; H, 9.19. On application of the alkali extraction method, using 10 g. of the acetylation product, there was obtained from the alkaline extracts 5 g. of material assumed to be 2-methyl-6-acetylcyclohexanone (giving the purple enol test and gray oily copper salt which could not be crystallized) and from the material insoluble in alkali, 1 g. of material (b. p. 168–183°) assumed to be mainly 2-methylcyclohexanone, and 2.5 g. of 2-methyl-2-acetylcyclohexanone (b. p. 190–222°, mostly at 220–222°). (*Anal.* Calcd. for $C_9H_{14}O_2$: C, 70.10; H, 9.15. Found: C, 69.75; H, 9.08) which gave no enol test or copper salt.

Summary

The acetylation of certain unsymmetrical aliphatic ketones with acetic anhydride in the presence of boron trifluoride to form 1,3-diketones has been carried out, and the proportions of the two possible acetyl derivatives have been determined.

Methyl ethyl ketone yields apparently only the methylene derivative; methyl *n*-alkyl ketones yield 90% of the methylene derivative and 10% of the methyl derivative; while methyl isobutyl ketone yields 45% of the methylene derivative and 55% of the methyl derivative. Methyl isopropyl ketone yields 68% of the methinyl derivative and 32% of the methyl derivative, while 2-methylcyclohexanone yields the methylene and methinyl derivatives in about equal amounts.

These results are compared with acylations effected by bases. Correlations are made between

(18) An alternate procedure was to extract the reaction mixture (after standing with the sodium acetate solution for a few hours) directly with ether, but apparently certain boron trifluoride complexes were not completely decomposed under these conditions and better yields of 1,3-diketones have been obtained by the steam distillation procedure.

The Preparation of β,β-Trehalose Octaacetate

BY CHESTER M. MCCLOSKEY,[1] RONALD E. PYLE AND GEORGE H. COLEMAN

In connection with work in this Laboratory on the chromatographic separation of the azoyl derivatives of sugars, it was necessary to prepare β,β-trehalose. Since procedures previously reported did not prove satisfactory for preparing moderate quantities of this compound, modification of one of these methods was undertaken.

Fischer and Delbrück,[2] who discovered β,β-trehalose octaacetate, prepared it by the action of silver carbonate and a small amount of water upon an ether solution of tetraacetyl-α-D-glucosyl bromide, in a yield of about 1%; they also obtained it from the action of phosphorus pentoxide on a chloroform solution of 2,3,4,6-tetraacetyl-β-D-glucose in a yield of 2%.

In 1932 Schlubach and Schetelig[3] prepared β,β-trehalose octaacetate by the condensation of tetraacetyl-α-D-glucosyl bromide and 2,3,4,6-tetraacetyl-β-D-glucose in a chloroform solution with silver carbonate, calcium chloride and iodine. The reduction value of the crude reaction mixture was determined by Bertrand's method and the condensation was calculated as 50%, based on the reduction value of pure tetraacetyl glucose. The yield of crystalline product was not given.

The procedure of Schlubach and Schetelig was repeated several times in this Laboratory. The best yield of crystalline β,β-trehalose octaacetate was not more than 4%. The conditions described by these authors were duplicated as nearly as possible. However, it may be that some necessary precaution was omitted, since the reaction product showed a reduction value corresponding to only 18.8% condensation.

This preparation has been modified to conform more closely to the technique used by Kreider and Evans[4] in the Koenigs and Knorr synthesis. By effecting condensation in the presence of Drierite as drying agent, a 10% yield of crystalline product, m. p. 180.5–181.5° cor., has been obtained. The reduction value of the crude reaction product indicated a condensation of approximately 30%. The non-crystalline residues from which no more product could be obtained, still contained two-thirds of the original condensation product as shown by reduction values. This problem is being investigated further.

(4) Kreider and Evans, THIS JOURNAL, **58**, 707 (1936).

The use of iodine has been found essential for satisfactory condensation. Excessive amounts of glucosyl bromide and elevated temperatures did not produce appreciably higher yields.

In a series of several runs the percentage yields calculated from the reducing values varied from 30–40%. The actual yield of crystalline product did not, however, in any case exceed 10.5%. In one run in which only 4.5 g. of iodine was used the percentage yield calculated from the reducing value was 30%. The yield of crystalline material was only 3.4%.

Experimental Part

2,3,4,6-Tetraacetyl-α-D-glucosyl Bromide.—This compound was prepared by the method of Karjala and Link[5] or Redemann and Niemann[6] from pentaacetylglucose or its glucose equivalent. The crude reaction mixture prepared by this method from 120 g. of glucose pentaacetate was poured with rapid stirring into 1.5 liters of ice-water. The precipitate, which solidified, was filtered off and ground in a mortar in order to break up the lumps. It was then returned to the filter funnel and washed thoroughly with ice-water and sucked as dry as possible. The precipitate without further drying was dissolved in 300 ml. of ether. The aqueous layer was separated and the ether layer cooled in a freezing mixture. The crystals which formed were filtered off and the filtrate which had partially evaporated during the filtration was cooled as before. In this manner several crops of crystals were obtained. The crystallization of the last portion was facilitated by the addition of a little ligroin to the ether. The crystals were air dried a short time and then in a vacuum desiccator over phosphorus pentoxide. The product can be kept indefinitely without decomposition. The yield of product melting at 87–88° (uncor.) was 121 g. (96%).

2,3,4,6-Tetraacetyl-β-D-glucose was prepared by a modification of the method of Georg.[7] A solution of 125 ml. of anhydrous acetone and 82.2 g. of tetraacetylglucosyl bromide was cooled to 0° in an ice-bath and 2.3 ml. of water added. To the cold solution 46.5 g. of silver carbonate was added in small portions, with thorough shaking or stirring, during a period of fifteen minutes. After about thirty minutes more shaking the mixture was warmed to 50–60° and filtered. The silver salts were washed with 65 ml. of dry acetone, removed from the funnel and warmed in a flask with 65 ml. more acetone, filtered and washed again on the funnel. The combined filtrates were concentrated under reduced pressure and at room temperature. When most of the solution was filled with crystals the concentration was stopped and the mixture warmed until solution was complete. To this acetone solution an equal volume of absolute ether and a similar volume of ligroin were added. The solution so obtained was cooled in a freezing mixture with gentle stirring. The crystals of tetraacetate soon formed and after ten minutes in the ice-bath to ensure complete crystallization were filtered and air-dried. The

solution was kept as anhydrous as possible since moisture interfered with the crystallization. The product so obtained melted at 133–135° (cor.). The yield was 56 g. (79%).

β,β-Trehalose Octaacetate.—In a 2-liter three-necked flask equipped with a mechanical stirrer, mercury seal, calcium chloride tube, and a 500-ml. dropping funnel, was placed 110 g. of 2,3,4,6-tetraacetyl-β-D-glucose, 180 g. of silver carbonate, 12 g. of iodine, 100 g. of powdered Drierite (previously dried for three hours at 500°), and 400 ml. of alcohol-free chloroform. The flask was covered with a dark cloth to prevent the entrance of light and stirred for thirty minutes. In 400 ml. of alcohol-free chloroform was dissolved 150 g. of 2,3,4,6-tetraacetyl-α-D-glucosyl bromide and the solution shaken with 50 g. of powdered Drierite for thirty minutes. At the end of the shaking, the solution of glucosyl bromide was decanted and added dropwise to the first mixture over a period of two hours. This was followed by a 100-ml. portion of chloroform used to wash the Drierite and the mixture was stirred for twelve hours. At the end of the stirring, the solid matter was filtered off and washed with 100 ml. of chloroform. The chloroform from the combined filtrate was removed by evaporation of the solution on a water-bath. The residue was dissolved in 900 ml. of benzene and the solution washed twice with 2 liters of water. Each washing was shaken for thirty minutes. Without drying, the benzene was removed from the solution by evaporation on a steam-bath and the residue dissolved in hot ethyl acetate. Ligroin was then added until the warm solution became turbid. Upon cooling, long needles of β,β-trehalose octaacetate formed. After three recrystallizations the melting point was constant at 180.5–181.5° cor., $[\alpha]^{25}D$ −18.4° (c = 3) in U. S. P. chloroform. The yield was 12.5 g. (6.5%). By working up the residues, 6.7 g. of additional product was obtained, giving a total yield of 19.2 g. (10%). Reduction values were determined by the method of Lane and Eynon[8] and expressed as the percentage of the reducing value of pure tetraacetylglucose. The residues from washing the benzene solutions of the product had reduction values approximately equal to pure tetraacetyl glucose. The reduction values of the residues from recrystallization indicated that some non-reducing material was still present.

Summary

A satisfactory method has been developed for the preparation of crystalline β,β-trehalose octaacetate from 2,3,4,6-tetraacetyl-α-D-glucosyl bromide and 2,3,4,6-tetraacetyl-β-D-glucose.

A Convenient Synthesis of *dl*-Tryptophan

BY H. R. SNYDER AND CURTIS W. SMITH

In an earlier work[1] it was discovered that quaternary salts containing a radical of the benzyl type can be used as carbon-alkylating agents. The methiodide of gramine (3-dimethylaminomethylindole, readily prepared from indole, formaldehyde and dimethylamine) was found particularly effective in the alkylation of active methylene compounds. This suggested that *dl*-tryptophan might be prepared by condensation of gramine methiodide with an alkali derivative of an acylaminomalonic ester. In view of the high yields previously obtained in reactions of gramine methiodide with malonic ester it seemed likely that the proposed synthesis would be much more practical than the earlier methods based on the condensation of indole-3-aldehyde with hippuric acid[2] or hydantoin.[3]

Gramine methiodide has been found to react smoothly with the sodium derivative of acetaminomalonic ester in the presence of dioxane. Ethyl α-acetamino-α-carbethoxy-β-(3-indole)-propionate (IV, R = CH_3) was obtained in yields of 63–70%. Saponification converted the ester to the acid (V, R = CH_3), and boiling a water suspension of the acid brought about decarboxylation. The resulting acetyltryptophan was converted to *dl*-tryptophan by alkaline hydrolysis. Two recrystallizations brought the product to analytical purity. The yield of *dl*-tryptophan, based on indole, was approximately 45%.

It is interesting to note that long boiling with 20% aqueous sodium hydroxide did not convert the substituted acetaminomalonic ester (IV) to the aminomalonic acid, but the acetyl group was

removed easily after the decarboxylation of the acetaminomalonic acid (V).

Experimental

Ethyl Acetaminomalonate.—The isonitroso ester, prepared by a modification of the method of Redeman and Dunn,[4] was reduced and acetylated without isolation of any of the intermediates. A solution of 400 g. of malonic ester in 450 g. of glacial acetic acid, in a 3-liter three-necked flask, was cooled in an ice-bath. With stirring, a solution of 518 g. of sodium nitrite in 710 cc. of water was added over a period of one hour, the temperature of the mixture being kept below 20°. Gases which escaped were led to the hood. The mixture was stirred for four hours after the addition of sodium nitrite was completed. The reaction mixture was extracted with three 500-cc. portions of ether. The combined ether extracts were washed with three 250-cc. portions of 10% sodium carbonate and with two portions of water. The ether solution was dried over calcium chloride and the ether was removed by distillation under reduced pressure. The residual liquid was dissolved in 1000 cc. of absolute alcohol and 25 g. of Pd-charcoal catalyst (10% Pd) was added. The mixture was hydrogenated (1500 lb. pressure, room temperature, at start) and when absorption of hydrogen was complete the catalyst was removed by filtration. To the cooled filtrate was slowly added 204 g. of acetic anhydride, and the resulting solution was cooled in ice. When crystallization appeared complete the first crop (127 g.) of the product was collected. Concentration and cooling of the mother liquor produced additional crops, the total yield being 217 g. The first fraction was pure (m. p. 95–96°), but later crops required recrystallization.

Ethyl α-Acetamino-α-carbethoxy-β-(3-indole)-propionate (IV).—After 6.9 g. (0.30 mole) of sodium had been powdered in 100 cc. of dry xylene, most of the xylene was decanted. Then 500 cc. of dioxane which had been distilled from sodium and 68 g. (0.314 mole) of acetaminomalonic ester were added and the mixture was stirred for fourteen hours in an oil-bath at 92°. To the resulting light yellow suspension was added 101 g. (0.32 mole) of gramine methodide (II)[1] and the mixture was stirred in an oil-bath at approximately 108° for nineteen hours and then at 125° for three hours. The hot dioxane was separated from a brown pasty solid by filtration through a heated Büchner funnel. After standing overnight in a refrigerator (+5°) the solution had deposited 64.5 g. of the product (IV); m. p. 125–135°. A second fraction of 4.7 g. (m. p. 135–142°) was obtained by concentrating the mother liquor to one-fourth volume. A third fraction (6.4 g., m. p. 158°) was obtained by extracting the solid from the first filtration with 200 cc. of boiling 95% ethanol, diluting with 200 cc. of hot water, and cooling.

The two fractions of IV which had crystallized from dioxane (69.2 g.) were dissolved in 160 cc. of boiling 95% ethanol and 160 cc. of warm water was added to the solution. After standing overnight in a refrigerator at 5° the solution deposited 61.7 g. of IV; m. p., 156–8°. The total yield of IV, m. p. 156–8°, was thus 68.1 g. or 63%; other runs gave yields in the range 63–70%. An analytical sample of IV was prepared by recrystallization from *n*-butyl ether and then from 50% alcohol–water solution; m. p. 158°.

Anal. Calcd. for $C_{18}H_{22}N_2O_5$: C, 62.44; H, 6.40. Found: C, 62.42; H, 6.24.

α-Acetamino-α-carboxy-β-(3-indole)-propionic Acid (V).—The ester (IV) was saponified by refluxing 33.62 g. (0.097 mole) with 19.2 g. (0.48 mole) of sodium hydroxide in 192 cc. of water for four hours. After treatment with charcoal, the solution was cooled in an ice-bath and 50 cc. (0.6 mole) of cold concd. hydrochloric acid was added with cooling so that the temperature of the solution did not exceed 25°. The solution was cooled for four hours, and the light pink precipitate was filtered off and dried over calcium chloride in an evacuated desiccator for fourteen hours; the yield of crude material, containing some sodium chloride, was 32 g.; m. p. 136–139°. The acid could be purified by dissolving it in ten volumes of water (containing a trace of sodium hydrosulfite) at 50° and cooling. The analytical sample, after two recrystallizations from 20% ethanol, melted with decomposition at 144.5°.

Anal. Calcd. for $C_{14}H_{14}N_2O_5$: C, 57.93; H, 4.86. Found: C, 57.71; H, 5.02.

***dl*-Tryptophan (VII).**—A mixture of 28 g. of the crude malonic acid (V) and 120 cc. of water was heated under reflux for two and one-half hours. The N-acetyltryptophan (VI) produced was less soluble than the malonic acid and in some runs it partially crystallized from the solution as the reaction proceeded. After the decarboxylation was completed, 16 g. (0.4 mole) of sodium hydroxide in 40 cc. of water was added and the solution was refluxed for twenty hours. The alkaline solution was treated with charcoal and acidified with 24 g. (0.4 mole) of glacial acetic acid. A copious white precipitate formed immediately, but the solution was stored in the refrigerator for twelve hours before the solid was collected. It was dissolved in 200 cc. of water containing 5 g. of sodium hydroxide. After treatment with charcoal, 100 cc. of 95% ethanol was added to the solution. The solution was warmed to 70°, acidified with 7.5 cc. of glacial acetic acid, and allowed to cool slowly. The flat plates which separated from the solution were filtered off and washed with two 40-cc. portions of water, two 40-cc. portions of ethanol and two 30-cc. portions of ether; yield 14 g. (81% calculated on the basis of IV); m. p. 272–280° (dec.). An analytical sample, m. p. 275–282° (dec.), was prepared by two recrystallizations from 33% ethanol.

Anal. Calcd. for $C_{11}H_{12}N_2O_2$: C, 64.69; H, 5.92. Found: C, 64.61; H, 5.90.

N-Acetyltryptophan (VI) was isolated from a similar run by allowing it to crystallize from the acidified solution after decarboxylation. For recrystallization, 11.7 g. of VI was dissolved in a solution of 100 cc. of water and 30 cc. of 95% ethanol, a few grains of sodium hydrosulfite were added, and the hot solution was treated with charcoal; yield, 8 g. (68.5%), m. p. 206° (lit.,[5] 206°). A sample recrystallized several times from very dilute ethanol was analyzed.

Anal. Calcd. for $C_{13}H_{14}N_2O_3$: C, 63.40; H, 5.73. Found: C, 63.20; H, 5.61.

Summary

A convenient and economical synthesis of *dl*-tryptophan is described. Indole is converted to gramine (3-dimethylaminomethylindole) by condensation with formaldehyde and dimethylamine; the methiodide of gramine is condensed with the sodium derivative of ethyl acetaminomalonate to give ethyl α-acetamino-α-carbethoxy-β-(3-indole)-propionate; α-acetamino-α-carboxy-β-(3-indole)-propionic acid is obtained by saponification of the ester and is decarboxylated to acetyltryptophan by boiling in water; *dl*-tryptophan is obtained by alkaline hydrolysis of the acetyl derivative. The yield of tryptophan, based on indole, is about 45%.

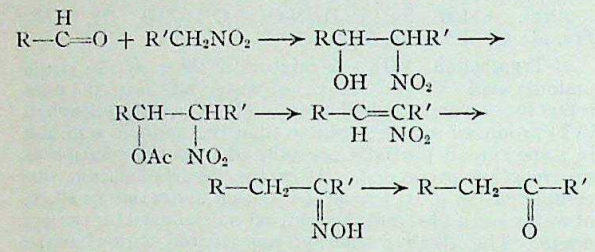
The Preparation of Ketones from Nitroölefins

BY DOROTHY NIGHTINGALE AND J. R. JANES[1]

The purpose of the investigation was to develop a method of preparation of aliphatic ketones from nitroparaffins by the following series of reactions



where R and R′ are aliphatic. It was first necessary to develop a satisfactory method for the preparation of nitroölefins.

The method of Schmidt and Rutz[2] as modified by Hass and co-workers[3,4] has been found suitable for the preparation of nitroölefins. We found that it improved the yield to add methanol to the aqueous sodium bicarbonate solution. The procedure is generally reliable and yields of nitroolefin are usually 90–95% with the best yields from esters of nitroalcohols with nine or more carbon atoms. The yield from nitroalcohol to nitroölefin via the ester is usually around 80–84%.

Bouveault and Wahl[5] have shown that nitroolefins of the structure $R-\underset{H}{C}=\underset{H}{C}-NO_2$ could be reduced to the aldoxime with zinc powder and acetic acid. Hass and Susie[3] have reported that subsequent workers have been unable to repeat the work of Bouveault and Wahl, but we have found that the reduction of nitroölefins of the structure $R-\underset{H}{C}=\underset{NO_2}{C}-R'$ to the ketoxime proceeded smoothly with a 50–60% yield in most cases.

The ketoximes were hydrolyzed to ketones by refluxing with 4 *N* sulfuric acid and a hydroxylamine acceptor (40% formaldehyde). Yields of ketone are around 80%, with an over-all yield from the nitroölefin of 40–48%. Syntheses of

some of these branched chain ketones such as 4-ethyl-2-octanone and 5-ethyl-3-nonanone by any other method would be long and tedious.

All efforts to condense nitroölefins such as 2-nitro-4-ethyl-2-hexene, 2-nitro-4-ethyl-2-pentene, 3-nitro-3-hexene and 1-nitro-1-heptene with butadiene and with cyclopentadiene under a variety of experimental conditions were negative, even using the experimental conditions of Alder, Rickert and Windemuth.[6]

Experimental

The nitroölefins are greenish-yellow liquids when freshly prepared and pure. The 1-nitro-1-ene olefins are unstable and gradually decompose, the 2-nitro-2-enes are somewhat more stable and the 3-nitro-3-enes are quite stable. Branched chain nitroölefins except 1-nitro-1-enes are very stable. The lower members of the series up to the nitroheptenes have sharp biting odors and are strong lachrymators, while the higher members beginning with the nitrononenes have a pleasant odor somewhat similar to camphor.

If the nitroölefins are distilled under pressures at or near atmospheric pressure, they decompose rapidly and exothermically to form a tar, sometimes with explosive violence. Distillation near 1 mm. is desirable.

Preparation of Nitroalcohols and their Derivatives.—The nitroalcohols were prepared by the method of Sprang and Degering.[7] Yields were consistently 70–80%. The properties of the nitroalcohols and the solid α-naphthylurethans, not previously reported in the literature, are summarized in Tables I and II. The urethans were prepared by warming 2 cc. of the nitroalcohol and 1.5 cc. of α-naphthyl isocyanate on a water-bath until the mixture became solid. The urethans were extracted with petroleum ether (86–100°). The higher molecular weight nitroalcohols gave uncrystallizable oils. The melting points were determined in a capillary tube heated in a copper block at one degree rise per minute. The urethans precipitate from petroleum ether as fine needles or small leaflets.

The esters of the nitroalcohols were prepared by the method of Tindall.[8] The acetic anhydride was removed in a partial vacuum and the esters distilled at 1 mm. Some nitroölefin was formed during distillation. The esters were used without further purification.

Preparation of Nitroölefins.—The preparation of 3-nitro-5-ethyl-3-nonene is typical. 3-Nitro-5-ethyl-4-nonanol acetate (83 g.) was placed in a one-liter round-bottom flask with 100 cc. of a 0.5 *N* solution of sodium bicarbonate and 200 cc. of methanol and refluxed eight hours. The mixture formed a fine emulsion at reflux temperature and, as cleavage proceeded, the nitroölefin gradually separated out as the emulsion disappeared and the water layer became clear. The nitroölefin formed a thick greenish globule which came to the top of the reaction mixture on cooling. With nitroölefins below the nitroöctenes the globule settled to the bottom of the flask.

The nitroölefin was extracted with two 100-cc. portions of ether. The ether extract was washed, and dried over anhydrous sodium carbonate and distilled; b. p. 94° (1 mm.); yield, 58 g. (90%). The lower nitroölefins were distilled through a three-foot column packed with glass helices and fitted with a still-head with a total condensation and variable take-off. Yields were usually 90–95%. The higher nitroölefins were pure enough to use without fractionation. The physical properties of the nitroölefins are given in Table III. The molecular refractivities showed exaltation.

The use of solid dehydrating agents led to more or less tar formation.

Ozonolysis of 3-nitro-3-hexene followed by reductive cleavage of the ozonide yielded propionaldehyde which was identified by conversion to propional dimethone, m. p. and mixed m. p. 149–150°.

Preparation of Oximes: 5-Ethyl-3-nonanone Oxime.—Zinc dust (50 g.) was placed in a 500-cc. three-necked conical flask equipped with a motor stirrer, dropping funnel and reflux condenser. An ether solution (200 cc.) of the above nitroölefin (43 g.) was added and stirred vigorously while a solution of 25% acetic acid (110 g.) was added through the dropping funnel over a two-hour period (four hours in some cases) at such a rate that the ether refluxed gently. After all the acid had been added, the reaction mixture was heated gently until it became colorless and bubbles of hydrogen ceased to form, usually four to six hours. The zinc acetate was separated by filtration and

extracted with ether in a Soxhlet extractor to recover absorbed oxime. The ether extract was added to the filtrate and the ether removed on a water-bath. The acetic acid was removed in a low vacuum and the residue, a greenish oil, distilled at 89–92° (1 mm.); yield 21 g. (52%). The yields of oxime were consistently 50–60%. They are viscous, strong-smelling liquids. Their properties are given in Table IV.

Preparation of Ketones: 5-Ethyl-3-nonanone.—The above oxime (17.5 g.) was refluxed one-half hour with 50 cc. of 4 *N* sulfuric acid and 22 cc. of formalin solution. The ketone was extracted with two 50-cc. portions of ether and the ether solution dried over anhydrous copper sulfate or Drierite. The ether was removed on a water-bath and the ketone distilled; b. p. 53° (1 mm.); yield 12 g. (80%).

Anal. Calcd. for $C_{11}H_{22}O$: C, 76.92; H, 12.82. Found: C, 76.62; H, 12.97.

This ketone, not described in the literature, was the only one of the ketones which would not form a solid derivative. The melting points of the semicarbazones of the other ketones agreed with those reported in the literature.

The reduction of 35 g. of 2-nitro-4-ethyl-3-hexene with hydrogen and Raney nickel at 45 lb. yielded 10 g. of 4-ethyl-2-hexanone as the principal product. A large amount of tar remained in the distilling flask.

Summary

A variety of aliphatic nitroölefins have been prepared in good yield by refluxing the acetates of nitroalcohols with an aqueous methanol solution of sodium bicarbonate.

Nitroölefins of suitable structure were reduced to the corresponding ketoximes in 50–60% yield by means of zinc and acetic acid.

The ketoximes were converted to ketones by hydrolysis with dilute sulfuric acid in the presence of formalin.

The α-naphthyl urethans of a number of nitroalcohols have been described.

The Reaction of Citronellal with Benzylmagnesium Chloride[1]

BY WILLIAM G. YOUNG AND SAMUEL SIEGEL

In attempting to prepare α-benzylcitronellol by the addition of citronellal to benzylmagnesium chloride, Rupe[1a] isolated an almost colorless, viscous liquid, distilling at 243–244°(9 mm.). After determining the elementary analysis for carbon and hydrogen, and the value of the molecular weight of the substance in benzene, he suggested that this material was formed by the addition of two moles of benzylmagnesium chloride to one mole of citronellal, the second mole of the Grignard reagent adding to the ethylenic double bond of the aldehyde. Later Gilman and Schulz[2] sought to disprove this contention by an indirect method. They added the aldehyde to a large excess of benzylmagnesium chloride. The mixture was then treated with carbon dioxide and the resulting acids were isolated. Since the product of the addition of a Grignard reagent to an ethylenic double bond would contain a carbon to magnesium linkage, it should react with carbon dioxide to form the salt of a carboxylic acid. Gilman and Schulz isolated phenylacetic acid but found no indication of the presence of any other acid. They concluded that the Grignard reagent had not added to the ethylenic double bond. Although these workers also isolated a liquid having the same properties as that reported by Rupe, they did not further investigate it. Since this indirect proof is not conclusive[3,4] and because certain evidence obtained in this Laboratory pointed to the possibility of the addition of Grignard reagents to the ethylenic double bond, a more thorough investigation of the above reaction was carried out.

Although Rupe was unable to obtain better than a 25% yield of α-benzylcitronellol, we have

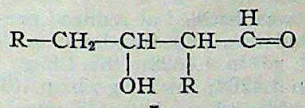
been able to increase the yield to 80% by using an excess of the Grignard reagent. An excess of aldehyde gives 70–80% of the more complex product.

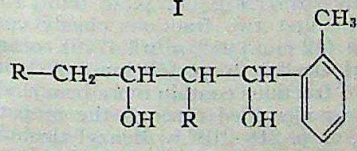
The complex material (which will hereafter be designated substance A) appeared to be homogeneous after several distillations. The elementary analysis and molecular weight indicated the formula $C_{27}H_{44}O_2$ (molecular weight, 400). There are two ethylenic double bonds and two active hydrogen atoms per molecule. Quantitative acetylation with acetic anhydride leads to the same value for the number of hydroxyl groups per molecule. There are also two citronellyl radicals per molecule. This was determined by comparing the amount of acetic acid obtained from A upon oxidation with chromic acid with that obtained upon identical treatment of α-benzylcitronellol.[5] Oxidation of A with alkaline potassium permanganate led to the formation of phthalic acid, which was recovered in good yields. No benzoic acid was isolated.

When A was heated with potassium acid sulfate, one molecule of water was lost. The resulting substance (B) contained one oxygen atom per molecule but neither an active hydrogen atom nor a carbonyl group. It was therefore a cyclic ether (IV).

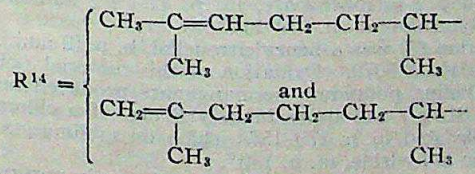
It is conceivable that A could have been formed in one of the following ways. (1) Two molecules of the aldehyde, under the influence of the Grignard reagent, might condense to form an aldol (I). This aldol would then react with a molecule of benzylmagnesium chloride at the ortho position (to satisfy the condition that phthalic acid be obtained after oxidation) to give, after hydrolysis, the glycol (II).



I

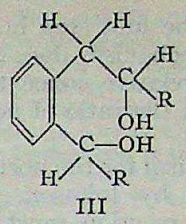


II

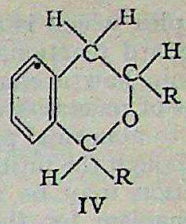


(2) Two molecules of the aldehyde and one molecule of benzylmagnesium chloride might react in such a way that one molecule of the aldehyde would become attached to the ortho position, the other to the methylene group of the benzyl radical as in III.

(5) Karrer, Helfenstein, Wehrli and Wellstein, *Helv. Chim. Acta*, **13**, 1084–1098 (1930).



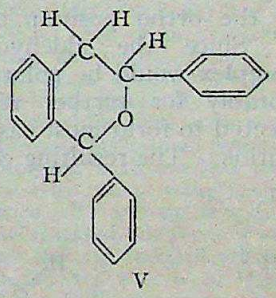
III



IV

The first path for the formation of A was disproved when it was shown that the product isolated from the reaction of the aldol of citronellal with benzylmagnesium chloride was the "normal" addition product (*i. e.*, it was oxidized to benzoic acid and not phthalic acid) and furthermore it readily lost two molecules of water to form a hydrocarbon.

The second path is in complete agreement with all observations. The glycol III should be dehydrated easily to form the cyclic ether IV. Indeed Schmidlin and Garcia-Banûs[6] have shown that benzaldehyde reacts with benzylmagnesium chloride to form a compound, analogous to III, which dehydrated during distillation and formed diphenylisochromane V.



V

The above results prove the correctness of the statement of Gilman and Schultz that benzylmagnesium chloride does not add to the ethylenic double bond of citronellal.

Discussion

In the reaction of benzylmagnesium chloride with citronellal, the concentration and order of addition of reactants play an important role in determining the character of the reaction products. If a large excess of Grignard reagent is used, a good yield of α-benzylcitronellol is obtained. In the formation of this compound, one mole of Grignard reagent and one mole of aldehyde have combined and no abnormal reaction has occurred. On the other hand, if equal amounts of the aldehyde and benzylmagnesium chloride are used, the product is largely one in which two moles of aldehyde and one mole of Grignard reagent have united. In this case the Grignard reagent has reacted abnormally since phthalic acid is obtained upon oxidation of the product.

Johnson[7] has suggested that "the normal and abnormal reactions are to be regarded as two possible transpositions within the initial coördination

(6) Schmidlin and Garcia-Banûs, *Ber.*, **45**, 3193 (1912).

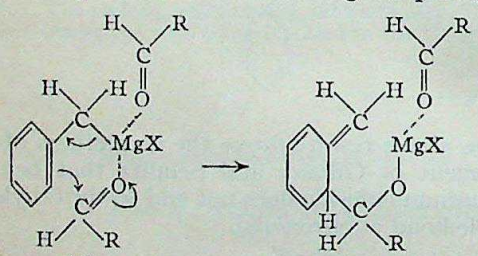
complex which is formed as the first step in all Grignard reactions." This mechanism does not explain how a change in the relative concentrations of reactants can influence the ratio of normal to abnormal products.

Though the intimate mechanism for the normal reaction may be as described by Johnson, the mechanism for the abnormal reaction must be modified.

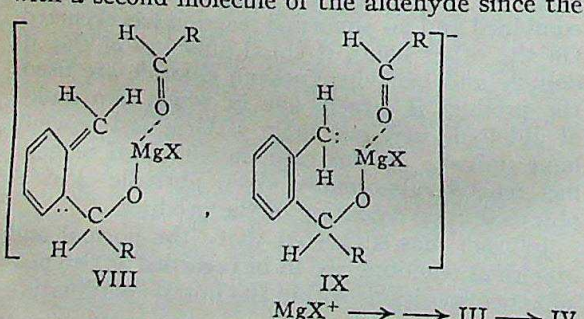
The relationship of concentration of reactants to the kind of product formed suggests that different intermediates are required for the normal and abnormal reaction paths. Since the abnormal reaction is favored by high concentrations of aldehyde, it is reasonable to suppose that the reaction complex for the abnormal reaction contains a larger number of aldehyde molecules than in the case for the normal reaction. Each complex may then react in a manner peculiar to itself and give rise to different products.

The coördination of several aldehyde molecules with one molecule of Grignard reagent may increase the tendency toward ionization of the carbon to magnesium bond and thus permit the activation of the ortho position through resonance (VI). Since the aldehyde molecules within the complex would be polarized and also situated favorably for further reaction, they would be expected to form most easily a bond at the ortho position. The resulting complex (VII)



VI VII

has an active hydrogen atom at the substituted ortho position, since by its removal, the benzenoid system is restored. This proton could be removed readily by another molecule of the Grignard reagent forming toluene and the intermediate VIII. In turn, this intermediate would be expected to react at the methylene position with a second molecule of the aldehyde since the

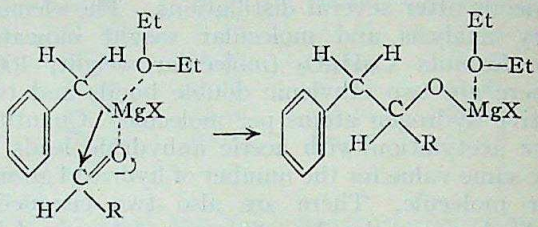


VIII IX

$MgX^+ \longrightarrow \longrightarrow$ III $\longrightarrow$ IV

resonance structure IX would contribute more to the stability of the ion than the non-benzenoid structure with the electron pair at the ortho or para position.

The coördination of only one aldehyde molecule with the Grignard reagent apparently does not allow for activation of the ortho position but leads to a normal reaction as follows



Experimental

Benzylmagnesium chloride was prepared in excellent yields (99%) by adding a solution of freshly distilled benzyl chloride (0.663 mole) in ether (200 ml.) to an excess of magnesium turnings (0.830 mole) covered with ether (100 ml). The Grignard reagent was filtered through glass wool before it was used.

To this vigorously stirred solution, cooled in an ice-bath, freshly distilled citronellal (52.0 g., 0.338 mole) was added dropwise. After the aldehyde had been added, the reaction mixture was allowed to warm up to room temperature (about two hours). It was hydrolyzed by pouring it over a mixture of cracked ice and ammonium chloride. The heat of the reaction melted the ice, leaving two phases. These were separated. The aqueous phase was extracted again with ether (100 ml.). The ether extracts were combined, washed with a little water, and dried over potassium carbonate. After the solvent was removed, the ethereal concentrate was transferred to a 250-ml. Claisen flask and distilled at reduced pressure.

Four fractions were obtained: (1) 27.0 g., distilling below 30°(4 mm.) (trapped in dry-ice); (2)12.0 g., b. p. (4 mm.) 75–100°; (3) 40.5 g., b. p. (3 mm.) 153–175°; (4) 21.5 g., b. p. (3 mm.) 200–235°. The boiler residue showed little or no decomposition.

When redistilled at atmospheric pressure, fraction (1) yielded 20 g. of toluene (b. p. 100–110°), the forerun being ether.

Fraction (2) was distilled at reduced pressure and arbitrarily separated into four fractions: (a) 1.1 g., b. p. (3 mm.) 60–62.5°, $n^{24.5}D$ 1.4622; (b) 4.8 g., b. p. (3 mm.) 62.5–65°, $n^{24.5}D$ 1.4762; (c) 1.6 g., b. p. (3 mm.) 65–70°, $n^{24.5}D$ 1.4948; (d) 1.4 g., b. p. (3 mm.) 75–116° $n^{24.5}D$ 1.4878. The first two fractions chiefly consist of isopulegol (b. p. (12 mm.) 91°, $n^{17}D$ 1.4729) contaminated by some benzyl alcohol (b. p. (10 mm.) 93°, $n^{20}D$ 1.5396). The last two fractions contain more benzyl alcohol. The isopulegol was identified through the preparation of its allophanate, m. p. 218–219°.[8] Benzyl alcohol was identified through the preparation of the acid phthalate, m. p. 103–105°; *p*-nitrobenzoate, m. p. 77–79°; and the 3,5-dinitrobenzoate, m. p. 110–111°.

Fraction (3) was α-benzylcitronellol, b. p. (3 mm.) 153–156°, $n^{24.5}D$ 1.5079. Oxidation of this material (2.01 g.) with alkaline potassium permanganate produced benzoic acid (0.815 g.) and approximately 3 mg. of a chloroform insoluble acid m. p. 170–185° which on sublimation gave phthalic anhydride, m. p. 130°.

When fraction (4) was redistilled, the main portion had the properties: b. p. (3 mm.) 234–235°, $n^{24.5}D$ 1.5120. According to the experimental procedure this fraction should correspond to the substance, which was claimed by Rupe to be the product formed by the addition of a molecule of the Grignard reagent to the ethylenic double bond in citronellal. However, it will be shown later that his material was apparently a dehydration product of the one we isolated.

The material, substance A, contained only carbon, hydrogen, and oxygen. It appeared to be homogeneous.

Anal. Calcd. for $C_{27}H_{44}O_2$: C, 80.93; H, 11.08. Found: C, 80.82; H, 11.07.

Identification of Substance A.—The molecular weight was determined cryoscopically in camphor[9] and also in benzene. In the first solvent the values were 360–370 and in the second 484–490 compared with the calculated value, 400. The high value for the molecular weight in benzene indicates association of the solute in that solvent. This phenomenon indicates that Rupe had isolated substance B, an ether, rather than substance A, a glycol. The analysis, he reported (C, 85.10; H, 10.28), is also in fair agreement with the values calculated for the cyclic ether (B) (see below).

Because of the difficulty of identifying the substance by simple degradations, a number of quantitative and semi-quantitative measurements for the various structural units in the substance were carried out.

The number of double bonds per molecule was estimated by means of quantitative bromination[10] and by hydrogenation with a barium sulfate-supported palladium catalyst.[11] The first method indicated 2.04 double bonds, the second 1.84 double bonds per molecule.

The Zerewitinoff method for estimating active hydrogen[12] showed 1.9–2.2 active hydrogens per molecule. No carbonyl groups were present.

A quantitative acetylation showed 1.90 hydroxyl groups per molecule.[13]

The number of citronellyl radicals in the molecule was determined by finding the amount of acetic acid which could be obtained by oxidation of the substance with chromic acid.[5] Since citronellal consists of a mixture of the isomeric limonene and terpinolene forms,[14] it was necessary to compare the amount obtainable from a compound prepared from the same sample of aldehyde. α-Benzylcitronellol, which was formed in the same reaction mixture as A, was used for this purpose.

Karrer's procedure[5] was modified, in order to separate the acetic from the benzoic acid, by following the suggestions of Young, Ballou and Nozaki.[15] In this way, α-benzylcitronellol forms 1.14–1.16 moles of acetic acid per mole of compound while A forms 2.61–2.66 moles of acetic acid per mole of A. This is in fair agreement with the presence of two citronellyl radicals per molecule of A.

Pyridine proved to be far superior to water as a solvent for the oxidation of A with potassium permanganate.[16] In this solvent, 1.09 g. of A yielded 0.325 g. of crude phthalic acid. This was identified by its melting point and the melting point and mixed melting point of the anhydride. No benzoic acid was isolated. This shows that substance A is the "abnormal" reaction product of benzylmagnesium chloride.

Dehydration of A.—Four grams of A was placed in a 10-ml. distilling flask. Potassium acid sulfate (1.0 g.) was added. The mixture was heated to 160° under reduced pressure (thirty minutes) until no more water was evolved. Another gram of the acid salt was then added and the heating continued. After one hour of this treatment, the contents of the flask were cooled and the oil which remained was separated from the acid with the aid of a little ether. This ethereal solution was washed with water and dried with magnesium sulfate. The product was then distilled at reduced pressure. A faintly yellow oil was obtained, b. p. (3 mm.) 215–217°, $n^{25.5}D$ 1.5090.

Anal. Calcd. for $C_{27}H_{42}O$; C, 84.77; H, 11.07. Found: C, 85.12; H, 10.83.

(9) Smith and Young, *J. Biol. Chem.*, **75**, 289 (1927).
(10) A. W. Francis, *Ind. Eng. Chem.*, **18**, 821 (1926).
(11) E. Schmidt, *Ber.*, **52**, 409 (1919).
(12) Kohler, Stone and Fuson, THIS JOURNAL, **49**, 3181 (1927).
(13) Porter, Stewart and Branch, "Methods of Organic Chemistry," Ginn and Co., 1927, p. 182.
(14) J. L. Simonsen, "The Terpenes," Vol. I, Cambridge University Press, London, 1931, p. 60.
(15) Young, Ballou and Nozaki, THIS JOURNAL, **61**, 12 (1939).
(16) Gilman and Kirby, *ibid.*, **54**, 345 (1932).

The analysis above shows the presence of one oxygen atom per molecule. This was shown to be neither a part of a hydroxyl group nor a carbonyl group by the Zerewitinoff method.[17] Bromination led to the value of 182 g. per double bond. Therefore, the dehydration product (B) must be a cyclic ether.

Preparation of the Aldol of Citronellal.—Citronellal (50 g., $n^{23}D$ 1.4479) was added slowly to a solution of potassium hydroxide (2 g.) in 50 ml. of 95% ethanol. The mixture was cooled in ice during the addition. A single phase resulted. The reaction mixture was allowed to stand overnight in a refrigerator. In the morning the solution had become slightly yellow. It was shaken at intervals and kept cold for eleven hours longer. The solution was poured into 200 ml. of water and 50 ml. of ether was added to aid in the separation of the reaction product. This ether phase was washed with sodium bicarbonate solution, then with water and finally dried over sodium sulfate. After the solvent was removed, the product was distilled rapidly under reduced pressure. A colorless liquid (b. p. (5 mm.) 170.5–173.0°; $n^{21.5}D$ 1.4850) was obtained (34 g. or 64% yield). Nine grams of lower boiling material (unreacted aldehyde) also was obtained. The aldol appeared to have become dehydrated to the extent of about 10%. This is indicated by the unsaturation to bromine. Calcd.: 165 g. per double bond; found, 142 g. per double bond.

To check upon the amount of Canizzaro reaction taking place, the aqueous phase from the preparation was acidified and extracted with ether. A small amount of a colorless oil was obtained (less than 1 g.).

Reaction of the Aldol with Benzylmagnesium Chloride.—A solution of 0.241 mole of benzylmagnesium chloride in 180 ml. of ether was cooled in an ice-bath. The aldol (25.0 g., 0.0815 mole) dissolved in 30 ml. of ether was added dropwise to the vigorously stirred Grignard reagent. After the addition of the aldol was completed, the mixture was allowed to warm up to room temperature. The product was hydrolyzed with cracked ice and ammonium chloride. The ether phase was separated, washed with water, and dried with anhydrous sodium sulfate. After the solvent was removed, the product was distilled rapidly from a Claisen flask at reduced pressure. The product (23.8 g.) was collected over a 10° range, b. p. (4 mm.) 226–236°; $n^{28.5}D$ 1.5157; unsaturation to bromine: calcd., 200 g. per double bond; found, 148 g. per double bond. The product was more fluid than substance A. This is probably due to the partial dehydration of the former.

Oxidation of the Product of the Grignard Reaction with the Aldol.—The product (1.42 g.) of the above Grignard reaction was oxidized by potassium permanganate in pyridine under conditions identical with those employed for substance A. There was isolated, in purified form, 0.256 g. of benzoic acid and six milligrams of phthalic acid. The latter was characterized by the melting point of the anhydride and by the brilliant fluorescein test.[18]

Dehydration of the Product of the Grignard Reaction with the Aldol.—The product (17.0 g.) of the reaction of the Grignard reagent with the aldol was dehydrated under conditions identical with those described previously for the dehydration of substance A. The crude distillate was collected over a twelve degree range, 203–215° (3 mm.). The middle fraction was redistilled and used for the analysis reported. Properties: b. p. (3 mm.) 204–206°, $n^{24.5}D$ 1.5278.

Anal. Calcd. for $C_{27}H_{40}$; C, 88.95; H, 11.06. Found: C, 88.81; H, 11.10; unsaturation to bromine, 134 g. per double bond.

The dehydration product is therefore a hydrocarbon. The value for the amount of unsaturation indicates that the product had partially cyclized during the treatment with acid. This was not unexpected.[14] If the material had not cyclized the weight per double bond would have been 91 g.

(17) This analysis was supplied by Dr. Haagen-Smit of the California Institute of Technology, Microchemical Laboratories.

Summary

Benzylmagnesium chloride reacts with citronellal to give α-benzyl-citronellol and substance A, a glycol formed from one mole of Grignard reagent and 2 moles of aldehyde.

The structure of A has been determined and it has been shown that the Grignard reagent does not add to the ethylenic double bond as postulated by Rupe.[1a]

A mechanism is suggested to account for the abnormal reaction of benzylmagnesium chloride during the formation of substance A.

Reaction of Acetaldehyde with Ethyl Bromide at 400°[1]

BY JACK G. ROOF

The kinetics of the pyrolysis of ethyl bromide has been studied extensively by Daniels and coworkers.[2] The primary step is thought to be the formation of an ethyl free radical and a bromine atom. As an independent method of checking on this primary step a series of experiments was carried out on the liberation of free radicals in ethyl bromide by the photolysis of acetaldehyde and ethyl bromide mixtures[3] at temperatures somewhat below that required to decompose the bromide at an appreciable rate. The experimental facts obtained supported the view that free ethyl radicals are formed in the thermal decomposition of ethyl bromide. In these latter experiments it was found that mixtures of acetaldehyde and ethyl bromide reacted rather rapidly in the dark at 357°, at which temperature acetaldehyde is stable and ethyl bromide decomposes at a very slow rate.

The purpose of the present paper is to describe the results of a further series of experiments on the dark reaction of these two compounds at temperatures near 400° in an apparatus better adapted to thermal reactions than was used previously for this mixture.

Experimental

Chemicals.—Acetaldehyde by Eastman Kodak Co. and ethyl bromide by Merck were used throughout. Each of these was dried over anhydrous cupric sulfate and distilled and sealed off in glass ampules under reduced pressure after the manner previously described.[3]

Apparatus.—A molten lead bath, modeled after that of Daniels,[2] was used as a thermostat. Reactions were carried out in Pyrex vessels. Pressures were measured by means of a thin glass diaphragm[4] used as a null-point instrument in an electrical circuit.

A two-liter glass reservoir, painted black to prevent any light reaction, was attached to the reaction system by means of capillary gates, designed after those of Veltman.[2a] The reservoir was evacuated to a pressure of *ca.* 10^{-4} mm. and warmed by a glow-coil to 60° or higher to aid in outgassing. The sealed reservoir was then cooled and bulblets of the reactants were broken in the reservoir by means of magnetic hammers. This storage vessel was so designed that samples of gas came into contact only with glass while in storage or while being transferred to the reaction vessel. By means of magnetically-operated hammers and tractors one could open the reservoir and let a gas sample into the reaction flask. Momentary heating of two thin-walled capillary goose-necks then sealed off both reservoir and reaction flask independently. The chief advantage of the reservoir was that one could maintain constant composition of reactants while studying the other variables of temperature and pressure over a series of experiments.

A micro-analysis apparatus, essentially that of Blacet and Leighton,[5] was available for analysis of products of the last few experiments. The gaseous products passed through a stopcock and through a trap cooled in dry-ice and were collected in the analytical apparatus by means of a Toepler pump. A lower temperature in the trap would have been desirable, in order to decrease the amount of unchanged reactants being introduced into the analytical apparatus.

Results

A few preliminary experiments were carried out on the pyrolysis of pure ethyl bromide. The plots of pressure *vs.* time were similar to those of Daniels. There were indications of an induction period in the reaction, but the pressures used were higher than those at which this phenomenon is pronounced.[2a]

Twenty-one experiments were then performed on acetaldehyde–ethyl bromide mixtures. A summary of the data is shown in Tables I and II. Pressure–time curves for three typical runs at 404° are shown in Fig. 1. Certain facts are immediately noticeable about these plots. There was a definite induction period of comparatively long duration, with the inflection point not being reached for a matter of minutes. This induction period was quite different from the "time lag" reported for the pyrolysis of ethyl bromide. In this latter case the pressure remained constant for several minutes and then started upward at a continuously decreasing rate as required for a first-order reaction.

For the mixtures there was an abrupt drop-off in the rate of pressure increase after a certain time. This "knee" was followed by a slow pressure rise which decreased in rate over a period of another hour or more, much after the fashion of ethyl bromide alone.

The rate of pressure increase for the mixture was many times as fast as that of ethyl bromide alone at the same pressure and temperature.

The higher the temperature (over the range studied, 372 to 408°) the more rapid was the rate of reaction. However, the general shape of the curve was not changed by temperature.

The first run in a "cleaned" flask[2a] was more rapid than succeeding ones made under similar conditions without introduction of air into the flask between runs. An increasingly darkening film was observed to deposit upon the walls of the flask during consecutive runs, as is the case in the ethyl bromide decomposition.

16	400	.378	125	181	1.18	3.0	..
17	404	.378	103	148	1.15	3.5	..

[a] Indicates data not observable. [b] N_a, mole fraction of acetaldehyde; P_0, initial pressure of mixture; P_b, pressure at "knee" in curve; P_∞, pressure at time indicated; $R = (P_b - P_0)/N_aP_0$; t_b, time at "knee" (estimated to nearest one-quarter minute).

Let P_0 designate the initial pressure, P_b the pressure at the knee in the curve, N_a the mole fraction of acetaldehyde, and t_b the time of occurrence of the knee. Define $R = (P_b - P_0)/N_aP_0$, the ratio of (the pressure increase before the break)/(the original partial pressure of the acetaldehyde). All values of R observed are given in Table I. This quantity had an average value of 1.11 ± 0.08 mean deviation. There was no consistent correlation between the value of R and the order of the runs after a flask was cleaned. Also there was no significant correlation between the observed value of R and the temperature of the reaction.

Under the same conditions of temperature and total pressure, the lower the partial pressure of acetaldehyde, the smaller the time interval until the break was reached. Also the pressure increases were less. Hence for low pressure of acetaldehyde ($N_a \sim 0.05$) the results were inconclusive. With the exception of the low pressure run 8, none of the other experiments, ranging from $N_a = 0.38$ to 0.63, offered such difficulty.

The inflection point in the rate curve was difficult to locate accurately, but it usually occurred after a pressure increase of about one-half to two-thirds of the value of $P_b - P_0$.

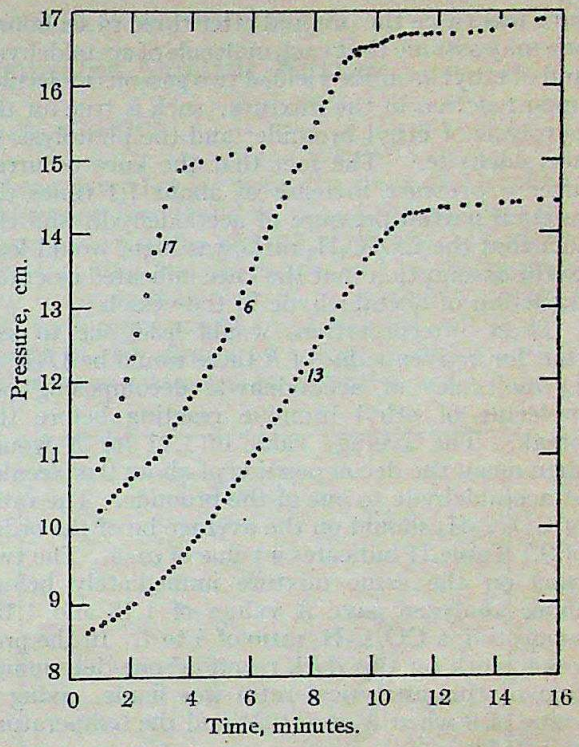

Fig. 1.—Pressure *vs.* time curves for three typical runs (404°): No. 17—$N_a = 0.378$; No. 6—$N_a = 0.562$; No. 13—$N_a = 0.604$.

In the first five runs the reaction was allowed to continue for a relatively long period of time. The ratio P_∞/P_0 seemed to approach the value of 2 as a limit.

In Table II are shown results on the analysis for carbon monoxide and ethylene in the last three runs with a mole fraction of acetaldehyde of 0.378. The break time, t_b, is estimated to have been of the order of five minutes. The R values on two preceding runs on this same mixture were 1.18 and 1.15.

TABLE II

DETERMINATION OF CO AND C_2H_4 IN THE REACTION PRODUCTS

Run	Temp., °C.	Time of reaction, minutes	Ratio CO/C_2H_4
20	404	2	4.30
19	405	5	2.77
21	402	192	1.48

Discussion

The presence of both ethylene and carbon monoxide in the products and the fact that the ratio R is greater than unity indicate that the pressure increase was due to decomposition of both reactants. Although the choice of both P_0 and P_b was subject to some doubt in each experiment, the fair consistency in the values of R indicates something of the mechanism of the reaction in the early stages. From the fact that the final pres-

Digitized by Arya Samaj Foundation Chennai and eGangotri

sure was twice the original after three to six hours, one may assume that each molecule of acetaldehyde and of ethyl bromide yielded two gaseous molecules upon reaction in the mixture; such is true for the pyrolysis of ethyl bromide[2] and the photolysis of acetaldehyde.[6] The fact that the knee occurred after a pressure increase of about 1.1 times the original partial pressure of acetaldehyde, and the fact that the CO/C_2H_4 ratio was high, would lead to the assumption that the knee indicated essential depletion of acetaldehyde in the vessel.

These interpretations would lead one to say that for a given value of R there would be $1/(R - 1)$ molecules of acetaldehyde decomposing per molecule of ethyl bromide reacting before the break. The average value of 1.11 for R would then mean the decomposition of about 9 molecules of acetaldehyde to one of the bromide. The ratio of CO/C_2H_4 should on the average be of the order of 9. Table II indicates a value of *ca.* 4. The two runs on the same mixture immediately before those analyzed gave R values of 1.18 and 1.15, suggesting a CO/C_2H_4 ratio of 5 to 7. In the previous work on this dark reaction[3] one determination of this analytical ratio was made, giving a value of 9 when N_a was 0.21 and the temperature was 355°.

If the decomposition of ethyl bromide proceeds by a chain mechanism, the chain length is short.[2a] At these temperatures acetaldehyde is itself stable, but the photolysis in the ultraviolet at temperatures above 300° occurs with quantum yields[6,7] of the order of 10^2 to 10^3. It is evident that in the present studies on mixtures the chain length of the acetaldehyde decomposition is of the magnitude of ten times that of the bromide.

The data presented herewith are considered to be in harmony with the postulated[3] decomposition of ethyl bromide into an ethyl free radical and a bromine atom, followed by reaction of the ethyl radical with CH_3CHO to form ethane, carbon monoxide and a methyl radical; this methyl radical then carries on the chain in the aldehyde decomposition. The presence of the ethyl bromide permits the acetaldehyde to decompose at this lower temperature, but it also shortens the chain length that would be possible in its absence.

(7) J. A. Leermakers, THIS JOURNAL, **56**, 1537 (1934).

The induction curve obtained in this reaction is quite different from the time-lag curves obtained at low pressures of pure ethyl bromide. The "auto-catalytic" initial part of each of the present curves indicates a progressive destruction of an inhibitor or the building up of a positive catalyst until the rate begins to drop off due to the decreasing amount of aldehyde left for reaction. Since this type of curve was observed in each case and not alone in the first run in a "cleaned" flask, it is not associated with the condition of the surface of the vessel. If it is due to destruction of an inhibitor, that inhibitor must have been introduced with each new sample of the mixture into the reaction chamber. The phenomenon may be due to building up of a positive catalyst. If there is a thermal reaction of acetaldehyde and ethyl bromide together to form a complex of long life, a curve of the type obtained might be expected. If such type of activated complex is involved, it must not dissociate into ultimate molecules but must of necessity give rise to free radicals to propagate the aldehyde chain.

When conditions permit resumption of this work, it is planned to study in detail the factors influencing the induction period of this reaction.

The author is indebted to Professors Farrington Daniels and Francis E. Blacet for suggestions concerning the interpretation and presentation of these data.

Summary

1. The dark reaction of mixtures of acetaldehyde and ethyl bromide at 400° has been studied from pressure measurements and analysis of the products.

2. A pronounced induction period of an autocatalytic type is obtained in the early stages of the reaction. A sharp decrease in the rate of pressure rise occurs after an increase of approximately 1.1 times the original partial pressure of acetaldehyde.

3 It is indicated that on the average the order of ten molecules of the aldehyde are decomposed per molecule of the bromide.

4. Correlations with previous work on the separate decomposition of these two substances is made.

Refractive Indices of the Normal Saturated Aliphatic Nitriles

BY A. DORINSON AND A. W. RALSTON

The aliphatic nitriles constitute an excellent series of compounds with which to test the hypothesis regarding the temperature dependence of the refractive indices of polar organic molecules advanced in a previous communication from this Laboratory.[1] There it was found that the refractive index of a straight chain fatty acid in the liquid state, plotted as a function of temperature, exhibited a sharp change of slope in the vicinity of 40°. This was ascribed to the influence of temperature on the orientation of the dipoles in the body of the liquid: at temperatures sufficiently elevated the thermal agitation of the molecules overcomes the restraint imposed by dipole interaction. A more extensive study of this effect is possible with the normal aliphatic nitriles because the members of this series up to pentadecylonitrile are liquids throughout the range necessary to demonstrate the effect.

The even carbon numbered nitriles used in this study were prepared by the catalyzed action of ammonia on the corresponding highly purified acids; the odd nitriles were prepared from the next lower fatty acids by the well-known sequence: ester → alcohol → halide → nitrile. The final purification consisted of a careful fractional distillation. Some of the nitriles, available from a previous investigation,[2] were treated with a few pellets of potassium hydroxide to remove fatty acids and water before distillation. Judged by the observation that the refractive indices of the entire series at 25°, from capronitrile to stearonitrile, fell on a smooth curve, the nitriles used were quite pure. Butyronitrile and valeronitrile were slightly less pure by this criterion. The freezing points[3] of several of the nitriles are: caprinitrile, −14.46°; lauronitrile +4.02°; myristonitrile 19.25°; palmitonitrile 31.40°; stearonitrile 40.88°.

The refractive indices were read on an Abbe type refractometer with jacketed prisms through which water from a thermostat was circulated. Temperatures were read on a calibrated thermometer.

The refractive indices of the nitriles are listed in Table I. These are the data as read directly on the refractometer, uncorrected for the effect of temperature on the prism of the instrument. A graphical representation is given in Fig. 1; here a correction whose magnitude amounts to 0.000006 $(t - 20)$ has been added to the original data for temperatures above 20°. The range of the graph has been extended by using the data of Merckx, Verhulst and Bruylants[4] at 15°. A definite change of slope occurs in the vicinity of 40–45°. In view of the fact that the dipole moment of the nitrile group is larger than that of the carboxyl group, some significance might be attributed to the occurrence of this change at a slightly higher temperature than was noted for the fatty acids.

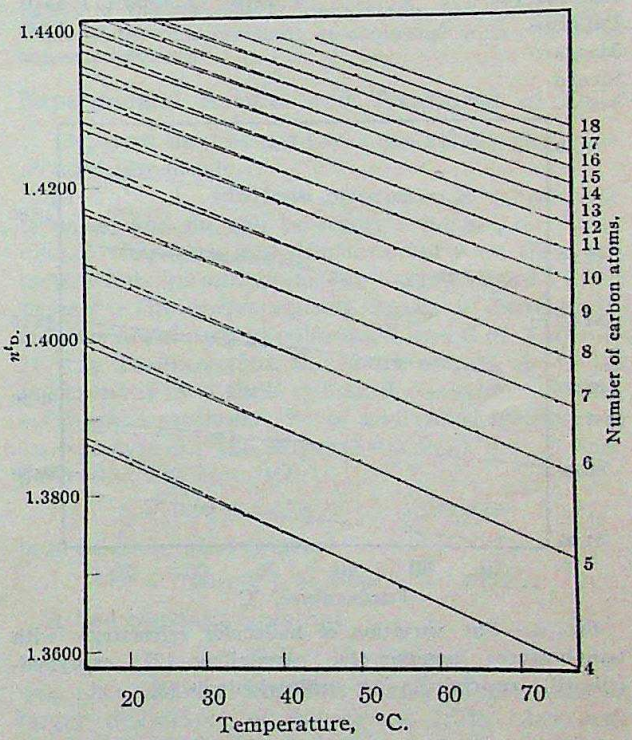

Fig. 1.—The variation of refractive index with temperature. Extrapolation is represented by the dotted line. The points at 15° are from the data of Merckx, Verhulst and Bruylants.[4]

The availability of reliable data on the densities of the nitriles[4,5] makes it possible to calculate their molecular refractivities. Several of these are plotted as a function of temperature in Fig. 2. Change of slope is more pronounced for the molecular refractivities than for the refractive indices themselves. The value of the molecular refractivity does not become constant above the inflection point, which indicates that other factors besides orientation of the dipoles affect its magnitude. It is also seen that the slope of molecular refractivity *vs.* temperature becomes steeper for higher members in the series. Careful examina-

tion of the graphs of the densities and of the refractive indices showed a distinct convergence of these curves at lower temperatures.

Highly purified specimens of *n*-heptane and *n*-octane were run as control substances. The refractive indices and the molecular refractivities of these compounds were found to be straight-line functions of temperature.

Summary

1. The refractive indices of the normal aliphatic nitriles from butyronitrile to stearonitrile inclusive were determined at a number of temperatures between 20 and 75°.

2. For each nitrile an abrupt change of slope in the refractive index *vs.* temperature curve occurs at 40–45°.

3. Corresponding graphs of the molecular refractivities also show a change of slope.

Heats of Dilution of Sodium Chloride in Ethylene Glycol at 25°[1]

BY W. E. WALLACE, L. S. MASON AND A. L. ROBINSON

The heats of dilution of electrolytes of nearly all the common valence types have been extensively studied in aqueous solution. These heats of dilution, when extrapolated to infinite dilution, have provided ample opportunity for comparison with the Debye–Hückel limiting law. Further comparison of experiment with theory could be provided by a comparable body of data in non-aqueous media. Theory requires that, in the limit, ΦL_2, the relative apparent molal heat content of the solute, be linear with respect to the square root of the concentration, regardless of the solvent medium, but that for a salt of a given valence type ΦL_2 be dependent on certain characteristics of the solvent, namely, the dielectric constant, the temperature derivative of the dielectric constant, and the volume–temperature relationships for the particular solvent.

Probably the only significant study of heats of dilution of electrolytes in strictly non-aqueous solvents is the work of Jackson, Smith, Gatty and Wolfenden[2] who determined these properties for

(1) This investigation was supported by a grant from the Buhl Foundation. This paper was presented to the Division of Physical and Inorganic Chemistry at the Pittsburgh meeting of the American Chemical Society, September, 1943.

a number of electrolytes in several solvents, including methanol, nitrobenzene, nitromethane and water.

Chord-area plots[3] of their data for sodium chloride, sodium iodide, sodium perchlorate and tetraethylammonium bromide in methyl alcohol indicate extrapolated slopes of the order of 5000 to 7000, as compared to their theoretically calculated limiting slope of 2610. A single measurement for the lowest concentration of sodium perchlorate studied suggests a reversal in the direction of the theoretical slope, although here as in the other cases insufficient data are available at low concentration to permit a significant comparison with theory.[4,5]

Ethylene glycol was selected as the solvent in the present work because the Debye–Hückel theoretical limiting slope for electrolytes in this liquid is appreciably different from the value in water. The glycol is of relatively low volatility and exhibits satisfactory solubility behavior toward electrolytes.

Experimental

Heats of dilution were measured with a Lange-type differential adiabatic calorimeter, the design and operation of which have been completely described elsewhere.[6a,b,c,d]

The sodium chloride used was a C. P. product, which was dried thoroughly and used without further purification.

The ethylene glycol was obtained by fractionation of the best grade material supplied by the Carbide and Carbon Chemicals Corporation and the Coleman and Bell Company. Using a 12-plate column, the fraction whose boiling range was 197.7 to 197.8° at 760 mm. pressure was selected. After a set of dilution experiments the solvent was recovered from the salt by distillation using a Yoe still. The physical properties of the material agreed well with published values. The material had a freezing point of −12.8°, a boiling point of 197.7–197.8°, and a refractive index, n_D 1.4336 at 15°. Values from the literature are: −12.6°[7] and −13.2°[8] for the freezing point; 197.85° at 760 mm.[7] for the boiling point; and 1.43312 at 15°[7] and 1.4314 at 20°[8] for refractive index.

The purified product exhibited a strong tendency to take on atmospheric moisture. This was prevented by handling the glycol in a closed container under a carefully dried atmosphere. In spite of these precautions, a slight increase in water content was noted during the course of the investigation. Titration of the solvent using Karl Fischer reagent[9] showed a water content of about 0.1% at the beginning of the study and about 0.4% at the conclusion.

One of the chief experimental difficulties appeared to lie in the relatively high viscosity of the glycol. The time of mixing of the solutions was materially longer than in the case of aqueous solutions, stirring heats were greater, and attainment of thermal equilibrium conditions was slower. Greater opportunity for heat exchanges between the two halves of the calorimeter undoubtedly reduced the precision of the measurements as compared with studies of aqueous solutions.

Experimental Results and Treatment of Data

The treatment of data was essentially the same as used previously.[10]

In Table I, dilutions between the concentrations m_1 and m_2 will be referred to as the "long chord" dilutions, and dilutions between the concentrations m_3 and m_2 as the "short chord" dilutions.[10] The corresponding heats of dilution in calories are shown in columns 4 and 6 of Table I. It was assumed that the short chords could be represented by a three constant equation. Using established methods[3,11a,b] of analytical treatment, an equation for the slope, $S = d(\Phi L_2)/dm^{1/2}$, was derived. The equation

$$S = 1580 + 63{,}720m^{1/2} - 1{,}193{,}000m \qquad (1)$$

may be integrated to give

$$\Phi L_2 = 1580m^{1/2} + 31{,}860m - 397{,}700m^{3/2} \qquad (2)$$

A two constant equation

$$S = 3170 - 29{,}050m^{1/2} \qquad (3)$$

was also derived, but was found to give much larger deviations of calculated from observed heat effects. A plot of the short chords together with the curves obtained from equations (1) and (3) is shown in Fig. 1. A three constant equation using the theoretically calculated limiting slope was also derived.

$$S = 1970 + 43{,}750m^{1/2} - 889{,}900m \qquad (4)$$

It was found that this equation fitted the experimental values almost as well as equation (1).

Comparison of a plot of equation (2) with a "point-to-point"[4,12] plot indicates that the error of extrapolation to infinite dilution was not greater than ± 5 calories. By combination of

(3) T. F. Young and O. G. Vogel, THIS JOURNAL, **54**, 3030 (1932).

(4) E. Lange and A. L. Robinson, *ibid.*, **52**, 4218 (1930), reported heats of dilution of potassium chloride in 15% sucrose solutions and in 5% urea solutions as solvents. Measurements were made to sufficiently low concentrations so that extrapolations to infinite dilution could be made. A linear relationship between ΦL_2 and $\sqrt{c}$ at the lower concentrations was observed. The values of the limiting slopes were about the same as for pure water, although the theoretical limiting slope (using the dielectric constant data of Kockel, *Ann. Physik*, **77**, 417 (1926)) had a sign opposite to the experimental slope in the case of the urea solutions. This discrepancy suggested a redetermination of the dielectric constants of the urea solutions. Calculations using later measurements of the dielectric constants (J. Wyman, Jr., THIS JOURNAL, **55**, 4116 (1933)) of the urea solutions provided reasonably good agreement between the experimental and theoretical limiting slopes.

(5) H. S. Harned, J. O. Morrison, F. Walker, J. G. Donelson and C. Calmon, *ibid.*, **61**, 49 (1939), have made a comprehensive study of the thermodynamic properties of HCl as a function of its concentration, the temperature and dielectric constant, by means of electromotive force measurements of the cell: H_2/HCl (m) dioxane (X), H_2O (Y)/AgCl − Ag in dioxane-water solutions having a dielectric constant range from 80 to 10 from 0 to 50°. It was found that observed values of $\bar{L}_2$ in dilute solutions at 25° displayed an increasing tendency to be higher than the limiting values as the dielectric constant decreased.

the long chord heats of dilution with those calculated from equation (2), a series of values of ΦL_2 for the entire concentration range studied was obtained. A least squares treatment of the values yielded the following equation for ΦL_2

$$\Phi L_2 = 2502m^{1/2} - 4036m + 2837m^{3/2} \quad (5)$$

The plot of equation (5) is shown in Fig. 2. Circles represent the experimental values.

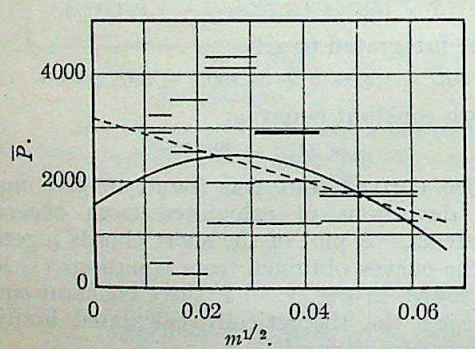

Fig. 1.—Plot of short chords ($\bar{P} = -\Delta H_{3\to 2}/\Delta m^{1/2}$) *vs.* $m^{1/2}$ and equations 1 and 3 for sodium chloride in ethylene glycol.

q-Values for the long chord dilutions were calculated from equation (5) and q-values for the short chord dilutions were calculated from equations (5) and (2). The deviations of calculated from observed values are shown in columns 5, 7 and 8, respectively, in Table I. Examination of these deviations shows that equation (2) is somewhat better than equation (5) for the short chord dilution range. This is perhaps to be expected considering that equation (2) was derived from the short chord range.

Relative Partial Molal Heat Contents.—Equations for $\bar{L}_1$ and $\bar{L}_2$ may be obtained directly from equation (5) by Rossini's method.[13]

$$\bar{L}_1 = -22.54m^{3/2} + 72.71m^2 - 76.68m^{5/2} \quad (6)$$

$$\bar{L}_2 = 3753m^{1/2} - 8072m + 7093m^{3/2} \quad (7)$$

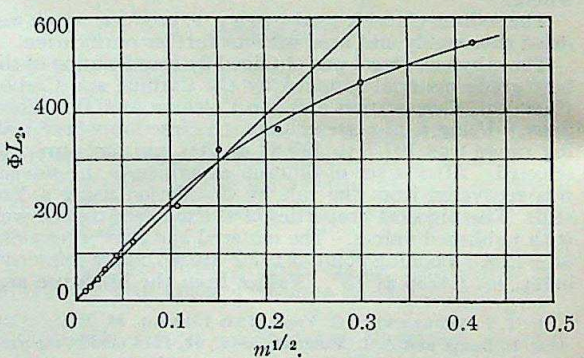

Fig. 2.—ΦL_2 (calories per mole of salt) *vs.* $m^{1/2}$. Curve is equation 5. The straight line is the theoretical limiting slope. Circles are experimental values.

Values of $\bar{L}_1$ and $\bar{L}_2$ at several rounded concentrations calculated from equations (6) and (7) are given in Table II.

ethylene glycol as determined by Gibson and Loeffler[14] together with the dielectric constant data of Akerlof[15] were used for the computation of the theoretical limiting slope for a uni-univalent electrolyte in this solvent. The value is 1970 cal.-kg.solvent-moles.$^{-3/2}$ The presence of 0.4% of moisture reduces the limiting slope by about 1%. The experimental limiting slopes are 1580 from equation (1) and 2502 from equation (5). The former value is to be recommended since it was obtained by a method specifically developed for the evaluation of such quantities. The probable error of the limiting slope of equation (1) has been calculated to be ±1188.[16] This value, although relatively large, indicates that the experimentally determined limiting slope is essentially in agreement with the theoretical slope.

A comparison of ΦL_2 values for sodium chloride in glycol with those in water[11b] in the concentration range studied shows that the heat effects in general are greater in glycol than in water by a factor of 5 or 6. This might have been anticipated from the theoretical limiting slopes (477 for water). The ΦL_2 curve for water shows a maximum in the neighborhood of $m^{1/2} = 0.4$. A maximum was not realized in glycol in the concentration range studied, although the shape of the curve (Fig. 2) indicates that a maximum might occur at $m^{1/2} = 0.6$ to 0.7.

It may be noted also that the ΦL_2 curve for aqueous solutions is below the limiting law curve over the complete concentration range, but that the curve for glycol is slightly above the limiting law in the lower concentrations (Fig. 2). The same is true for $\bar{L}_2$ values in the two solvents. This behavior with decreasing dielectric constant is in qualitative agreement with the behavior of hydrochloric acid in dioxane–water mixtures.[5]

Summary

Heats of dilution of sodium chloride in ethylene glycol have been measured from 0.17m to 0.0001m at 25°. Equations for the relative apparent molal heat content of the solute and for the relative partial molal heat contents of the solute and solvent have been derived.

The experimental limiting slope is in agreement with the theoretically calculated limiting slope.

Factors Determining the Course and Mechanisms of Grignard Reactions. XII. The Effect of Cobaltous Chloride on the Reaction of Methylmagnesium Bromide with Alicyclic Chlorides

BY M. S. KHARASCH, FRANCES ENGELMANN AND W. H. URRY

Introduction.—It was recently shown[1] that, in the presence of cobaltous chloride, phenylmagnesium bromide reacts with aliphatic halides (methyl, ethyl, propyl, *n*-butyl bromides and *t*-butyl chloride) to yield biphenyl and the saturated and unsaturated hydrocarbons derived from the alkyl halide used. A free radical mechanism was postulated to explain these results. In order to study the behavior of alicyclic free radicals in solution, the reactions of a number of alicyclic chlorides with methylmagnesium bromide in the presence and in the absence of cobaltous chloride have now been investigated.

Procedure.—The Grignard reactions were carried out according to the directions of Kharasch, Lewis and Reynolds,[1] with two modifications: a trap cooled in dry-ice was placed between the reaction flask and the gas collector, and a 10% excess of Grignard reagent was used. Twenty-gram samples were used in reactions with bornyl and isobornyl chlorides. With *cis*- and *trans*-2-methylcyclohexyl chlorides and cyclohexyl chloride, 50-g. samples were used in the cobaltous chloride catalyzed reactions, and 25-g. samples in the control experiments. In the reactions catalyzed by cobaltous chloride, the mixtures were refluxed for five hours and allowed to stand overnight. In the control experiments where no cobaltous chloride was used, refluxing was continued for twenty-eight hours.

The reaction products were analyzed by procedures described in detail in the experimental part.

Results.—The results of the reactions between the alicyclic halides and methylmagnesium bromide (shown in Table I) indicate that the normal condensations are extremely slow, and that, consequently, the secondary reaction (elimination of hydrogen chloride and formation of the unsaturated compounds) predominates.

The reaction of methylmagnesium bromide and the alicylic halides takes an entirely different course when about 5 mole per cent. of cobaltous chloride is first added to the Grignard reagent. The results are summarized in Table II.

The column headed "Unsaturated Compound" refers to cyclohexene and bornylene in experiments

TABLE I

REACTION OF METHYLMAGNESIUM BROMIDE WITH ALICYCLIC CHLORIDES

Alicyclic chloride	Reaction,[a] %	Addition product	Unsaturated compound	Gas evolved
2-Methylcyclohexyl-(*trans*)	46	10	33	Pure methane
2-Methylcyclohexyl-(*cis*)	49	10	34	Pure methane
Bornyl	5			
Isobornyl	90		90	Pure methane

[a] The extent of the reaction was determined by halogen titration (Kharasch and Fields, THIS JOURNAL, **63**, 2316 (1941)).

cobaltous chloride is particularly striking in the case of bornyl chloride which, in the absence of cobaltous chloride, reacts only to the extent of 5%, even if the reaction mixture is heated for twenty-eight hours. These results are, in our estimation, best explained by a free radical chain reaction.

(1) $CH_3MgBr + CoCl_2 \longrightarrow CH_3CoCl + CoClBr$
(2) $CH_3CoCl \longrightarrow CH_3\cdot + CoCl\cdot$
(3) $RCl\ (Alicyclic) + CoCl\cdot \longrightarrow R\cdot + CoCl_2$
(4) $R\cdot \longrightarrow R_{-H} + R_{+H}$
(5) $R\cdot \longrightarrow R{:}R^4$
(6) $CH_3\cdot + C_2H_5OC_2H_5 \longrightarrow CH_4 + C_2H_6 + C_2H_4$

However, the alicyclic free radicals differ significantly from the lower aliphatic free radicals (up to butyl) in that the reaction (5), the dimerization of the free radicals, does not occur with free aliphatic radicals, but takes place to the extent of 26% with the free cyclohexyl and 2-methylcyclohexyl radicals, and to the extent of 63% with the free bornyl radical. Since the free radicals derived from bornyl or isobornyl chloride are the same, the formation of 32% less dimer from the isobornyl chloride can be ascribed only to the greater ease of elimination of hydrogen chloride from that molecule. The formation of equal quantities of the saturated and unsaturated hydrocarbons in the reaction with bornyl chloride, and the preponderance of the unsaturated over the saturated compound (44 to 19%) in the reaction with isobornyl chloride is in full agreement with this view.

TABLE II

REACTION OF METHYLMAGNESIUM BROMIDE WITH ALICYCLIC CHLORIDES IN THE PRESENCE OF COBALTOUS CHLORIDE[a]

Alicyclic chloride	Reaction, %	Dimer, %	Unsatd. compound, %	Satd. compound, %	Gaseous products, % Methane	Ethane	Ethene
Cyclohexyl	86	26	29	27	85	9	6
2-Methylcyclohexyl-(*trans*)	87	27[b]	23	28	77	15	8
2-Methylcyclohexyl-(*cis*)	89	22	31	34	83	9	8
Bornyl	98	63	20	15	72	19	9
Isobornyl	94	31	44	19	77	15	8

[a] Cobaltous chloride (5 mole per cent.) was used in all experiments. [b] About 6% of an unidentified higher polymer was also isolated.

with bornyl and isobornyl chlorides, and to methylcyclohexene or cyclohexene in the experiments with the cyclohexyl chlorides. The "unsaturated compound" resulting from the reactions of bornyl and isobornyl chlorides is believed to be a mixture of camphene and bornylene because a 10% increase in unsaturation was observed when esterification was carried out under more drastic conditions.[2] Control samples of camphene gave the same unsaturation value when either method of esterification was used. The column headed "Saturated compound" refers to camphane in the bornyl and isobornyl chloride experiments, and to methylcyclohexane or cyclohexane, respectively, in the experiments with 2-methylcyclohexyl or cyclohexyl chloride.

Discussion

It is of considerable theoretical interest to note that in the uncatalyzed experiments the *cis*- and *trans*-forms of 2-methylcyclohexyl chloride react alike, while bornyl and isobornyl chlorides differ considerably in their stability. Isobornyl chloride reacts by elimination of hydrogen chloride to the extent of 90% in about one hour. Bornyl chloride is surprisingly stable in this respect.

In general, the catalyzed reactions are very much faster than the uncatalyzed ones. The reaction probably comes to an end while the reaction mixtures are allowed to warm from +5° to room temperature; they are certainly complete before the end of the first hour during which the mixture is kept at the boiling point of ether.[3]

This enhanced reactivity in the presence of

The non-dimerization of the simple free alkyl radicals which do not possess sufficient energy to react with the solvent, and the dimerization of the free alicyclic, benzyl and substituted benzyl radicals, supports the hypothesis previously submitted.[5b] In this connection, it is important to note that, although resonance stability in the free radical is important insofar as the tendency to dimerize is concerned, the dimerization of free alicyclic radicals and other radicals in which resonance (as currently interpreted) plays only a minor part must have a different origin. The facts cited are compatible, however, with the view that only free radicals derived from weakly electro-

negative radicals dimerize, and that the free benzyl or substituted benzyl radicals, which stabilize themselves through resonance, are members of a larger class of free radicals derived from weakly electronegative radicals, in many of which resonance plays only a very minor part. In other words, other things being equal, resonance is a sufficient but not a necessary condition for dimerization.

Experimental

Reagents.—Dow methyl bromide and Mallinckrodt magnesium turnings were used in the preparation of the Grignard reagent. The Grignard reagent was made by the method of Kharasch and Kleiman,[5b] filtered through a sintered glass disk, and titrated for basicity and halogen content immediately before use.

Anhydrous cobaltous chloride was prepared by heating the hydrated salt at 150° *in vacuo*.

The bornyl chloride was prepared according to the directions of Fisher.[6] The pinene used was first distilled over sodium; the fraction boiling between 153° and 156° was used in the preparation.

Isobornyl chloride was prepared from camphene (m. p. 41.2–41.6°) according to the directions of Meerwein and Van Emster.[7] Cyclohexyl and 2-methylcyclohexyl chloride (*cis*) were prepared according to the directions of Zelinski.[8] *trans*-2-Methylcyclohexyl chloride was prepared according to the method given for menthyl chloride by Cumming, Hopper and Wheeler.[9]

Analysis.—The reaction products from the bornyl and isobornyl chloride experiments were analyzed by the method of Hesse.[10] The amount of bibornyl was determined by distilling the ether from an aliquot portion of the ether extracts. The residue was heated on a steam-bath. A stream of air was blown over the warm material until the loss in weight per hour came to a small constant value. The weight of the remaining residue corrected for the known loss was taken as the weight of the bibornyl. In the analysis for camphene, ether from another aliquot portion was removed by fractional distillation through a 37-centimeter column filled with single-turn glass helices. The last of the ether was removed *in vacuo* while the residue was maintained at −18°. The camphene was converted to the ester according to the directions of Bertram and Walbaum.[11] The ester and mixed terpenes were dissolved in ether; the solution was washed with water and with sodium carbonate. The ether was removed as before. The saponification equivalent of the mixture was determined by the method of Shriner and Fuson.[12] The formation of the ester and the saponification were conducted in a closed flask to avoid loss of the highly volatile camphene and ester. Corrections, determined by blank runs, were made for hydrogen chloride removed from the bornyl and isobornyl chlorides during the saponification, and for losses due to the volatility of camphene. The amount of camphane was determined by difference.

Bibornyl and camphane were identified by their melting points (88–90° and 150°, respectively). Camphene was identified by conversion to the *p*-nitrobenzoyl ester of isoborneol (long needles, m. p. 133°). The melting point of this material was not lowered by admixture with a known sample of isobornyl *p*-nitrobenzoate.

In the reaction with cyclohexyl chloride and the 2-methylcyclohexyl chlorides, the products were separated by fractional distillation in a 12-plate concentric tube column.

The product of the reaction between cyclohexyl chloride and methylmagnesium bromide in the presence of cobaltous chloride was distilled and three fractions collected: (1) b. p. 81–84°, a mixture of cyclohexene and cyclohexane; (2) b. p. 83° at 110 mm., unreacted cyclohexyl chloride; and (3) b. p. 68° at 2 mm., bicyclohexyl. The product of the reaction between 2-methylcyclohexyl chloride and methylmagnesium bromide in the presence of cobaltous chloride was distilled and three fractions collected: (1) b. p. 63.5 to 67.5° at 140 mm.; b. p. 101–104° at 760 mm. (a mixture of methylcyclohexene and methylcyclohexane); (2) b. p. 101–102° at 133 mm. (unreacted 2-methylcyclohexyl chloride); (3) b. p. 104–106° at 3 mm. (2,2′-dimethylbicyclohexyl). The amounts of unsaturation in the cyclohexene–cyclohexane and methylcyclohexane–methylcyclohexene fractions were determined by bromide–bromate titration.[13]

The gas analyses were made according to the procedure of Kharasch, Lewis and Reynolds.[1] The gas collected was in all cases approximately 70% of the amount calculated from the amount of reaction determined by Volhard titration.

Summary

1. The reactions of some alicyclic chlorides with methylmagnesium bromide in the presence and in the absence of cobaltous chloride have been studied.

2. The significance of the formation of the dimers in the presence of cobaltous chloride is discussed.

Factors Determining the Course and Mechanisms of Grignard Reactions. XIII. The Effect of Metallic Halides on the Reaction of Sterically Hindered Acid Halides with Methylmagnesium Iodide

BY M. S. KHARASCH, R. MORRISON AND W. H. URRY

Introduction

The usual products of the reaction between acid halides and Grignard reagents are ketones and tertiary alcohols. However, highly significant observations on the reaction of tri-substituted benzoyl halides and Grignard reagents show that the reaction may take a different course. Thus, Fuson and Corse[1] found that, when 2,4,6-trimethyl- or triethylbenzoyl chloride was added to an ether solution of methylmagnesium iodide, only the monoketone (1) was formed. However, when the order of addition was reversed, the reaction product was a mixture consisting of 35% of the expected ketone (I) and 38% of the substituted benzil (II). Fuson and Corse[1] represent the mechanism of these reactions as follows

$$R_3C_6H_2COCl + CH_3MgI \longrightarrow \underset{(I)}{R_3C_6H_2COCH_3} + MgICl \quad (A)$$

$$2R_3C_6H_2COCl + 2CH_3MgI \longrightarrow \underset{(II)}{(R_3C_6H_2CO-)_2} + C_2H_6[2] + 2MgICl \quad (B)$$

Because of the uniqueness of the reaction (B), and because of our finding that methylmagnesium bromide does not undergo this reaction, a thorough investigation of the reaction of 2,4,6-trimethylbenzoyl (mesitoyl (β-isodurylyl)) chloride with Grignard reagents was undertaken.

Factors Influencing the Reaction of Mesitoyl Chloride with Grignard Reagents.—The effects of the following experimental conditions on the products formed in the reaction of mesitoyl chloride with Grignard reagents were thoroughly investigated: (a) the order of addition of the reagents; (b) the purity of the magnesium, and the age of the Grignard reagent; (c) the effect of the halides of iron, copper and manganese; (d) the effect of the halogen atom in CH_3MgX; (e) the effect of cobaltous chloride.

(a) As already demonstrated by Fuson and Corse,[1] the order of addition of the reagents plays an extremely important part in the reaction between methylmagnesium iodide and mesitoyl chloride. Our results (K, M and U), as well as those of Fuson and Corse (F and C) are given in Table I. The somewhat larger yield of the substituted benzil (II) obtained by us is readily accounted for by the findings presented under headings (c) and (d) (*q. v.*). The 50% yield of the substituted benzil (II) is a mean of sixteen experiments carried out in the dark and in the light; in the presence and in the absence of air. The average deviation in these experiments was about ±2%.

TABLE I

EFFECT OF THE ORDER OF ADDITION OF REAGENTS ON THE REACTION OF MESITOYL CHLORIDE AND METHYLMAGNESIUM IODIDE

Conditions	% Yield based on acid chloride used: Ketone F and C	Ketone K, M and U	Substituted benzil F and C	Substituted benzil K, M and U
Grignard added to acid chloride	35	25	39	50
Acid chloride added to Grignard	86	83	0	0

(b) Because of the known effects of traces of metallic halides on the course of Grignard reactions,[3] the reaction of mesitoyl chloride with methylmagnesium iodide prepared both from Dow sublimed magnesium and from Mallinckrodt magnesium was investigated. Considerable variations in the yield of the substituted benzil (II) were at once apparent; it also became equally clear that the difference tended to disappear when the Grignard reagent prepared from the Mallinckrodt magnesium was aged by allowing it to stand before use. No such aging effect was noted with Grignard reagent prepared from Dow magnesium. It is significant that the highest yield of (II) prepared from Mallinckrodt magnesium is about equal to the yield of this substance obtained from Grignard reagent of any age prepared from Dow magnesium. The observations are summarized in Table II.

TABLE II

EFFECT OF AGE OF GRIGNARD REAGENT AND PURITY OF MAGNESIUM ON THE REACTION BETWEEN MESITOYL CHLORIDE AND METHYLMAGNESIUM IODIDE

Magnesium used	Age of Grignard	% Yield based on acid chloride: Ketone	Benzil
Mallinckrodt	1 hour	40	31
Mallinckrodt	1 day	35	38
Mallinckrodt	30 days	18	54
Dow	1 hour	25	50
Dow	14 days	26	52

(c) It was suspected that the differences observed with the various magnesiums might be due to metallic impurities. It has been shown[4] that

(1) Fuson and Corse, THIS JOURNAL, **60**, 2063 (1938).

(2) The formation of ethane in reaction (B) was not demonstrated experimentally by Fuson and Corse. This product was probably assumed because of the similarity of the reaction with that of the benzyl halides on methylmagnesium iodide; in this latter reaction, bibenzyl and ethane are formed in equivalent amounts (Fuson, THIS JOURNAL, **48**, 2681 (1926)).

(3) For previous references, see Kharasch and Fuchs, THIS JOURNAL, **65**, 504 (1943).

(4) Kharasch, Kleiger, Martin and Mayo, *ibid.*, **63**, 2305 (1941).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Dow sublimed magnesium is practically free of all heavy metals, except for 0.01% of lead; Mallinckrodt magnesium, on the other hand, contains 0.05–0.10% Mn, 0.01% Cu, 0.01% Sn and 0.01% Fe. In support of this hypothesis, we find that the addition of a little copper, manganese or iron halide to the Grignard reagent tends to increase the amount of the ketone (I) at the expense of the substituted benzil (II). The observations are summarized in Table III.

TABLE III

EFFECT OF METALLIC HALIDES ON THE REACTION BETWEEN MESITOYL CHLORIDE AND METHYLMAGNESIUM IODIDE

Metallic halide 1 mole %	% Yield based on acid chloride Ketone	Benzil
None	26	52
$MnCl_2$	88	1
$MnCl_2$ (0.1 mole %)	75	5
$FeCl_3$	85	7
Cu_2Cl_2	85	2
Cu[a]	45	30

[a] Grignard reagent prepared from a mixture of Dow magnesium and copper–magnesium alloy.

(d) and (e): in an attempt to find an explanation for the observations recorded in (a), (b) and (c), we examined the reaction of methylmagnesium bromide with mesitoyl chloride. Here, even under the optimum conditions (use of Dow magnesium, etc.), only traces of the substituted benzil (II) were obtained. Methylmagnesium chloride would doubtless act like the bromide. The formation of substituted benzil (II) from mesitoyl chloride is, therefore, specific for the iodide Grignard reagent. However, in the presence of a little cobaltous chloride, methylmagnesium bromide gives a fair (but probably not the optimum) yield of (II). These results are given in Table IV.

TABLE IV

EFFECT OF THE HALIDE OF THE GRIGNARD IN THE REACTION WITH MESITOYL CHLORIDE

Grignard reagent[a]	% Yield based on acid chloride Ketone	Substituted benzil
CH_3MgI	25	50
CH_3MgBr	87	1
$CH_3MgBr + CoCl_2$	35	31[b]
$CH_3MgI + CoCl_2$	17	63

[a] In each of these reactions, the Grignard was added to the acid chloride. [b] The lower total yield of known products is accounted for by the formation of an unidentified tarry material.

The fact that mesitoyl chloride forms a substituted benzil (II) when treated with (1) methylmagnesium iodide or with (2) methylmagnesium bromide and cobaltous chloride[5] but does not form such a benzil when treated with (3) methylmagnesium bromide alone suggests a common mechanism for the reactions with (1) and (2).

(5) Phenylmagnesium bromide reacts with mesitoyl chloride in the presence of cobaltous chloride to give 4% of the substituted benzil (II), 41% of phenyl mesityl ketone and 21% of *sym*-diphenyldimesitylpinacol.

In the reaction with (2), there is abundant evidence that the Grignard reagent exercises its reducing action on the acid chloride by first forming the cobalt subhalide (CoCl), which acts as a chain carrier. The essential features of the postulated mechanism are as follows

(1) $CH_3MgBr + CoCl_2 \longrightarrow CH_3CoCl + MgBrCl$
(2) $CH_3CoCl \longrightarrow CH_3\cdot + \cdot COCl$
(3) $RCOCl + CoCl\cdot \longrightarrow RCO\cdot + COCl_2$
(4) $2RCO\cdot \longrightarrow RCOCOR$
(5) $CH_3\cdot + C_2H_5O\text{-}C_2H_5 \xrightarrow{\text{gas}} CH_4\ (80\%) + C_2H_6\ (10\%) + C_2H_4\ (10\%)$

It seems probable, therefore, that, where methylmagnesium iodide is used, a similar free radical must operate, although no chain reaction is required to account for the result. It is assumed that methylmagnesium iodide can react in two ways

(6) $CH_3MgI \longrightarrow CH_3^- + (MgI)^+$
(7) $CH_3MgI \longrightarrow CH_3\cdot + MgI\cdot$

The active reagents, insofar as the reaction with mesitoyl chloride is concerned, are, therefore, similar; where methylmagnesium bromide and cobaltous chloride are used, cobaltous subhalide is the reducing agent; where methylmagnesium iodide is used, the reducer is magnesious iodide.[6] This assumption, however, requires similarity in gaseous products of the reaction. Here there appeared at first to be a disagreement with experiment, for Fuson and Corse[1] (see Introduction) in writing the over-all reaction indicated that ethane is the exclusive gaseous product of the reaction (B). However, our experience has shown that whenever methyl radicals are formed in ether solution, the gas evolved consists, within ±5%, of about 80% methane,[7] 10% ethane and 10% ethylene. The latter gases are presumably formed in the cleavage of the ether molecule by the free methyl radicals. The gas evolved during the addition of the mixture of methylmagnesium bromide plus cobaltous chloride (5 mole per cent.) to the mesitoyl chloride is a mixture of methane (74%), ethane (16%) and ethylene (10%).[8] The molecular weight of the gas resulting from the interaction of methylmagnesium iodide with mesitoyl chloride is 18.0. This figure corresponds to a mixture containing 85% of methane and 15% of the heavier gases (ethane and ethylene).

(6) The observation of Fuson and Corse (THIS JOURNAL, 61, 975 (1939)) that a mixture of magnesium and magnesium iodide reduces diortho-substituted acid halides as well as diortho-substituted diketones to enediols may be looked upon as further support of this hypothesis.

(7) The somewhat lower figure given for methane (62%) and higher figures for ethane (18%) and ethylene (20%) given by Kharasch, Lewis and Reynolds (THIS JOURNAL, 65, 493 (1943)) were probably due to small losses of methane during the evacuation of the vessel. Our recent improved technique eliminates this slight error in the analyses.

(8) The gas evolved, when addition of the Grignard reagent has been completed and the reaction vessel is allowed to warm to room temperature, is almost pure methane. This gas is probably formed in the reaction between the ketone (I) and the Grignard reagent, a reaction known to take place slowly in the cold (Kohler, Stone and Fuson, THIS JOURNAL, 49, 3181 (1927)).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Evidently, if the reaction proceeds as outlined by Fuson and Corse,[1]

$$2RCOCl + 2CH_3MgI \longrightarrow RCOCOR + C_2H_6 + 2MgClI$$

the amount of ethane is too small and the amount of methane is too large to be strictly accounted for by enolization of the ketone. The amount of methane, however, is compatible with the hypothesis that free methyl radicals are formed (*cf.* equations (1) to (5)). On the other hand, another difficulty presents itself. The 15% of the heavier gas is not a mixture of equal parts of ethane and ethylene, but is almost pure ethane. Two explanations for this fact suggest themselves. In the first place, if 12% of the reaction proceeds according to the mechanism of Fuson and Corse[1] and 88% according to the mechanism suggested in reaction (7) and reactions (1) to (5), then the gas should contain only about 3% of ethylene, a quantity which we may have overlooked because of difficulties in the analytical procedure. Secondly, free methyl radicals in the presence of such reactive molecules as methylmagnesium iodide may react in a manner different from that indicated in equation (5). Thus, although removal of the hydrogen atom from the ether molecule may still be the dominant reaction (80–85%), the secondary cleavage of the ether molecule (15%), because of the stability of the magnesious iodide, may be outstripped by the faster reaction with the Grignard reagent.

$$CH_3\cdot + CH_3{:}MgI \longrightarrow C_2H_6 + MgI\cdot$$

Of the two alternative explanations, we prefer the latter, since it not only reconciles the facts recorded in this paper, but also explains observations which we hope to report in the near future.

Methylmagnesium iodide thus can react by either an ionic or a free-radical mechanism. The former is apparently much the faster of the two. The free-radical mechanism comes into play only where substances which can be reduced by magnesious iodide are present, and where the normal reaction of the Grignard reagent with the organic molecule is comparatively slow. High dilution of both components, and particularly of the Grignard reagent should, therefore, favor the free-radical reactions of the alkyl magnesium iodides.[9]

Experimental Details

Materials.—Mallinckrodt magnesium turnings or Dow sublimed magnesium was used. Methyl bromide was obtained from the Dow Chemical Company; bromobenzene from the Eastman Kodak Company. The bromobenzene was carefully fractionated before use. The methyl iodide was Mallinckrodt reagent grade. It was carefully distilled before use and was free from traces of iodine. The cuprous chloride was the usual anhydrous reagent. Anhydrous cobaltous and manganous chlorides were prepared from the hydrates by heating *in vacuo:* the former was heated to 150°, and the latter to 200°. Anhydrous ferric chloride was prepared from pure iron wire and chlorine.

Preparation of Grignard Reagents.—The Grignard reagents were prepared in a three-neck flask equipped with a mercury-sealed stirrer, reflux condenser, dropping funnel, and (in the case of the methylmagnesium bromide) an inlet tube extending nearly to the bottom of the flask. The apparatus was flushed with dry nitrogen and flamed before use.

Bromobenzene, diluted with enough dry ether to give a two-molar solution, was added to an excess of magnesium covered with a small amount of ether; the rate of addition was such that refluxing was maintained. After all the halide had been added, the mixture was refluxed for about an hour to insure completion of the reaction, and then filtered under nitrogen pressure through a coarse sintered glass filter. The reagent was stored under nitrogen in a brown bottle, and was titrated just before use.

Methylmagnesium iodide was prepared in a similar manner. The filtered Grignard reagent was always clear; where Dow magnesium was used, the liquid was water white.

The methyl bromide gas was bubbled into the flask containing excess magnesium and part of the ether at such a rate as to maintain refluxing. Portions of ether were added from time to time so that the final concentration was about two-molar. The Grignard reagent was refluxed, filtered, and stored as indicated previously.

Reaction of Phenylmagnesium Bromide with Mesitoyl Chloride.—The mesitoyl chloride (b. p. 86–88° at 4 mm.) was prepared from mesitoic acid according to the directions of Fuson, Corse and McKeever.[10]

Cobaltous chloride (0.01 mole) was added to phenylmagnesium bromide (0.28 mole in 330 ml. of ether) contained in a three-neck flask equipped with a mercury-sealed stirrer, reflux condenser, and dropping funnel. The flask was cooled in an ice-bath. The resulting black mixture was siphoned under nitrogen pressure into the dropping funnel and added slowly to a second three-neck flask equipped like the first, and containing 0.10 mole of mesitoyl chloride and 0.01 mole of $CoCl_2$ in 330 ml. of dry ether; the second flask was kept cool in an ice-bath. The addition was complete in ninety minutes. The mixture was stirred for thirty minutes longer at room temperature, and then allowed to stand overnight.

The product was decomposed with ice and hydrochloric acid, the ether layer separated, and the water layer extracted twice with ether. The combined ether layers were washed first with sodium bicarbonate, then with water, and finally dried over sodium sulfate. The ether was removed and the residue was steam distilled. From the distillate there was obtained a solid (4.3 g.) which, after crystallization from alcohol, melted at 66–68°. This substance was identified as biphenyl by its melting point and by the fact that it did not depress the melting point of an authentic sample of biphenyl.

After the steam distillation, the residue remaining in the flask was poured into ethyl alcohol; a light yellow solid separated (wt. 4.7 g., m. p. 228–232°). This substance, After several crystallizations from benzene and sublimation under high vacuum, yielded a white solid (m. p. 237–238°).

Anal. Calcd. for $C_{32}H_{34}O_2$: C, 85.33; H, 7.55. Found: C, 84 97; H, 7.37.

This material did not depress the melting point of *sym* diphenyldimesitylpinacol prepared by another method The yield of pure material was 21% based on the acid chloride used.

The alcohol was removed from the filtrate and the residue distilled at 1 mm. pressure. A colorless liquid which boiled at 130–140° was collected. This substance was identified as 2,4,6-trimethylbenzophenone; the yield was 41% based on the acid chloride used.

The residue remaining in the flask was a black tar. From this tar, a yellow solid (0.5 g., m. p. 119–120°) was obtained by sublimation in high vacuum. This substance was identical with the hexamethylbenzil obtained by re-

(9) The tendency of the Grignard reagent to dissociate into magnesious iodide and an organic free radical should increase with the decreasing electronegativity of the organic radical (*cf.* Kharasch and Weinhouse, *J. Org. Chem.*, 1, 209 (1936)).

action of methylmagnesium iodide with mesitoyl chloride. The yield of this material was 4% based on the acid chloride used. The material which could not be sublimed weighed 3 g.

When phenylmagnesium bromide was added to mesitoyl chloride (in the absence of cobaltous chloride), only 2,4,6-trimethylbenzophenone was isolated. The yield was 90%, based on the acid chloride used.

Reactions of Methylmagnesium Bromide and Mesitoyl Chloride in the Presence of Cobaltous Chloride.—The procedure was similar to that previously described, except that the Grignard reagent was mixed with the catalyst in a flask cooled in an ice-salt bath, and the dropping funnel into which the mixture was siphoned was equipped with a cold-finger filled with a mixture of ice and salt. Mesitoyl chloride (0.06 mole), methylmagnesium bromide (0.15 mole) and cobaltous chloride (0.0075 mole) were used. The reaction mixture was worked up in the usual manner. The quantities of the products formed are recorded in Table IV.

A total of 1700 cc. (corrected to standard) of gas was collected. The first 500 cc. of this gas was rejected. The molecular weight of the gas contained in the second 500 cc. was 19.4, and the unsaturation amounted to 10%. The gas analyses were made by the method of Kharasch, Lewis and Reynolds.[7]

When methylmagnesium bromide was added to mesitoyl chloride in the absence of cobaltous chloride, an 87% yield of 2,4,6-methylmesityl ketone was obtained; there was only a trace of the substituted benzil.

Reaction of Methylmagnesium Iodide and Mesitoyl Chloride.—In all experiments with these reagents, the concentrations and proportions of reactants, as well as the rate of addition and the manner of working up the products, were the same as previously described. The isolation procedure was similar to that of Fuson and Corse. The results of the experiments are given in Tables I, II, III and IV.

In the experiments in which metallic halides were used, the metal halide was usually added to the Grignard reagent; the resulting mixture was added to the mesitoyl chloride dissolved in ether. In the cobaltous, copper and iron chloride experiments, the Grignard reagent turned almost black; when manganous chloride was used, the solution remained clear and colorless.

Summary

1. In the reaction between mesitoyl chloride and methylmagnesium iodide it has been shown that: (a) the order of addition of the reactants is important; (b) light and small amounts of oxygen have no effect upon the reaction; (c) the use of pure magnesium in making the Grignard reagent and aging of the reagent made from ordinary magnesium give higher yields of 2,4,6,2′,4′,6′-hexamethylbenzil; (d) traces of the halides of iron, copper, and manganese limit the reaction to the normal addition; (e) small amounts of cobaltous chloride increase the yield of the substituted benzil, as is also the case when methylmagnesium bromide is used.

2. A mechanism has been proposed to account for the products of the reaction of mesitoyl chloride with Grignard reagents.

Unsaturated Esters of Glycolonitrile

BY DAVID T. MOWRY

In aqueous solution a mixture of formaldehyde and sodium cyanide reacts like glycolonitrile and sodium hydroxide.

$$CH_2O + NaCN + H_2O \rightleftharpoons HOCH_2CN + NaOH$$

With benzoyl chloride a typical Schotten–Baumann reaction occurs to give cyanomethyl benzoate[1] in 45% yields.

$$C_6H_5COCl + HOCH_2CN + NaOH \longrightarrow C_6H_5COOCH_2CN + NaCl + H_2O$$

In extending this reaction we have found that good yields (53–73%) of cyanomethyl esters of α,β-unsaturated acids can be obtained from the corresponding acid chlorides. Acrylyl chloride, however, gives poor yields because of a side reaction leading to the formation of an ester, $C_6H_9O_3N$, the structure of which has not yet been established. Furthermore, dibasic acid chlorides, such as fumaryl chloride, give only insignificant yields of diesters by the aqueous method. These esters are satisfactorily prepared by the method of Hechenbleikner[2] in which the acid chloride is treated with glycolonitrile in anhydrous ether in the presence of a tertiary amine.

Inasmuch as it has been observed[3] that acetyl chloride gives low yields in the Schotten–Baumann reaction, it is not surprising that the method is of little value for the preparation of cyanomethyl esters of saturated aliphatic acids. A better procedure appears to be the reaction of the sodium salt of the acid with chloroacetonitrile.[4] The properties of the unsaturated esters are reported in Table I.

Experimental

Reagents.—The methacrylyl, crotonyl, cinnamoyl and α-methylcinnamoyl chlorides were prepared by the action of thionyl chloride on the acids. Acrylyl chloride was prepared in 27% yields by the action of phosphorus oxychloride on sodium acrylate[5] and in 35% yield by dehydrohalogenation[6] of β-chloropropionyl chloride over alumina at 250°. β-Chlorocrotonyl chloride was obtained from ethyl acetoacetate and phosphorus pentachloride.[7] Fu-

[a] Prepared by Dr. W. Frederick Huber.

maryl and mesaconyl chlorides were made from maleic anhydride and phthalyl chloride.[8]

Glycolonitrile.—A modification of the cyanohydrin interchange method[9] was used for the preparation of glycolonitrile.

To a concentrated aqueous solution of 1040 g. of sodium bisulfite was added 720 g. (10.0 moles) of methyl ethyl ketone with stirring and cooling by addition of ice. A solution of 520 g. of 95% sodium cyanide was then added in a similar manner. The resultant supernatant oil was separated and mixed with 871 g. of 37% formalin, to which 5 g. of sodium cyanide had been added. After this solution had been stirred at 35° for two hours, 30 g. of phthalic anhydride was added and the material distilled. The regenerated ketone and water were removed at 100 mm. The product was then rapidly distilled at 20–30 mm. (slight decomposition), b. p. 100–120°. When the distillation was about two-thirds completed, the residue became very viscous. The flame had to be removed and the flask cooled immediately to avoid violent dissociation and polymerization caused by superheating. The crude product was refractionated without decomposition over 5 g. of phthalic anhydride, giving 228 g. (40% yield) of glycolonitrile, b. p. 99–100° (17 mm.), $n^{25}D$ 1.4090.

Cyanomethyl Acrylate (Method A).—Acrylyl chloride (233 g., 2.6 moles) was added dropwise to a briskly stirred solution of 236 cc. (2.7 moles) of 37% formalin and 154 g. (2.9 moles) of 95% sodium cyanide in 300 cc. of water at 10°.

Stirring was continued for one hour after addition was complete, while the solution was allowed to rise to room temperature. The supernatant oil was taken up in several volumes of ether, washed with dilute solutions of sodium carbonate and hydrochloric acid. Distillation over hydroquinone of the dried ether solution gave 46 g. (17%) of cyanomethyl acrylate, b. p. 42–43° (1 mm.), and 50 g. of a compound, $C_6H_9O_3N$, b. p. 82–83° (1 mm.), $n^{25}D$ 1.4248, which did not decolorize a carbon tetrachloride solution of bromine.

Anal. Calcd. for $C_6H_9O_3N$: C, 50.36; H, 6.34; N, 9.79. Found: C, 50.74; H, 6.27; N, 9.94.

Solid acid chlorides such as cinnamoyl chloride were dissolved in dioxane to facilitate dropwise addition to the aqeuous solution.

Cyanomethyl Cinnamate (Method B).—Glycolonitrile (28.5 g., 0.5 mole) was added slowly with stirring to a solution of 86 g. of cinnamoyl chloride (0.5 mole) and 60 g. of dimethylaniline (0.5 mole) in 100 cc. of anhydrous ether at 5–10°. The solution was allowed to warm to room temperature and stirred for two hours before dilution with two volumes of ether and washing with dilute solutions of sodium carbonate and hydrochloric acid. Evaporation of the ether gave 72 g. (75%) of crude cyanomethyl cinnamate, m. p. 57–60°. Three recrystallizations from dilute ethanol gave large colorless plates, m. p. 62.7–63.0°.

Summary

The reaction of an aqueous solution of sodium cyanide and formaldehyde with benzoyl chloride has been extended to the acid chlorides of monobasic α,β-unsaturated acids. The cyanomethyl esters of acrylic, methacrylic, crotonic, β-chlorocrotonic, cinnamic, α-methylcinnamic, fumaric and mesaconic acids are reported.

The Condensation of Isobutyraldehyde with Aliphatic Ketones

By S. G. Powell and French Hagemann[1]

It has been shown that certain straight chain aliphatic aldehydes condense with methyl ethyl ketone through the methylene group of the ketone,[2] whereas homologous methyl ketones which contain six or more carbon atoms appear to condense through the methyl group.[3] On the other hand, the condensation of α-methylbutyraldehyde, α-ethylbutyraldehyde and α-ethylcaproaldehyde with various methyl ketones has been found to take place through the methyl group.[4]

The same alkaline condensing agents which bring about the above-mentioned reactions with aliphatic aldehydes cause aromatic aldehydes to react with the methyl group of the ketone, while acids bring about condensation with the methyl-

ene group.[5] No similar behavior seems to have been observed in the case of aliphatic aldehydes.

The course of the reaction between the simplest *alpha*-branched chain aldehyde, isobutyraldehyde and unsymmetrical methyl ketones has been established only in the case of methyl ethyl ketone, which Thoms and Kahre[6] found to condense through the methyl group. Therefore, it seemed desirable to investigate the reaction of isobutyraldehyde with other ketones.

Isobutyraldehyde was condensed with methyl *n*-propyl, methyl *n*-butyl, methyl isobutyl, methyl *n*-amyl and methyl *n*-hexyl ketones in the presence of dilute potassium hydroxide and the resulting ketol was dehydrated to the unsaturated ketone. The structure of the unsaturated ketone was determined by ozonolysis, and in each case the condensation was found to take place upon the methyl carbon atom. By repeated fractionation of the crude unsaturated ketone resulting from the reaction between isobutyraldehyde and methyl *n*-amyl ketone there was obtained a small fraction which consisted chiefly of the compound formed by methylene condensation. It is possible that similar small quantities of the methylene isomer may have formed in the other condensations.

When the ozonides were decomposed, the expected 1,2-dicarbonyl compounds were oxidized by the hydrogen peroxide to mixtures of acids which were identified.

$$(CH_3)_2CHCH{=}CHCOCH_2R = (CH_3)_2CHCHO + RCH_2COCHO + H_2O_2$$
$$RCH_2COCHO + H_2O_2 = RCH_2COOH + HCOOH$$

In the neutral fraction of the decomposition products, in addition to isobutyraldehyde, appreciable amounts of acetone and acetone peroxide were identified. The last two substances must have been formed by oxidation of the isobutyraldehyde by the hydrogen peroxide.

Further proof of the structure of the unsaturated ketones in the case of methyl *n*-amyl and methyl *n*-hexyl ketones was obtained by reducing them to the corresponding saturated ketones and oxidizing the latter to a mixture of acids which were identified. Also, the saturated ketone from the methyl *n*-amyl ketone condensation was found to be identical with *n*-amyl isoamyl ketone prepared by another method.

Thoms and Kahre gave the structure of the condensation product of di-ethyl ketone and isobutyraldehyde as $(CH_3)_2CHCH{=}CHCH_2COCH_2CH_3$, whereas Franke and Köhler[7] gave the structure as $(CH_3)_2CHCH{=}C(CH_3)COCH_2CH_3$. As no proof of structure was given in either case, this work was repeated. The unsaturated ketone was ozonized and the ozonide decomposed in the presence of hydroxylamine. Since methylethylglyoxime was identified as a product, the correct structure is that given by Franke and Köhler.

It was not possible to reduce completely some of the unsaturated ketones to the saturated alcohols with sodium and alcohol or moist ether, even though a large excess of sodium was used. 2-Methyl-3-decen-5-one, 2-methyl-3-undecen-5-one and 2,7-dimethyl-5-octen-4-one yielded products which were still unsaturated, but which gave the saturated alcohols upon hydrogenation with platinum oxide catalyst.

In order to explain this behavior, 2-methyl-3-decen-5-one was treated with sodium and ethyl alcohol. The analysis and the molar refraction of the product agreed closely with that calculated for an unsaturated alcohol, $C_{11}H_{22}O$. Ozonolysis established its formula as $(CH_3)_2C{=}CHCH_2CHOHCH_2CH_2CH_2CH_2CH_3$. Acetone, but no isobutyraldehyde, and an aldehyde which appeared to be unsaturated were found as ozonolysis products. The semicarbazone of the latter compound was prepared and found to melt at 169–170° (cor.); van Romburgh[8] reported the melting point of the semicarbazone of α-octenaldehyde as 163°. Analysis of the compound corresponded to octenaldehyde semicarbazone. α-Octenaldehyde would result from the dehydration of β-hydroxycaprylaldehyde which would be the primary ozonolysis product of this alcohol. Apparently in the presence of the alkaline reduction medium the double bond shifts from the α-β to the β-γ position. In the latter position the ethylenic bond is very resistant to reduction by sodium and alcohol or water.

Experimental Part

The physical properties and analyses of the ketones and alcohols prepared in the course of this investigation are collected in Table I. The melting points and analyses of the new derivatives prepared are listed in Table II.

Condensations.—All of the condensations were carried out by the addition of a mixture of one mole proportion of aldehyde and one-half mole of ketone to two and one-half moles of ketone and excess alcoholic potassium hydroxide as previously described.[2a] The rate of addition was regulated so as to keep the temperature below 35°.

Dehydrations.—The ketols were dehydrated by slow distillation at atmospheric pressure in the presence of a small amount of iodine.[9] The distillate was separated from water and the distillation repeated with fresh iodine. Drying over anhydrous magnesium sulfate and fractionation gave the desired unsaturated ketone.

The crude unsaturated ketone from the methyl *n*-amyl ketone condensation was put through a 28-plate fractionating column at atmospheric pressure. From 246 g. were obtained the following fractions: up to 205°, 15 g.; 205–223°, 45 g.; 223–224°, 85 g. A large viscous residue of about 100 g. remained in the pot, due to decomposition and resinification during the long-continued heating at high temperature. Refractionation of the 205–223° portion gave 28 g. of material boiling from 208–218°, which upon redistillation at reduced pressure yielded 14.2 g. boiling at 103–105° (24.5 mm.). This material gave a very strong positive iodoform reaction,[10] whereas the 223–224° fraction gave a negative reaction.

2,7-Dimethyl-4-octanol	81–82	7.95	8.10

[a] Ref. (11). [b] Whitmore, Revukas and Smith, THIS JOURNAL, 57, 706 (1935). [c] Ref. (10), p. 142. [d] Ref. (10), p. 143. [e] Reichstein, *Helv. Chim. Acta*, 9, 800 (1926). [f] This compound showed no depression in melting point when mixed with the hydantoin of *n*-amyl isoamyl ketone obtained by oxidation of *n*-amylisoamylcarbinol prepared by the Grignard method.

The 5,5-disubstituted hydantoin derivative[11] of the 223–224° fraction melted at 135–136° while that of the 103–105° (24.5 mm.) fraction melted at 175–176°. Ozonolysis showed that the latter fraction consisted chiefly of 2-*n*-butyl-5-methyl-3-hexen-2-one.

Reduction of Unsaturated to Saturated Ketones.—The unsaturated ketones were converted to the corresponding saturated ketones by vapor phase hydrogenation over supported nickel catalyst maintained at 200°.

Reduction of Saturated Ketones to Alcohols.—2-Methyl-5-nonanone and 2,7-dimethyl-4-octanone were reduced to the corresponding alcohols by dissolving 0.1-mole proportion in 100 ml. of absolute ethyl alcohol and adding 0.4 mole of sodium. After initial cooling, the reaction was completed upon the steam-bath. The solution was then diluted with 400 ml. of water, the insoluble layer separated, washed with water and steam distilled. Extraction of the distillate with ether, drying over potassium carbonate and removal of the ether yielded the desired alcohol.

Reduction of Unsaturated Ketones to Alcohols: (1) Preparation of 2-Methyl-5-decanol.—Four-tenths mole (67 g.) of 2-methyl-3-decen-5-one was dissolved in 500 ml. of ether and placed in a flask containing a suspension of 250 g. of sodium bicarbonate in 500 ml. of water. Sixty grams (2.6 moles) of sodium metal cut in narrow strips was added piece by piece. After completion of the addition, the ether layer was separated and dried over anhydrous sodium sulfate. There was obtained 34.5 g. of material boiling from 120–128° (24 mm.). Redistillation yielded a sample boiling at 124–126° (24 mm.) which upon analysis gave C, 76.75 and H, 13.61. Calcd. for $C_{11}H_{24}O$: C, 76.67; H, 14.04.

As the material was apparently still partially unsaturated, the reduction was completed by catalytic hydrogenation. Twenty-nine grams of the substance was dissolved in 150 ml. of 95% ethyl alcohol and treated with hydrogen at about three atmospheres pressure using 0.3 g. of platinum oxide as catalyst.[12] Upon redistillation the pure compound boiled at 122.5–123° (24 mm.).

(2) Preparation of 2-Methyl-5-undecanol.—Four-tenths mole (74 g.) of 2-methyl-3-undecen-5-one was reduced with moist ether as above yielding 50 g. of material of b. p. 135–140° (27 mm.). A sample boiling at 135° (24 mm.) obtained by redistillation gave the following analysis: C, 77.84; H, 12.92. Calcd. for $C_{12}H_{26}O$: 77.35; H, 14.07.

Thirty grams of this material was reduced catalytically

as above. Distillation of the alcohol gave 22 g. of material boiling from 129–134° (24 mm.). Upon redistillation the compound boiled at 132–133° (24 mm.).

(3) **Preparation of 2-Methyl-2-decen-5-ol.**—Twenty grams (0.12 mole) of 2-methyl-3-decen-5-one was dissolved in 200 ml. of absolute ethyl alcohol and 71 g. (0.75 mole) of metallic sodium added. After completion of the reaction the solution was diluted with water, the oily layer separated, washed with water and steam distilled. The distillate was extracted with ether and dried over potassium carbonate. Distillation gave 8.6 g. (42%) of colorless, rather viscous liquid, b. p. 129.5–131° (30 mm.); d^{20}_4 0.8422; $n^{20}D$ 1.4473; M_D (obs.), 54.05; M_D (calcd.), 54.07.

Anal. Calcd. for $C_{11}H_{22}O$: C, 77.58; H, 13.02. Found: C, 77.34; H, 13.27.

The 3,5-dinitrobenzoate was an oil which could not be made to crystallize.

Ozonolysis.—For production of ozone, a generator similar in design to that described by Henne[13] was used. The ozone content of the issuing gas was about 8% by weight at a flow of about 3 liters per hour.

(1) **Unsaturated Ketones Obtained from Methyl Ketones.**—Ozone was passed through the sample (0.1 to 0.15 mole), cooled by an ice–salt mixture, until the sudden liberation of iodine in a solution of potassium iodide serving as a trap for the exit gases indicated completion of the reaction. All of the ozonides were viscous yellow liquids possessing reeking odors. Decomposition was immediately carried out by adding the ozonide dropwise, with stirring, to a boiling mixture of 200 ml. of water, an excess of zinc, and a trace of hydroquinone and silver nitrate.[14] The volatile decomposition products were allowed to distill over during the addition of the ozonide, and, after addition was complete, distillation was continued until all steam-volatile products were removed, more water being added if necessary. The residue was then acidified with an amount of sulfuric acid equivalent to the zinc used and the mixture distilled with repeated additions of water until no more acid material came over. In each case an appreciable amount of white solid deposited on the walls of the condenser. This was identified as acetone peroxide by its melting point of 131.5–132.5°, both alone and when mixed with a known sample prepared by oxidation of acetone with Caro's acid.[15]

The distillate was neutralized with sodium hydroxide and the neutral material removed by distillation. In each case this was found to consist of isobutyraldehyde, identified as the 2,4-dinitrophenylhydrazone, acetone, identified by conversion to dibenzalacetone, and a high boiling fraction which was not investigated further.

The remaining solution was evaporated to dryness, an equivalent amount of dilute sulfuric acid added and the liberated acids distilled off by repeated additions of water. The distillate was extracted with ether, the ether solution was dried over calcium chloride, the ether was removed and the acids fractionated. The aqueous layer was neutralized with sodium hydroxide and evaporated to dryness. The sodium salts were treated with *p*-bromophenacyl bromide,[10] and in all but one case the product was the formic acid ester, m. p. 140–141°, alone and when mixed with an authentic sample. In the case of the small lower boiling fraction of the unsaturated ketone from the methyl *n*-amyl ketone condensation, the formic acid ester was found and in addition a larger quantity of the acetic acid ester, m. p. 84.5–85.5°, alone and mixed with a known sample.

Table III lists the acids which were found in the ether soluble fractions. In each case mixed melting point determinations with known samples of the derivatives were made to confirm the identity of the compounds.

(2) **Unsaturated Ketone Obtained from Diethyl Ketone.**—Three-hundredths mole of 4,6-dimethyl-4-hepten-3-one was dissolved in 25 ml. of ethyl acetate and ozonized as above. The solution of ozonide was poured into 100 ml. of water containing 0.12 mole each of hydroxylamine hydrochloride and sodium acetate. The mixture was stirred for two hours, then distilled to remove ethyl acetate and other volatile material. To the residue was added 1 g. of ammonium chloride and ammonium hydroxide until alkaline to litmus. A solution of 3.7 g. of nickel acetate was then added and the mixture allowed to stand overnight. The orange-brown precipitate of nickel salt was filtered and dried; yield, 1.0 g. (18%).

The dry salt was shaken with 5% sulfuric acid and the solution extracted with ether. Evaporation of the ether left a white solid residue, which, after recrystallization from water, melted at 172–173°. A sample of methylethylglyoxime was prepared by treating isonitrosodiethyl ketone (prepared from diethyl ketone by treating with ethyl nitrite) with hydroxylamine hydrochloride and sodium acetate. The melting point was 172–173° and a mixed melting point with the above material was also 172–173°.

(3) **2-Methyl-2-decen-5-ol.**—Four and two-tenths grams of the alcohol was dissolved in 10 ml. of glacial acetic acid and ozonized as above. The colorless ozonide solution was diluted with 50 ml. of ether and decomposed by addition of 5 g. of zinc dust followed by dropwise addition of 5 ml. of water. The mixture was stirred and refluxed until a drop of the solution no longer gave a blue color when shaken with starch–iodide solution, then the sludge of zinc and zinc acetate was filtered off and washed with ether. The filtrate and washings was almost neutralized with powdered sodium bicarbonate, then shaken with sodium carbonate solution, washed with water and dried over anhydrous magnesium sulfate.

After removing the ether, about 3 g. of yellow liquid remained. The material appeared to decompose, splitting out water when distillation was attempted, so it was purified by means of steam distillation. A colorless liquid possessing a penetrating aromatic odor somewhat similar to that of *n*-heptaldehyde was obtained which readily gave a purple color with fuchsin-aldehyde reagent, and rapidly absorbed bromine in carbon tetrachloride solution without evolution of hydrobromic acid. The semicarbazone of this material melted, after two recrystallizations from dilute methanol, at 169–170°. The melting point of α-octenaldehyde semicarbazone was reported by van Romburgh[8] as 163°.

Anal. Calcd. for $C_9H_{17}N_3O$: C, 58.99; H, 9.35; N, 22.93. Found: C, 58.72; H, 9.14; N, 22.73.

The ether which had been removed by distillation was found to contain acetone, identified by conversion to dibenzalacetone, mf. p. 111.5–112.5°, both alone and when mixed with an authentic sample.

Oxidation of Saturated Ketones to Acids: (1) **Methyl *n*-Amyl Ketone Condensation.**—Five-hundredths mole of 2-methyl-5-decanone was oxidized with 0.15 mole of sodium dichromate, 0.6 mole of sulfuric acid and 250 ml. of water as previously described.[2a,16] Considerable carbon dioxide was evolved at the start and throughout the course of the oxidation. A total of 0.09 mole of acid was obtained. *n*-Caproic acid was identified in the water-insoluble acid fraction by conversion to the 2-alkyl benzimidazole,[17] m. p. 157–158°, which showed no depression when mixed with the known *n*-caproic acid derivative, m. p. 158–158.5°. Acetic acid was shown to be present in the water-soluble fraction by preparing the *p*-toluide, m. p. 146.5–147.5°, alone and when mixed with known aceto-*p*-toluide.

(2) **Methyl *n*-Hexyl Ketone Condensation.**—Five-hundredths mole of 2-methyl-5-undecanone, oxidized as above, gave 1.1 moles of total acids. *n*-Heptoic acid was identified in the water-insoluble fraction by conversion to the piperazonium salt,[18] m. p. 97–98°, which showed no depression when mixed with authentic piperazonium di-*n*-heptoate, m. p. 96–97°. Isovaleric acid was also shown to be present by preparing the piperazonium salt, m. p. 140–141°, alone and mixed with known piperazonium di-isovalerate, m. p. 140–141°. The presence of acetic acid in the water-soluble fraction was shown by preparing the *p*-toluide, m. p. 146.5–147.5°, which exhibited no depression when mixed with known aceto-*p*-toluide.

Preparation of 2-Methyl-5-decanone.—From 0.6 mole of isoamyl bromide, 0.6 mole of *n*-hexaldehyde and 0.6 mole of magnesium there was obtained 38 g. (37%) of 2-methyl-5-decanol boiling at 122–126° (28.5 mm.). Twenty-nine grams (0.17 mole) of the alcohol was oxidized to the ketone by adding dropwise, with stirring, to a mixture of 0.057 mole of sodium dichromate, 0.226 mole of sulfuric acid and 100 ml. of water. Rate of addition was controlled so that the temperature did not rise above 50°. The mixture was stirred for one hour longer, then the insoluble layer was separated, washed with sodium carbonate solution and water and dried over potassium carbonate. Distillation gave 21.5 g. (75%) of *n*-amyl isoamyl ketone, b. p. 113–118° (28.5 mm.); hydantoin, m. p. 193–194°.

Summary

1. It has been shown that isobutyraldehyde, in alkaline reaction medium, condenses through the alpha methyl carbon atom of the following methyl ketones: *n*-propyl, *n*-butyl, isobutyl, *n*-amyl and *n*-hexyl. A small fraction consisting chiefly of the unsaturated ketone resulting from methylene condensation was isolated in the methyl *n*-amyl ketone condensation.

2. Isobutyraldehyde condenses through the alpha methylene carbon atom of diethyl ketone.

3. Reduction of 2-methyl-3-decen-5-one with sodium and ethyl alcohol yielded 2-methyl-2-decen-5-ol.

4. The following new compounds have been prepared and characterized: 2-methyl-3-nonen-5-one, 2,7-dimethyl-5-octen-4-one, 2-methyl-3-decen-5-one, 2-methyl-3-undecen-5-one, 2-methyl-5-nonanone, 2,7-dimethyl-4-octanone, 2-methyl-5-decanone, 2-methyl-5-undecanone, 2-methyl-5-nonanol, 2-methyl-5-decanol, 2-methyl-5-undecanol, and 2-methyl-2-decen-5-ol.

5. The 5,5-disubstituted hydantoins of the following ketones have been prepared and characterized: 2-methyl-3-nonen-5-one, 2,7-dimethyl-5-octen-4-one, 2-methyl-3-decen-5-one, 3-*n*-butyl-5-methyl-3-hexen-2-one, 2-methyl-3-undecen-5-one, 7-methyl-4-octanone, 2-methyl-5-nonanone, 2,7-dimethyl-4-octanone, 2-methyl-5-decanone, 2-methyl-4-undecanone, and 4,6-dimethyl-3-heptanone.

6. The following new derivatives have been prepared and characterized: the nitroguanylhydrazones of 2-methyl-5-decanone and 2-methyl-5-undecanone; the 2,4-dinitrophenylhydrazone of 4,6-dimethyl-4-hepten-3-one; the semicarbazone of 2,7-dimethyl-4-octanone; the 3,5-dinitrobenzoates of 2-methyl-5-nonanol and 2,7-dimethyl-4-octanol.

Electrolyte Catalysis in the Ammonolysis of 9-Phenyl-9-chlorofluorene by Liquid Ammonia[1]

BY P. M. WILLIAMSON,[2] ROBBIN C. ANDERSON AND GEORGE W. WATT

Studies on the ammonolysis of both esters and organic halogen compounds by liquid ammonia[3] have provided numerous examples of acceleration of the rates of these reactions by ammonium salts. Since ammonium salts behave as acids in liquid ammonia solutions,[4] it has been assumed that the observed catalytic effects are to be attributed to acid catalysis. Earlier work in these Laboratories,[5–7] has led to the suggestion[7] that catalysis by ammonium salts is fundamentally no different from similar effects produced by non-onium type salts. As a result of their studies on both ammonolytic and aminolytic reactions, Audrieth, Scott and Hill[8] have expressed tentatively this same opinion and have suggested the use of the term "electrolyte catalysis."

In an earlier paper,[7] data on the autocatalyzed ammonolysis of 9-phenyl-9-chlorofluorene and on the influence of added ammonium chloride have been presented. Work described in the present paper includes the effects produced by another ammonium salt (ammonium nitrate) and two non-onium type salts (sodium chloride and sodium nitrate). These studies provide quantitative proof of the assumption that, at least in one case, effects heretofore attributed to acid catalysis are not uniquely due to the fact that ammonium salts behave as acids in liquid ammonia but rather that these effects are more properly looked upon as typical examples of a more general electrolyte catalysis.

Experimental

Materials.—All materials were prepared and/or purified as described previously[5-7] with the exception of ammonium nitrate, in which case the C. P. reagent grade material was recrystallized three times from water, dried at 150°, and stored under anhydrous conditions.

Procedure.—Experimental data reported in this paper were obtained by procedures identical with those described by Williamson, Anderson and Watt.[7]

Data.—Sample data relating to reactions involving excess liquid ammonia and 0.3000-g. samples of 9-phenyl-9-chlorofluorene in the presence of sodium nitrate are given in Table I, while the experimental data relating to sodium chloride, sodium nitrate, and ammonium nitrate are represented graphically by Figs. 1, 2 and 3. On these graphs, each point represents the average of at least two independent measurements which were reproducible within 2%.

Discussion

The essential reaction already has been shown[7] to be the autocatalyzed formation of 9-phenyl-9-aminofluorene and ammonium chloride by the interaction of 9-phenyl-9-chlorofluorene and liquid ammonia. The results summarized in Figs. 1, 2 and 3 show that the reaction is also catalyzed by ammonium nitrate, sodium chloride, and sodium nitrate. Since preliminary calculations indicated that the catalytic effect is directly proportional to the concentration of the catalyst, the rate equation for the catalyzed reaction was concluded to be of the form

$$-dC_{C_{19}H_{13}Cl}/dt = k_1(a - x) + k_2(x)(a - x) + k_3c(a - x)$$

where a = the initial concentration of 9-phenyl-9-chlorofluorene, x = moles/l. of 9-phenyl-9-chlorofluorene ammonolyzed at time t, c = concentration of some added electrolyte other than ammonium chloride, and k_1, k_2 and k_3 are, respectively, reaction velocity constants for the un-

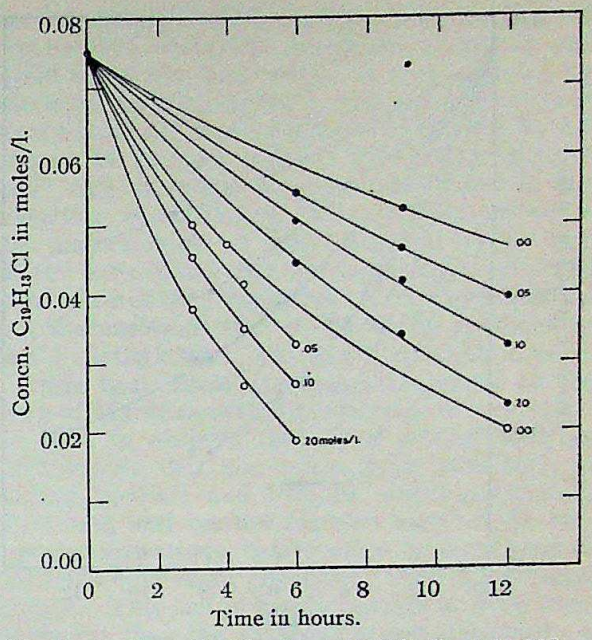

Fig. 1.—Sodium chloride: O, at 25.08°; ●, at 15.08°.

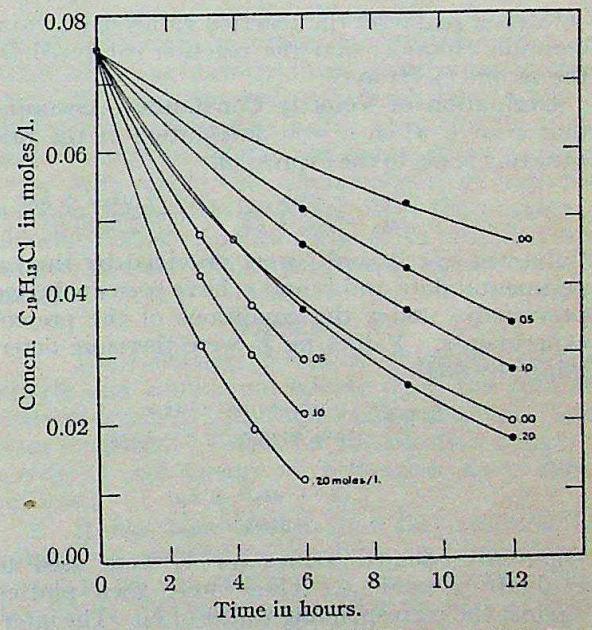

Fig. 2.—Sodium nitrate: O, at 25.08°; ●, at 15.08°.

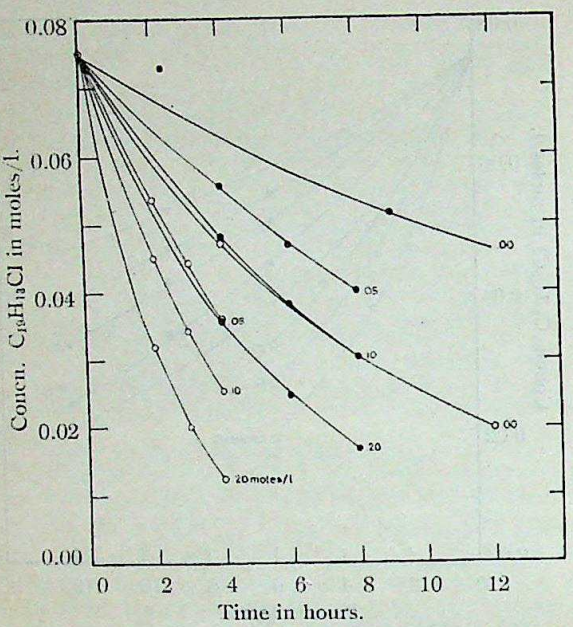

Fig. 3.—Ammonium nitrate: ○, at 25.08°; ●, at 15.08°.

catalyzed reaction, the reaction catalyzed by ammonium chloride, and the reaction catalyzed by the second electrolyte.

Evaluation of Velocity Constants.—Assuming that $x = 0$ when $t = 0$, integration of the rate equation leads to the expression

$$\log \frac{ack_3 + ak_1 + ak_2x}{-cxk_3 + ack_3 - k_1x + ak_1} = \frac{(k_1 + ak_2)t + k_3ct}{2.3026}$$

Values of a, c, x and t were provided by the experimental data and k_1 and k_2 have been evaluated previously[7] under the conditions of the present experiments. Values for k_3 were therefore determined by setting

$$y_1 = \log \frac{ack_3 + ak_1 + ak_2x}{-cxk_3 + ack_3 - k_1x + ak_1}$$

and

$$y_2 = \frac{(k_1 + ak_2)t + k_3ct}{2.3026}$$

Different assumed values for k_3 were used to evaluate y_1 and y_2. These were then plotted against the corresponding values of k_4. The intersection of the two curves determined a value of k_3 for the set of data used. For each added electrolyte at a given temperature, nine such values were determined. These were then averaged by the method of least squares.

The resulting values of the various velocity constants are summarized in Table II. By use of these constants, values for x under different experimental conditions were calculated and, in general, these values agreed with the experimental data within 2–3%. Values of k_3 decrease consistently with increase in the concentration of the electrolyte (*e. g.*, 0.2690 in 0.05 *M* NaCl, 0.2536 in 0.1 *M*, and 0.2302 in 0.2 *M*). This trend is not surprising since the electrolyte is probably not completely dissociated in the liquid ammonia solutions. The value c, used in calculating k_3, should, therefore, be corrected by the use of an activity coefficient. Quantitative data on activities of the various solutes in liquid ammonia are not available but there is good qualitative evidence from conductance data, etc.,[9] that the probable changes in these activities are sufficient to account for both the magnitude and direction of the variations in the calculated values of k_3.

TABLE II

VELOCITY CONSTANTS AND APPARENT ENERGY OF ACTIVATION

Catalyst	Velocity constants (15.08°C.)	Velocity constants (25.08°C.)	Energy of activation, cal./mole
None	0.0349	0.0807	14,300
NH_4Cl	.409	.953	14,400
NaCl	.242	.694	17,900
$NaNO_3$	.405	1.012	15,600
NH_4NO_3	.690	1.638	14,800

Energy of Activation.—Values for the *apparent* energy of activation were calculated from the rate constants at 15.08 and 25.08° using the Arrhenius equation. These results are summarized in Table II. The values given are all reproducible to within ±800 cal./mole.

Because of experimental difficulties, including the high vapor pressure of ammonia at elevated temperatures and the very limited solubility of 9-phenyl-9-chlorofluorene at lower temperatures, it was not feasible to study the influence of variation of temperature over a wide range. Accordingly, values obtained by assuming the applicability of the Arrhenius equation do not provide an adequate basis for definite conclusions as to the mechanism of the catalytic effect. Nevertheless, it is significant that in no case is the energy of activation lower than that for the uncatalyzed reaction. This same effect has been observed previously for a number of other ammonolytic reactions.[6] The results indicate clearly that the ordinary concept that catalysis involves a lower energy of activation is not necessarily applicable to catalysis of ammonolytic reactions in liquid ammonia.

Electrolyte Catalysis.—The results summarized in Figs. 1, 2 and 3 show that the ammonolysis of 9-phenyl-9-chlorofluorene is catalyzed not only by salts which behave as acids in liquid ammonia but also by certain non-onium salts. The rate of reaction in the presence of sodium nitrate is even greater than in the presence of ammonium chloride.

Since, in the experiments involving added non-onium type salts, ammonium chloride must always be present as a product of the ammonolytic reaction, it might be suggested that the observed change in rate of reaction is a result of a change in the activity of the ammonium chloride. Shatenshtein and Markova[10] have attributed the in-

fluence of non-onium type salts upon the "acid-catalyzed ammonolysis" of pilocarpine to the resultant change in the activity of the acid. Such an explanation is certainly not tenable in the present case. The form of the rate equation indicates that there is a second catalytic effect which is additive to that of the ammonium chloride. The quantity of ammonium chloride present varies continuously, but there appears to be no correlation whatever between this variation and the observed catalytic effect. The total electrolyte concentration undoubtedly has some effect on the activity of the acid, but it is not to be expected that the addition of sodium nitrate would change the activity more than would the addition of an equivalent quantity of ammonium chloride.

Comparison of the data for sodium and ammonium salts indicates that the ammonium salts are slightly more effective catalysts than are the corresponding sodium salts. It is possible that the actual catalysts are the ammonium and sodium ions which might distort materially the carbon–chlorine bond. Comparison of the chlorides and nitrates does not, however, show any consistent variation for the different cations. This lack of consistency may arise simply from the fact that the activities of the various salts at the same concentration are different. However, it is also possible that the associated ion-pairs of a salt such as sodium chloride, which should have a large dipole moment, may influence the activation of a carbon–halogen bond in liquid ammonia and thus tend to catalyze the ammonolytic cleavage. Unfortunately, quantitative data on activities are not available and these possibilities cannot be tested at present.

After completion of the present experiments, there became available a publication in which Markova and Shatenshtein[11] describe what might appear to be a rather comprehensive study of the kinetics of the ammonolysis of organic compounds involving carbon–halogen bonds. It is impossible to evaluate their results effectively since no information is given with regard to the experimental methods employed, even though time intervals of less than five minutes were involved in some measurements while in others two liquid phases were present in the reaction mixtures. So far as one can determine from their publication, all rate constants were calculated using the equation for a first order reaction, yet in some experiments equimolar quantities of halide and liquid ammonia were used. It was assumed by Markova and Shatenshtein that the sole reaction involved in each rate measurement was the formation of the primary amine. Fernelius and Bowman[3] call attention to numerous cases of the formation of secondary and tertiary amines in the ammonolysis of alkyl halides. Otto and Watt[12] have found that the ammonolysis of ethyl iodide (one of the compounds studied by Markova and Shatenshtein) at 0° yields 48.8% ethylamine, 31.8% diethylamine, and 18.4% triethylamine.

Aside from these questionable aspects of the work of Markova and Shatenshtein, it is of interest here to observe that their results indicate qualitatively that non-onium type salts such as sodium bromide and lithium, sodium, calcium, strontium, and barium nitrates may all, at certain concentrations, catalyze the ammonolysis of ethyl chloride more effectively than ammonium nitrate. This fact is hardly consistent with their viewpoint that the catalysis is fundamentally a function of the acid present.

In view of the results obtained in the present study, it becomes important to determine whether other salts, particularly those of different charge type, will show catalytic effects similar to those exhibited by the sodium salts. Quantitative data are also needed on the influence of non-onium type salts upon the ammonolysis of organic halogen compounds involving other than carbon–chlorine bonds. Studies designed to provide such information are now in progress in these Laboratories.

Summary

1. The influence of sodium chloride, sodium nitrate and ammonium nitrate upon the rate of ammonolysis of 9-phenyl-9-chlorofluorene has been described. Values for the reaction velocity constants and energy of activation have been recorded.

2. It has been shown that this reaction is subject to electrolyte catalysis by ammonium salts and by non-onium type salts as well. The bearing of this fact upon earlier theories of acid catalysis has been discussed.

3. Attention has been directed to certain questionable aspects of related work described by Markova and Shatenshtein.

[COMMUNICATION NO. 946 FROM THE KODAK RESEARCH LABORATORIES]

Some Effects of Solvents upon the Absorption Spectra of Dyes. III. Temperature and Organic Solutions of Cyanine Dyes

BY S. E. SHEPPARD AND H. R. BRIGHAM

Some reference to the influence of temperature on solutions of cyanine dyes was made in Part I.[1] The experiments reported there have been extended, particularly to include both polar and non-polar solvents, and both neutral (otherwise dipolar) and ionized cyanine dyes.

Apparatus and Experimental Procedure

Apparatus.—The cell used to measure the spectral absorption of these dyes is shown in Fig. 1. The cooling mixture was contained in a Dewar flask which had plane windows sealed in the bottom of each wall and parallel to each other. The cell in which the sample was placed was a cylindrical glass tube which had a plane window sealed onto one end, and this cell was set on the inside window of the Dewar flask. Then, in order to eliminate trouble caused by frost forming on the surface of the solution being measured, a cylindrical tube with windows sealed on each end parallel to each other was evacuated and placed inside the cell containing the solution. This tube was held in position by a holder so that the bottom was parallel to and at a known distance from the cell window. The distance between these two cell windows, *i. e.*, the thickness of the solution, was obtained by having the holder for the evacuated cell connected to a micrometer screw graduated to 0.1 mm. The plunger is long enough so that the lower end of the liquid to be examined is at the temperature of this liquid, while the upper end is free from external frost, because maintained at room temperature.

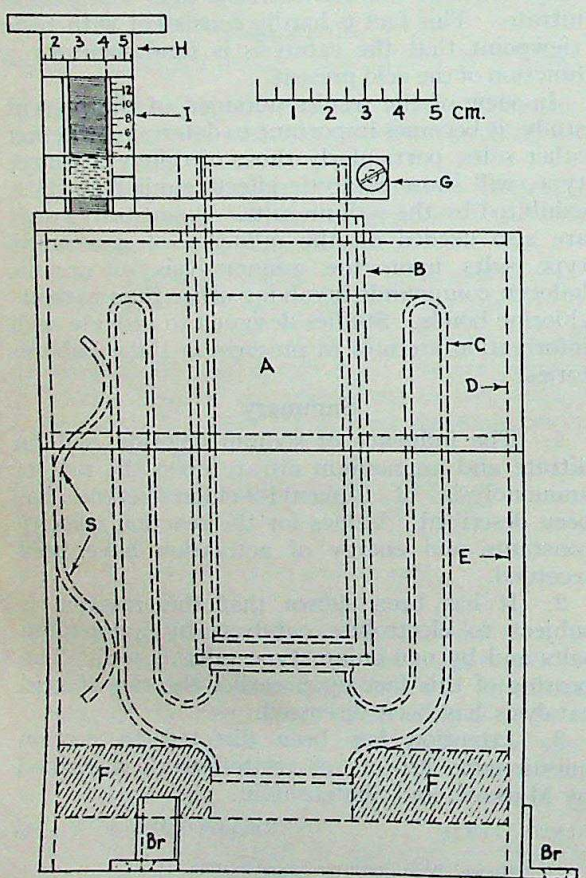

Fig. 1.—A, Cylindrical evacuated plunger; B, absorption tube holding sample; C, Dewar flask, note optical flats sealed in bottom; D and E, top and bottom of container; F, circular positioning block for Dewar flask; G, arm holding plunger; I and H, scale and vernier for plunger; S, positioning spring for Dewar flask; Br, mounting brackets.

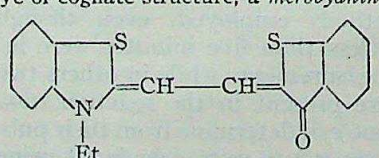
A Hilger spectrometer, with a glass prism and calibrated for light in the visible part of the spectrum, was used for most of these measurements. The transmission was measured by the use of two barrier-layer photocells connected in a series-opposing circuit and with a potentiometer in each arm of the bridge. One of the photocells was held beneath the Dewar cell and was illuminated by part of the monochromatic light from a tungsten source after passing through the spectrometer. The second photocell was illuminated directly by the other portion of the same beam of light. The current was balanced out by means of the potentiometer so as to give a null reading instrument. The transmission is inversely proportional to the ratio of the resistance in the circuit when the solvent is in the light beam and when the dye solution is in the beam.

Other data were obtained on an instrument in which the spectrophotometer of the apparatus was replaced by a Bausch and Lomb monochromator. This was used with a photoelectric cell and amplifier. The transmission was measured by the ratio of the galvanometer deflection with the sample to that with the solvent in the beam.

Procedure.—The absorption spectra of dissolved ionized (cyanine) dyes are practically unaffected by the polarity of the solvent,[1] in respect of the position of absorption bands. We used as solvent for these a mixture of ethanol and diethyl ether, 50% each by volume. This solution became more viscous as the temperature was lowered and set to a clear glass at about −145°. This could be cooled somewhat below that temperature without losing transparency. However, at about −180°, the glass suddenly crystallized and shattered into opaque crystals, particularly if the sample was jarred. Most of the measurements were, therefore, made above −180°. As a neutral or non-ionized dye of cognate structure, a *merocyanine* having the structure (I) was employed. Three solvents were used with this, of diminishing polarity, *viz.*, a 50:50 mixture of *ethanol* and *methanol*, *diethyl ether*, and *hexane*.



(Dye XXIII)

In the experiments in which a complete spectral absorption curve in the visible was measured at temperatures above −75°, the desired temperature was obtained by adding "dry-ice" to alcohol in the Dewar flask. For lower temperatures, liquid nitrogen was introduced into the Dewar flask in sufficient quantity to produce the desired temperature and still not have the dye solution immersed in the liquid nitrogen. The evaporation of the liquid nitrogen below the level of the inner window of the Dewar cell held the temperature of the solution constant for a time sufficient to make the measurements. The spectral ab-

sorption was measured as quickly as possible, beginning at the point of maximum absorption and making readings on each side of the maximum. Thus, errors due to any change in the temperature would least affect the maximum position in the absorption spectrum. The temperature was measured by a calibrated thermocouple immersed in the dye solution.

For temperatures above the lowest, equilibrium was obtained by first cooling the sample slightly below the desired temperature and then letting it warm up. In some cases, readings were made on either side of the point of maximum absorption at various temperatures by allowing the same sample to warm up gradually and taking a series of readings at definite temperatures.

The cyanine dyes studied, the molecular extinction coefficient of the main band, the half-width of this band, and the area under the total absorption curve in the visible which has been defined above as the band strength at the various temperatures, are given in Table I. The extinctions were calculated on a concentration of dye in solution corrected for thermal cubic expansions.

TABLE I

Dye	Temp., °C.	$\epsilon \times 10^{-4}$	Half width in mμ	Relative band strength (area sq. cm.)

Experimental Data

To conserve space, only selected typical absorption curves are shown; *e. g.*, in Fig. 2 the full absorption curves of Dye VIIa (pinacyanol chloride) for 298°, 202° and 108°K. The fall in

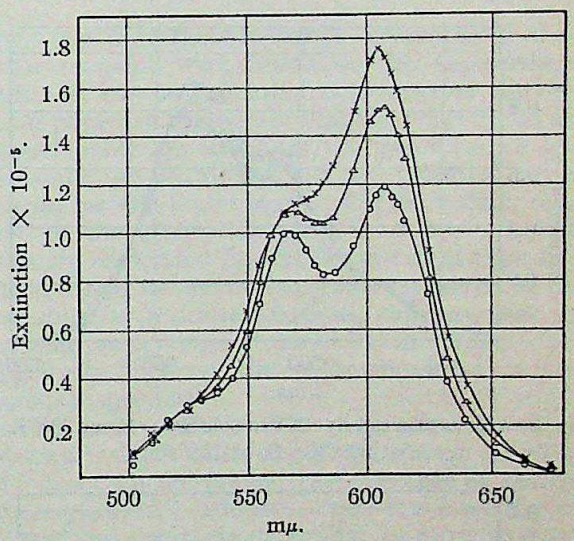

Fig. 2.—Absorption of dye VIIa solution: ×, at 298°K.; Δ, at 202°K.; O, at 108°K.

total absorption is discussed later. More important features are: (i) there is little or no displacement of the absorption peak, (ii) the structure of the (multiple) band becomes better defined, that is, the β and γ auxiliary bands[2] show up more clearly. There is some evidence in this example, but less in other cases examined, that with falling temperature the γ and β bands are actually strengthened relative to the α band. This may indicate some tendency to "dimerization" in the organic mixed solvent at low temperatures, a phenomenon otherwise observed with these dyes only in aqueous solution.[2] However, evidence has been presented recently[3] by G. N. Lewis, *et al.*, for spectral absorption of "dimerization" type of methylene blue in 95% ethanol at low temperature (170°K.). Dimerization and associated spectral changes will be discussed more fully in later papers.

If a phenyl group be attached to the quinoline nuclei, producing the isomeric dyes XVIa and XVIIa, the resultant molecules are more soluble in solvents of low or zero polarity. At the same time, the isomers differ in that XVI has a planar, and XVII a non-planar, configuration. These structural differences are reflected in the absorption spectra, and in the influence of temperature on the absorption spectra. The planar dye XVI indicates below 25° (298°K.) no change in band strength (*cf.* Fig. 3), but the band structure becomes sharper. With the corresponding non-planar dye XVIIa (*cf.* Fig. 4), the intensity of absorption, as shown both by the extinction at the maximum and by the band strength, actually increases as the temperature is lowered. Similar behavior, but in less marked degree, is shown by the planar and non-planar isomers XVIIIa and XIXa (*cf.* Table I).

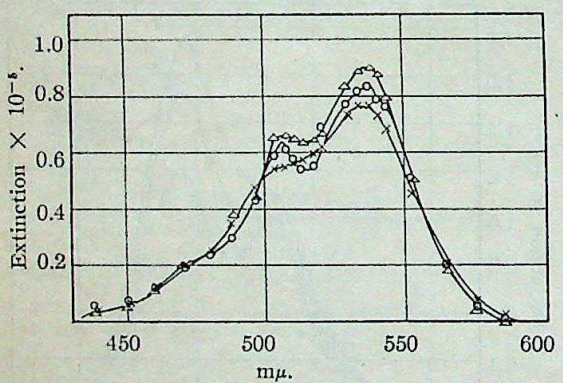

Fig. 3.—Absorption of dye XVIa solution: ×, at 298°K.; Δ, at 229°K.; O, at 153°K.

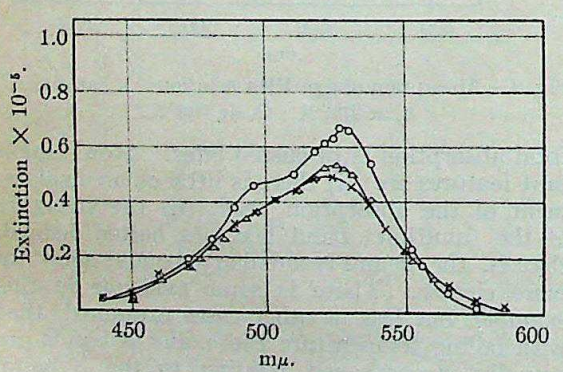

Fig. 4.—Absorption of dye XVIIa solution: ×, at 298°K.; Δ, at 215°K.; O, at 95°K.

The behavior of a neutral cyanine dye (merocyanine, dye XXIII) on change of temperature in three different solvents—different in respect of molecular polar moment—is shown in Table II.

Discussion

The first feature apparent in the effect of temperature on cyanine dye solutions is the sharpening of the band structure with fall of temperature. This is to be attributed to the progressive

TABLE II

EFFECT OF TEMPERATURE CHANGE ON MEROCYANINE DYE SOLUTIONS

elimination of rotational and vibrational energies—the latter, however, corresponding only to low energy values, of the order of rotational quanta. Larger vibrational energies, say from 600 to 2000 cm.$^{-1}$, the coupling of which with fundamental electronic transitions determines the main band structure of aromatic and heterocyclic molecules, of the polyenes,[4] and also of the cyanine dyes,[5] are not extinguished until very low temperatures are reached.

A secondary result of such sharpening of the band structure is liable to be an increase in the extinction at the position of maximum absorption. While this is generally observed for the early stages of lowering of temperature, it was generally found to be followed by a fall both of the extinction at λ_m and of band strength (Fig. 5). We were inclined to attribute this fall

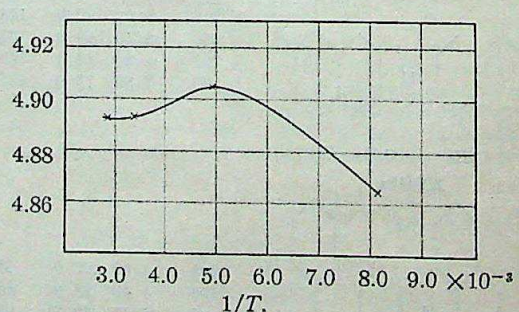

Fig. 5.—Temperature and extinction of dye Va.

to desolution of the dye, in consequence of reduced solubility at lower temperatures; another possibility will be noted later. In the case of dye XVIIa—the non-planar isomer of XVIa—no decrease of the extinction was observed (Fig. 6) and again with XIXa, the non-planar isomer of XVIIIa, a maximum value of log ϵ (at 4.75)

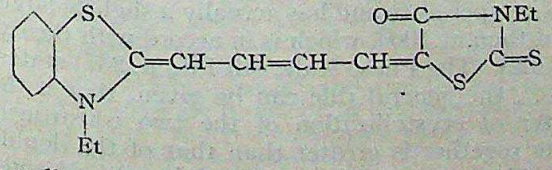
was not reached until a very considerable lowering of temperature had been effected. As noticed elsewhere,[4] these non-planar dyes have a much more diffuse band and lower extinction than their planar isomers. The observations suggest that as lower temperatures are approached, the deviation from planarity tends to become less—possibly because of the lowering of thermal energy and increased capacity of the molecule to remain in a strained configuration. It is also possible that the solubility is less affected by temperature fall, which may be connected with a diminished ease of crystallization of non-planar dyes. It has been indicated elsewhere,[2] that such non-planar cyanines have less tendency to dimerize and do not form spectrally distinguishable mesophases.

Whereas the ionized cyanines dissolved in the diethyl ether–ethanol mixture showed little or no displacement of the absorption maxima in respect of wave length on change of temperature, the behavior of the non-ionized merocyanine (Dye XXIII) in various solvents is very different. In each solvent used, the absorption maxima are shifted toward the longer wave length; the shift or "red displacement" is least in the case of the mixed alcohols solvent of highest polarity, and greatest for the solvent (ethyl ether) of moderate polarity, while hexane, of zero polar moment, shows an intermediate value. These results, though less extensive than is desirable, appear to be in reasonable accord with the observations on solvents of differing polarity discussed in Part I.[1] In that, the alcohols were shown to behave as "superpolar" solvents, in which the "red displacement" approached a saturation value. In the case of solvents of zero polar moment, it may be presumed that lowering the temperature could increase the refractive index, and thereby have some, but not a large, displacement effect. There remains to be explained, therefore, the relatively large effect of lowered temperature with solvents of moderate polarity, such as *ether*.

Before dealing with this problem, and in view of the sparsity of data, it is desirable to note that another type of merocyanine dye synthesized by Dr. L. G. S. Brooker, having the structure



as well as certain related compounds, have been found by Dr. C. West[6] to exhibit qualitatively very similar properties on change of temperature of their solutions. "In non-polar solvents, *e. g.*, hexane, and in strongly polar solvents, the position of the absorption band is not very dependent on temperature. In solvents of intermediate polarity, the position of the band is strongly temperature dependent." A restatement of the effect

(6) Private communication.

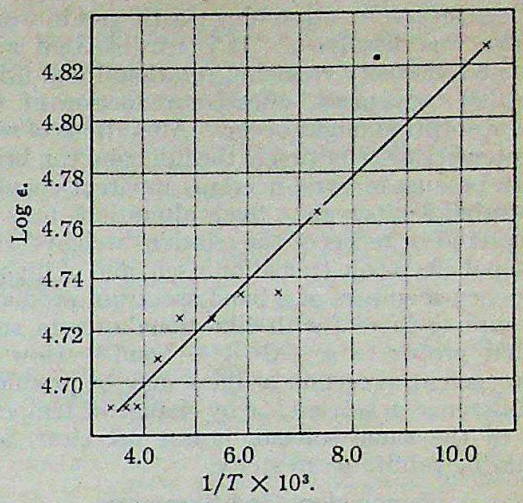


Fig. 6.—Temperature and extinction of dye XVIIa.

is to say that these solvents behave as if their polar moment were raised as the temperature falls. It has been pointed out, however, in previous papers of this series[1] that the polar moments ascertainable are either for the gas state, or less certainly for solutions, and are practically unknown for the liquid state. The fact that, relative to the absorption spectra of dyes, certain strongly associated liquids behave *as if* they had much higher moments than those measured in the gas state or in dilute solutions, suggests that increasing association at lower temperatures does effectively increase the polar moments of the liquids in question.

The total shift of the absorption band of (neutral) dyes with change of polar moment of solvent (in the present case, because of change of temperature) indicates that the coupling of *solvent* and *dye* molecules must be very sharp—practically an "all or none" affair. Otherwise, there would be no sharp or total displacement of the spectrum, but displacement associated with diffusion. This would happen if, for example, there were varying orientation of the same polar solvent molecule to the dye molecule, producing some sort of variable polarization of the latter. Actually, nothing of the sort seems to happen.

A change of capacity factor, *e. g.*, of the number of molecules effective, is observed, however, in the aforementioned changes of band strength and ϵ_{max} (extinction at peak of absorption band). In the case of fall of absorption with drop in temperature, two possibilities suggest themselves. One, already mentioned, is separation of the dye as crystals owing to decreased solubility. Another is reduction of number of (planar) dye molecules per unit time, *e. g.*, 10^{-8} sec.—suitably oriented to the electric vector of the light beam. As the temperature falls, the viscosity of the solvent increases; in fact, the mixed alcohol-ether solvent forms a clear glass at about 128°K. The importance of the orientation of planar dye molecules for the degree of absorption (extinction coefficient)

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

has been shown by stretching elastic gels in which the dye was dissolved.[2] It is feasible that with increased viscosity reducing rotational and other brownian movement, effective reduction of the total absorption might occur. Alterations of *relative* intensity distribution in the full band can bring about, because of band-overlap, apparent changes of infraband intervals. Such alterations may be interpreted in terms of the relative "weights" of a principal electronic transition itself, and of higher[7] frequency members of a band spectrum produced by coupling thereof with vibrational quanta, such as that proper to a —C=C— bond.[4] How an enhancement of certain of these may be produced by difference in solvent, or by change of temperature of the same solvent, is not yet clear, and should be profitable to study.

Conclusions and Summary

Some effects of change of temperature on the absorption spectra of cyanine dyes in organic solvents have been measured over a temperature range from *ca.* 300 to 90°K. In this range the ionized cyanine dyes showed no appreciable displacement of the wave lengths of maximum absorption. The spectra became appreciably sharper as the temperature fell, which is attributed to suppression of rotational and low order vibrational energies. Temperatures were not reached sufficiently low to eliminate the vibrational quanta responsible (by coupling with the electronic transition) for the auxiliary absorption bands. The sharpening produced at first an increase in ϵ_{max} (or log ϵ_{max}) but as the temperature was further lowered a reduction in band strength occurred—less or absent in the case of non-planar dyes. Non-ionized merocyanine dyes show a greater or less displacement of the spectrum with change of temperature, depending upon the polarity of the solvent. A notably sharp coupling of solvent and soluble (dye) molecules is indicated by this displacement.

RECEIVED SEPTEMBER 29, 1943

(7) Rarely lower; the lower values $\nu_0 - \Delta\nu$ seem to be generally prohibited in absorption. The "extra" band of merocyanines in the gas state or in non-polar solvents[2] may be an exception.

The System Potassium Carbonate–Sodium Carbonate–Water at 100 and 150°[1]

BY GUY ERVIN, JR., A. L. GIORGI AND C. E. MCCARTHY

Introduction

A study of the solubility relations in aqueous solutions of the carbonates of sodium and potassium was undertaken at this Laboratory in connection with a laboratory and pilot-plant investigation[1a] of a process for the production of potassium carbonate from wyomingite, a leucite-bearing rock found in Wyoming. The process involves a base-exchange step by which a solution containing a mixture of sodium and potassium carbonate is obtained. For the separation of the carbonates it is proposed to evaporate at 100°, producing the monohydrate, $Na_2CO_3 \cdot H_2O$, followed by the anhydrous double salt, $K_2CO_3 \cdot Na_2CO_3$. The resulting solution is cooled to 25°, crystallizing out potassium carbonate sesquihydrate, $K_2CO_3 \cdot 3/2H_2O$. The mother liquor from the crystallization step is recirculated to the double-salt step, and the double salt is recirculated to the original solution, thus effecting a continuous process with no material discarded. An accurate knowledge of solubility is essential to operation of the process.

Two previous studies of this system in the high-temperature range have been made in Russia[2] in connection with a similar technological problem on the treatment of solutions obtained by alkaline leaching of nepheline. At 50° and lower the system has been adequately studied by Hill and Miller.[3] The authors' results at 100° are in essential agreement with those of Makarow and Schulgina. However, those authors present data at 120, 140, and 145° which indicate that the double-salt field becomes smaller with increasing temperature and ceases to exist at 145°; upon the basis of this result they propose evaporation at 145°, thus simplifying the process by eliminating the need for recycling the double salt. In the present study at 150° conclusive evidence was obtained to prove that the double salt exists at this temperature and has actually a slightly larger field than at 100°, which is in accord with theory. Findlay (The Phase Rule, 8th Ed., p. 237) states: " . . . the general rule can be given, that if the water of crystallization of the two constituent salts together is greater than that of the double salt, the latter will be produced from the former on raising the temperature." This is a direct result of van't Hoff's law of mobile equilibrium, which is a particular case of the theorem of Le Chatelier.

Experimental Procedure

The sodium carbonate and potassium carbonate used were Baker C. P. reagents. Qualitative tests showed the absence of impurities. For the majority of the runs the

initial complexes were made by mixing standardized solutions of these compounds plus $Na_2CO_3 \cdot H_2O$ or $K_2CO_3 \cdot 3/2H_2O$ or both. Sodium carbonate monohydrate was prepared by recrystallizing anhydrous sodium carbonate, while $K_2CO_3 \cdot 3/2H_2O$ was purchased as such. In some cases the anhydrous compounds stored in the oven at 120° were used directly.

The equipment was the same as that employed by Schroeder, Berk, and Gabriel,[4] who have described it fully. Briefly, it consisted of a set of steel solubility bombs of about 250-milliliter capacity. The top of each was fitted with an internal solution sampler tube, and the bottom contained a wire screen and drain plug. A sample of solution was taken, and the solid was separated from the residual solution while maintaining the operating temperature. The air thermostat was arranged so that these operations could be performed without opening the door of the thermostat.

The bombs were thoroughly tested for leaks at 150° using sodium carbonate solution. The temperature of the bomb itself was determined by means of a thermocouple and potentiometer; the hot junction of the thermocouple was wrapped around one of the bomb studs. The temperature of the 100° runs was 101.1±0.1°, and the 150° runs were at 150.0±0.1°.

A separate set of runs was made at 100° in ordinary chemical glassware. A 1-liter, three-neck flask was fitted with a mercury-seal stirrer, a thermometer, and a sampling pipet and was mounted in an oil thermostat. Samples of solution were obtained by pipetting a portion of the clear supernatant solution into a weighing bottle, finding the weight and making up to volume for analysis. Solid samples were obtained by pipetting a slurry onto a preheated sintered-glass filtering crucible, to which suction was applied.

The chemical compositions were determined by an acid titration to the methyl orange end-point in conjunction with a direct sodium determination[5] by the triple acetate method. Potassium was determined by difference. When the weight ratio of potassium carbonate to sodium carbonate exceeded 10:1, potassium was removed as the perchlorate before the sodium determination.[6] The acid titration is accurate to ±0.1% and the sodium determination to ±0.5% when prior removal of potassium is unnecessary. When potassium is removed, however, the accuracy is only ±10%. Since this occurred when the sodium was less than 5% in solution, the error was never greater than 0.5 of a percentage unit of sodium carbonate and averaged much less than this.

Tests for equilibrium consisted of obtaining check results on duplicate mixtures run for widely different lengths of time. In the case of the glass apparatus, solution samples were taken at twelve-hour intervals until three successive analyses checked within 0.5%. The time allowed for equilibrium was at least thirty-eight hours at 100° and at least twenty-two hours at 150°. Working at 50° or lower Hill and Miller[3] allowed eighteen to twenty-four hours for equilibrium with a simple salt and forty-eight hours for equilibrium with a double salt or solid solution. Makarow[2] and Schulgina allowed thirty hours at 100°, five to six hours at 120°, and three to three and one-half hours at 140 to 145°. It is known that the proportion of solid in the mixture should be low if equilibrium is to be reached in a reasonable time. In this work the solid was below 10% of the mixture at 100° and below 25% at 150°.

Identification of Solid Phases.—The solids were removed from the bombs, dried in air or in a desiccator over anhydrous potassium carbonate, and submitted for microscopic examination and in some cases for X-ray analysis. The optical properties of Na_2CO_3 and $Na_2CO_3 \cdot H_2O$ were found in the literature,[7] while those of $K_2CO_3 \cdot Na_2CO_3$ and $K_2CO_3 \cdot 3/2H_2O$ were obtained at this station. $K_2CO_3 \cdot Na_2CO_3$ is hexagonal, $N_\epsilon = 1.422 \pm 0.003$, $N_\omega = 1.531 \pm 0.003$, crystals equi-dimensional or slightly elongate, $K_2CO_3 \cdot 3/2H_2O$ is monoclinic or triclinic, $N_\alpha = 1.474 \pm 0.003$, $N_\beta = 1.483$ (approx.), $N_\gamma = 1.510 \pm 0.003$, $2V(+) = 66°$ (computed), extinction inclined 15 to 20°. The examination effected a positive identification of all solid phases. One difficulty was encountered. In that part of the double-salt field nearest the $K_2CO_3 \cdot 3/2H_2O$ field, $K_2CO_3 \cdot 3/2H_2O$ was always found associated with $K_2CO_3 \cdot Na_2CO_3$. The cause was crystallization from the retained mother liquor which was always present in high proportion because of the extreme fineness of the double salt. Taking this into consideration, the point nearest the $K_2CO_3 \cdot 3/2H_2O$ field which showed double salt should be the invariant point, $K_2CO_3 \cdot 3/2H_2O$–$K_2CO_3 \cdot Na_2CO_3$. The invariant point as located by chemical evidence checked with this point at both temperatures.

As a further check on the identity of the solid phases, X-ray patterns were obtained on a few samples. These included the double salt at the two extremities of its field at 150° and one sample from each phase area at both temperatures. Patterns for all the compounds occurring in the system at these temperatures were found in the literature.[8] The patterns always agreed with the microscopic identifications.

Accuracy.—Sources of error included lack of equilibrium, weighing errors, and errors in the chemical analyses. The sampler tubes each weighed about a kilogram, and weighings were accurate to the nearest tenth of a gram. No runs were accepted in which the sample weighed less than 10 g. so that the weight of sample was accurate to at least 1%. The sample usually weighed 25 to 30 g. The error in the chemical analyses was less than this, except for the low sodium-concentrations.

A measure of the over-all accuracy of the results was obtained by algebraic extrapolation of the tie lines.[9] The composition of the solution, of the initial complex, and of the solid phase should all fall on the same straight line. Using the solid-phase composition as given by the microscope and the composition of the initial complex, a tie line is obtained, and the deviation of the solution composition from this line may be calculated. By means of this calculation, the average deviations were found to be ±0.5% potassium carbonate and ±0.3% sodium carbonate. These deviations show the combined effect of all the errors involved. At the invariant points, where such an extrapolation is not possible, duplicate determinations were averaged, and the average deviation from the mean was calculated. The average deviations were again ±0.5% potassium carbonate and ±0.3% sodium carbonate. Five determinations were made at each invariant point on the 100° isotherm, four determinations at the invariant point ($K_2CO_3 \cdot 3/2H_2O$–$K_2CO_3 \cdot Na_2CO_3$ at 150°), and one at the other 150° invariant.

The wet residues were also analyzed in some cases but were considerably less accurate than the other determinations. Nevertheless, they furnish further chemical evidence for the correctness of the results. The variation was usually no more than 1–2 percentage units.

Experimental Results and Discussion

The 100° Isotherm.—The chemical compositions are given in Table I. The solid phase in equilibrium with each solution is indicated in the last column. The table includes three sets of data: runs made in the glass apparatus, runs made in the solubility bombs, and a preliminary set of runs made in the bombs, in which equilibrium was attained in the solution but not in the solid. In the preliminary set, the initial complexes were made up by adding the anhydrous salts to

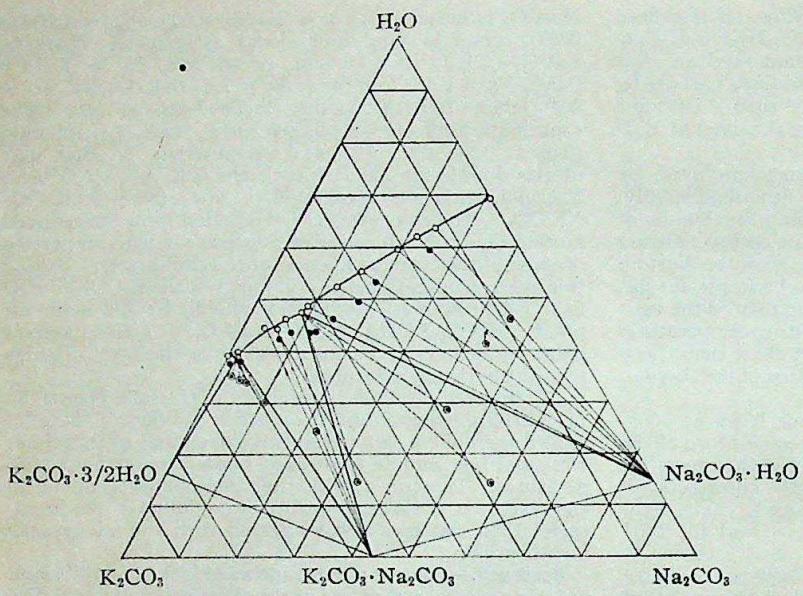

Fig. 1.—The 100° isotherm: O, solutions; ●, initial complexes; ◉, wet residues.

the bombs followed by the proper amount of water. Caking of the anhydrous salts prevented true equilibrium in the times allowed, as indicated by microscopic examination of the solids and by the divergence of the tie lines. The agreement with the subsequent experiments, in which the complexes were formed by mixing solutions and hydrated salts, indicates that equilibrium with respect to the solution was reached, and the results are included as a substantiation of the solubility curve. The type of run is designated in the first column as G for glass, B for bomb, and P for preliminary. The compositions of the mixtures given in the fourth and fifth columns are wet residues for the runs marked G and initial complexes for those marked B; they are not reported for those marked P because these mixtures were not at equilibrium.

The data of Table I are plotted in Fig. 1, omitting the preliminary set of runs. In drawing the tie lines the composition of the solid was taken as a fixed point and the best straight line drawn through that composition and the compositions of the mixture and solution. The isotherm has three branches, corresponding to $K_2CO_3 \cdot 3/2H_2O$, $K_2CO_3 \cdot Na_2CO_3$, and $Na_2CO_3 \cdot H_2O$ as solid phases. The monohydrate has the largest field, and $K_2CO_3 \cdot 3/2H_2O$ has a very small field in accord with its high solubility. The anhydrous double salt is seen to be incongruently soluble, reacting with water to give $Na_2CO_3 \cdot H_2O$ and a solution richer in potassium carbonate than the double salt.

The agreement of the authors' data with those of Makarow and Schulgina at 100° is fairly close. They report a composition of 45.8% K_2CO_3 and 8.5% Na_2CO_3 for the monohydrate-double salt invariant which compares with the present result of 44.0% K_2CO_3 and 8.6% Na_2CO_3. Their compositions at the invariant, $K_2CO_3 \cdot 3/2H_2O$–$K_2CO_3 \cdot Na_2CO_3$ are 58.6% K_2CO_3 and 2.0% Na_2CO_3 as compared with 59.2% K_2CO_3 and 1.5% Na_2CO_3 from the authors' data.

The 150° Isotherm.—The data are shown in Table II and plotted in Fig. 2. The only change from the 100° isotherm is the replacement of $Na_2CO_3 \cdot H_2O$ by anhydrous Na_2CO_3. The location of the invariant point Na_2CO_3–$K_2CO_3 \cdot Na_2CO_3$ is very close to the $Na_2CO_3 \cdot H_2O$–$K_2CO_3 \cdot NaCO_3$ invariant at 100°. The $K_2CO_3 \cdot 3/2H_2O$–$K_2CO_3 \cdot Na_2CO_3$ invariant is at a considerably higher potassium carbonate concentration so that the field has widened somewhat. The double salt is still incongruently soluble.

As stated in the introduction, results at 150° are directly contradictory to those of Makarow and Schulgina. The use of steel containers, adequate time for equilibrium, and positive identification of the solid phases by means of the microscope and the X-ray attest to the validity of the authors' results. Although no consistent explanation can be given for the disagreement with the results of Makarow and Schulgina, there

Acknowledgement is gratefully made to Mr. Robert D. Pike, consulting chemical engineer of Pittsburgh, Pa., who initiated the work and contributed many helpful suggestions. The authors also wish to express their indebtedness to Drs. A. Gabriel and F. Chayes for the petrographic examinations and to H. F. Carl for the X-ray identifications.

Summary

1. The system K_2CO_3–Na_2CO_3–H_2O has been investigated at 100° and 150°, employing the usual chemical methods and in addition identifying the solid phases by means of microscopic examination and X-ray patterns.

2. At 100° the isotherm has three branches: that of $K_2CO_3 \cdot 3/2H_2O$, $K_2CO_3 \cdot Na_2CO_3$, and $Na_2CO_3 \cdot H_2O$.

3. The 150° isotherm also has three branches corresponding to $K_2CO_3 \cdot 3/2H_2O$, $K_2CO_3 \cdot Na_2CO_3$, and Na_2CO_3. The field of the double salt is slightly more extensive here than at 100°. The continued existence of the anhydrous double salt on increasing the temperature is in accord with the theorem of Le Chatelier.

4. The double salt is incongruently soluble in the temperature range studied and decomposes in contact with water to give solid $Na_2CO_3 \cdot H_2O$ or Na_2CO_3 plus a solution relatively richer in potassium carbonate.

Studies on Silicic Acid Gels. XV. The Effect of Temperature upon the Time of Set of Alkaline Gel Mixtures

BY CHARLES B. HURD, RENATO C. POMATTI,[1] JOHN H. SPITTLE[2] AND FRANK J. ALOIS[3]

Introduction

The effect of temperature on the time of set of silicic acid gels is definite for gel mixtures with *p*H below 7. With these acidic mixtures, a rise in temperature causes a decrease in the time of set[4] in mixtures containing weak acids,[5] or strong acids.[6,7] The energies of activation for these acidic mixtures have been reported.[5,6,7]

The behavior of alkaline gel mixtures, with *p*H values above 8.0, shows some surprising results when the effect of temperature on time of set is studied. Increased temperature with alkaline gel mixtures of solutions of sodium silicate and phosphoric acid has been shown to decrease the time of set.[8] A calculation of the energy of activation gave about 24,000 calories. For these mixtures, due to the buffering power of the phosphates formed, the *p*H remained constant from the first reading after the solutions were mixed until the gel had set.

With alkaline gel mixtures made from solutions of sodium silicate and acetic acid having *p*H values above 8.5, the results of Munro and Pearce,[9] and results in this laboratory, have shown a curvature in the relation between logarithm of time of set and the reciprocal temperature. This made calculation of the energy of activation impossible. In addition, the *p*H of the sol has been shown to increase noticeably from the time of mixing until the gel has set. Our own earlier experiments showed that, in the highest *p*H range where it is possible for a gel to set, raising the temperature increased the time of set. This phenomenon deserved further investigation. The results are given herewith.

Experimental

The gel mixtures were prepared by mixing solutions of sodium silicate, E brand Philadelphia Quartz Company, diluted to 1.25 *N* in NaOH equivalent, and dilute acetic acid in the manner previously described.[4,5] Time of set was found by the "tilted rod" method.[4]

Measurement of the *p*H presented difficulty. The Quinhydrone method, which has been shown satisfactory for acidic mixtures[10] in the presence of silicic acid, fails above *p*H 8. Earlier work on alkaline gel mixtures,[11] and the more recent work of Munro and his co-workers,[12,13,9] have utilized indicators and standardized buffers to measure the *p*H. Munro and Pearce[9] found the *p*H measured by the glass electrode, in the range *p*H 9.5–11.0, to be 0.2 to 0.4 unit lower than that given by indicators. In our work on alkaline mixtures containing phosphoric acid,[8] we have found that the life of a Beckmann glass electrode was very short, the alkali and silica destroying the surface and also the reproducibility of the readings of the electrode after four or five determinations.

In the work reported here, we have used both the indicator method and the glass electrode. The indicators were phenol red for *p*H 7.8–8.4; thymol blue, *p*H 8.0–9.8, and LaMotte purple, 9.6–11.0. The buffer solutions were made up from directions from Clark[14] of boric acid, potassium chloride and sodium hydroxide, or of sodium carbonate and borax. The *p*H of the buffers was determined by the Beckmann Glass Electrode Apparatus, but the particular glass electrode was not allowed to come into contact with any silicates. The indicator method procedure was standard, using a white porcelain spot plate.

In addition, some determinations were made by the Leeds and Northrup Glass Electrode Apparatus, using home-made glass electrodes. These were blown from Corning #015 special electrode glass, and were checked in a buffer after each immersion in silicate mixtures. They were discarded when they failed to check.

Time of set was determined at three temperatures for a series of mixtures, using a fixed volume of sodium silicate solution and varying quantities of acetic acid. Mixtures were reproducible, that is, two mixtures made up with the same volumes of acetic acid gave the same *p*H and time of set.

In Fig. 1 are shown the logarithm of time of set against reciprocal absolute temperature for a series of silicic acid gel mixtures produced by mixing solutions of sodium silicate and acetic acid. Temperatures were 0°, 25.1°, and 38.5°. All mixtures were alkaline. The *p*H was determined with indicators. Between the first reading and the time of set, the *p*H rose 0.2 to 0.5 of a *p*H unit, especially in the higher range. The concentrations of Na^+, 0.391 gram ion per liter, and SiO_2, 0.642 gram mole per liter, were the same for all. The concentration of Ac^- in gram ions per liter, and the *p*H, are given by Table I. The *p*H given was recorded immediately after mixing.

TABLE I

CONCENTRATION OF ACETATE ION AND *p*H OF THE GEL MIXTURES SHOWN IN FIG. 1

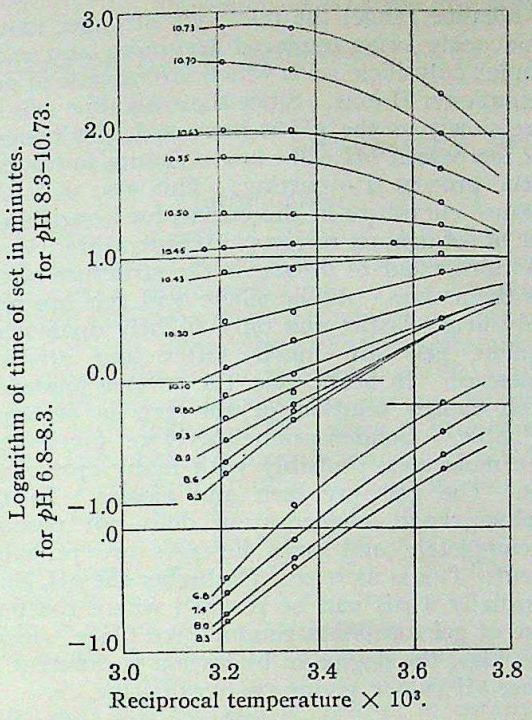

Fig. 1.—Logarithm of time of set of silicic acid gel mixtures of different *p*H as a function of the reciprocal absolute temperature.

The curvature shown by Munro and Pearce[9] is apparent here. Their Figs. 1, 2, 3, 4, and 5 for their control gels are duplicated among the 18 curves of our Fig. 1, although we have not found the decrease of logarithm of time of set at our highest temperature as pronounced as theirs. It is apparent that at least in our mixtures above *p*H 10.5, a rise of temperature from 0 to 38° increased the time of set. For *p*H 10.45, there was very little change in the time of set as the temperature was increased. This was checked at several more temperatures, and is shown in Fig. 1 by extra points for the mixture in Table I containing 0.246 gram ion of Ac^- per liter. This value is italicized in Table I.

Unfortunately, for simplicity of treatment, the *p*H in these mixtures was found to change somewhat with time and with temperature. Also, the concentration of silica changed, to a small degree, the slope of the curves, which are shown in Fig. 1. We have not yet studied this second effect carefully.

The change in *p*H with time was studied, using the Leeds and Northrup apparatus and Corning #015 home-made glass electrodes. Two curves are shown in Fig. 2, the *p*H being corrected for Na^+ ion effect. The concentrations are for Curve 1, $Na^+ = 0.394$, $SiO_2 = 0.652$, $Ac^- = 0.253$, and for Curve 2, $Na^+ = 0.394$, $SiO_2 = 0.652$, and $Ac^- = 0.238$. The *p*H is seen to rise and become constant after the gel has set. These mixtures contain a strong base and less than an equivalent amount of a weak acid.

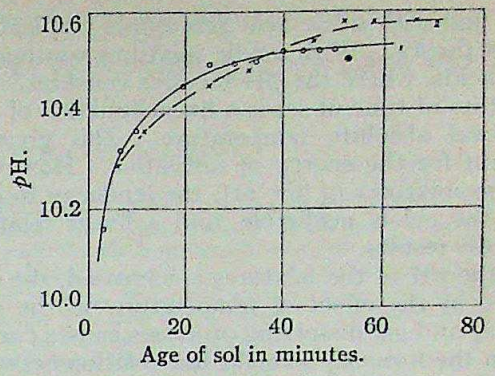

Fig. 2.—Effect of age of sol upon *p*H.

We have tried to liquefy these alkaline gels with *p*H over 10.5 by allowing them to set at 25° and then rapidly raising the temperature to 50° or dropping it to 0°. In no case have we been able to liquefy the gel. Apparently, once the gel is set, it remains set, even though the rate of setting at the higher temperature would not have allowed it to set in the time elapsed in setting at the lower temperature and the short time required for heating.

Discussion

There is general agreement that silicic acid gels produced by the setting of gel mixtures with *p*H above 8.0 differ in many ways from the acid gels. Several workers have noted that gel mixtures of *p*H above 11.0 apparently do not set to form gels.[15] Our results substantiate this. It is also well known that gels already set may be dissolved in dilute sodium hydroxide solution, *i. e.*, by raising the *p*H well above 11.0.

There must, therefore, be two processes possible so far as the hydrous silica is concerned. One may be described as the formation of a monosilicic acid, or at least a simple silicic acid, from the silicate ions. These simple silicic acids condense to form polysilicic acids and eventually form a gel.[16] This may be shown as follows:

$$\text{Silicate ion} \rightleftarrows \text{Simple silicic acid} \rightleftarrows \text{Polysilicic acid} \rightleftarrows \text{Gel}$$

$$\text{Setting of gel} \longrightarrow \qquad \longleftarrow \text{Solution of gel}$$

The action of strong alkali reverses the process which occurs during gelation. This occurs easily in solutions of *p*H 13 or higher.

In gel mixtures with *p*H between 11 and 13, the tendency to form a gel must be opposed by the reverse effect. This makes the gels set more and more slowly as the *p*H is raised, until somewhere between *p*H 11 and 13, the mixtures will never set. It is hardly likely that a rise in temperature will affect these two opposed tendencies equally. Such a situation is true in simple chemical equilibria, the temperature affecting the rates of the opposing reactions unequally, thus causing a change in the equilibrium constant.

We find with silicic acid gels ample verification of this theory. With acidic mixtures containing weak acids, where the *p*H remains constant,[5] the logarithm of time of set is a linear function of the reciprocal absolute temperature. This gives a constant for the energy of activation. However, in these mixtures of low *p*H, the tendency to dissolve the gel is negligible, and a linear relation naturally results.

As the *p*H of the mixtures is increased, the difference in the effect of temperature on the gel-forming and gel-dissolving processes causes curvature in the formerly straight line relation between logarithm of time of set and reciprocal absolute temperature. This curvature is seen in the control curves of Munro and Pearce[9] and our curves of Fig. 1. It is unfortunate that only two temperatures were used for the alkaline gel mixtures containing phosphoric acid,[8] otherwise curvature might have been found there, also.

It would appear possible to find silicic acid gels in a very narrow *p*H range, above 11, which would be thermally reversible, since it is apparent that rise of temperature accelerates the dissolving process more than the setting process. We have been unable to find reports of such gels in the literature. We have made careful experiments to try to find such thermal reversibility, but have been unable to liquefy any of our alkaline gels by raising the temperature. Possibly this was because the gels could not be liquefied in the time available. We are attempting to find such gels, but the experiments will take a very long time, probably over six months or a year. They must be very slow setting gels and, if found, will be in a fairly narrow *p*H range between 11 and 13.

A second effect which changes the rate of the setting process is a change in the *p*H of the mixture between the time of mixing and time of set. This does not occur to a measurable degree in acidic mixtures which contain weak acids,[5,17] nor in the alkaline mixtures containing phosphoric acid,[8] since all of these mixtures are well buffered. It does occur, however, in acidic mixtures containing strong acids,[6,7] and in alkaline mixtures containing acetic acid, reported by Munro and Pearce,[9] and also in all of our work here. Figure 2 shows this.

In unbuffered mixtures, the *p*H rises between the time the mixture is produced and the time it sets to form a gel. This rise of *p*H is almost certainly due to the decrease in ionizability of the silicic acids during the condensation. This effect has already been described for acidic gel mixtures.[6] Now the same thing is occurring in the alkaline range, the relatively stronger monosilicic acids being replaced by more and more complex polysilicic acids which are capable of producing fewer H ions. Since these alkaline gels set more slowly as the *p*H is increased, this concurrent increase in *p*H will cause a change in the rate as the process is occurring. This also will tend to cause curvature in the curves for logarithm of time of set against reciprocal temperature.

A third point to discuss is the structure of the gels themselves. Acidic silicic acid gels are relatively firm, elastic, and only slightly opalescent. Alkaline gels are much softer and strongly opalescent. In acidic gels, the reverse tendency, which causes solution of the gel, is certainly negligible. Condensation therefore gives very large molecules, probably with many cross linkages. The gels are firm and elastic. In the alkaline range, condensation does not proceed so completely and cross linkages are probably absent. This is more true the higher the *p*H, since eventually a *p*H can be reached where the final stage of gel formation cannot take place. Probably, also, the degree of hydration is different at higher *p*H values, giving greater opacity.

Summary

A study has been made of the setting of alkaline silicic acid gels containing sodium silicate and acetic acid, especially as to the anomalous effect of temperature. In the higher *p*H range, above 10.5, rise of temperature produces increase in time of set. This differs from the effect with gel mixtures of *p*H below 10, where rise of temperature causes decrease in time of set.

No energy of activation can be calculated for these gel mixtures with *p*H above about 10.

The effect is probably due to the fact that rise of temperature accelerates the process of dissolving of the gel to a greater extent than it accelerates gel formation.

In mixtures with *p*H much above 11, the solution process is predominant and gels do not form.

During the process of setting, the *p*H of these poorly buffered alkaline mixtures increases considerably. This affects the rate of the process. It is probably due to the fact that the more complex the polysilicic acid is, the less is its tendency toward ionization.

No thermally reversible silicic acids were found.

Alkaline gels are softer and less elastic than acid gels, since condensation and cross linkage formation probably do not proceed so far in the alkaline gels.

Studies on Silicic Acid Gels. XVI. The Effect of Radiant Energy upon the Time of Set

BY CHARLES B. HURD AND WINTERTON U. DAY[1]

Introduction

The effect or lack of effect of radiant energy upon the time of set of silicic acid gels has been mentioned a number of times in the literature. With the exception of the statement by Ray and Ganguly[2] that ultraviolet radiation from a mercury vapor tube definitely accelerated the setting of the gel, the statements concerning the effect of light have indicated that there is little if any effect. One of us has already made such a statement.[3] A reading of these statements concerning the negligible effects of light upon the time of set, except for that of Ray and Ganguly,[3] already mentioned, leads to the belief that the matter has not been carefully studied. Such a study, however, is relatively simple.

It would be rather surprising if a reaction of the type believed to occur in the setting of a silicic acid gel, namely, a reaction of condensation,[3] should be found to be affected noticeably by radiant energy. We have therefore made some careful experiments to detect the effect, if any. The results are reported herewith.

In addition, we have conducted one series of experiments with the General Electric Company's Recording Spectrophotometer, giving transmittance curves in terms of the age of the gel mixture.

Experimental

The gel mixtures were prepared by mixing solutions of sodium silicate, "E" brand Philadelphia Quartz Company, and acetic acid, in the manner described in former publications from this Laboratory,[4] using the same water thermostats and testing for time of set by the "tilted rod" method.

The mixtures were placed in 100-cc. Pyrex Griffin beakers in the thermostat. The volume in each beaker was 80 cc. Several duplicate samples were run in each case, the result given being the average. Three sources of radiation were used, a 100-watt Mazda bulb, a highvoltage iron spark, 18,000 volts, which gave lines from 4000 to 2200 Å, and a capillary mercury arc giving about the same range.

With the Mazda lamp, the samples run in the "light" were in clear beakers covered by clear watch glasses or cellophane covers. It made no difference whether glass or cellophane covers were used. For the iron and mercury radiation experiments, only cellophane covers were used. All runs in the "dark" were made in the same size beakers, heavily painted on the outside with aluminum paint. They were covered with watch glasses, heavily painted on the upper side with aluminum paint. The mixtures, of course, were exposed to light for a few seconds as they were being prepared.

The most essential factor here is the temperature. It is very easy, unless great care is exercised, to have the radiation received by the gel mixture cause a slight temperature rise. Since the time of set is very greatly affected by the temperature, this can be a real source of error. We have controlled the temperature in the following manner. The 100-watt Mazda lamp was suspended over the beakers in the thermostat and it was lowered to the position nearest to the beakers, which still gave no noticeable temperature rise on a sensitive thermometer. The thermometer may not be left in the mixtures while the radiation is being received, since the bulb intercepts sufficient radiation to show a false indication of a rise. The radiation was allowed to fall in the beakers and their contents, both the unpainted and the painted, for about five minutes. Then the light was turned off and the thermometer inserted in the gel mixtures.

We are confident that the Mazda lamp was as near to the contents of the beakers as possible without causing a rise in temperature of the contents. Water filters for shutting off a portion of the rays were considered, but not used. We are not so confident that we succeeded in having the mercury and the iron spark sources as close as they might have been without producing a temperature rise, since the apparatus was clumsy and much more difficult to adjust to the minimum distance. However, the mixtures were exposed to intense radiation through their cellophane covers.

At this time, it was possible to run one series of mixtures using the General Electric Company Recording Spectrophotometer,[5] in order to determine the transmission characteristics of these silicic acid gel mixtures during the process of gel formation. A copy of the curve is shown.

Data and Discussion

The data reported in Table I are the averages of six determinations each, the "dark" and "light" running side by side in the thermostat.

TABLE I

EFFECT OF RADIATION UPON TIME OF SET OF SILICIC ACID GEL MIXTURES

Type of radiation	Time of set in minutes "Light"	"Dark"	Temp. in °C.	Concentrations in gram moles or gram ions per liter SiO_2	Na^+	$HC_2H_3O_2$
Mazda	150	149	25.6	0.667	0.407	0.875
Mazda	1186	1182	25.6	.498	.305	2.570
Iron	151	152	25.6	.667	.407	0.875
Iron and mercury	95	95	29.0	.667	.407	.624

It is obvious from this that we have been unable to detect any significant effect of radiation upon the time of set, using radiation which does not incidentally produce a rise in temperature. At least in the case of the radiation in the visible spectrum, the Mazda lamp, we had all of the radiation possible without a temperature rise. The discrepancies in time are certainly below the possible experimental error in determination of times of set, namely, about 1%.

In Fig. 1 is given a tracing of the curves drawn by the Recording Spectrophotometer for a mixture containing SiO_2 0.67, Na^+ 0.41, and $HC_2H_3O_2$, 0.55 g. mole per liter. The room temperature was 26°. The curves were drawn at

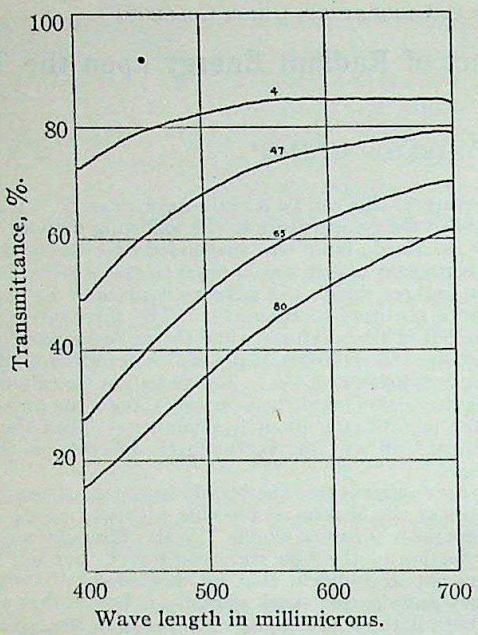

Fig. 1.—Transmittance of silicic acid gel mixtures as a function of wave length and age of sol.

four, forty-seven, sixty-five and eighty minutes after mixing, as indicated on the curve. The gel set in seventy-five minutes.

These transmittance curves are smooth, indicating no particularly strong absorption in any band. The curve of the mixture four minutes old shows the start of loss of the radiation of shorter wave length. This tendency increases with the age of the sol, until at age eighty minutes, which is five minutes after the gel has set, transmittance of radiation of 4000 Å. is only 0.15, while that of radiation 7000 Å. is 0.63 compared to a maximum of about 0.85 at the start, as shown on the four-minute curve. These results are probably due to the preferential scattering of radiation of smaller wave length. This scattering has been studied carefully by several investigators and the results reported.[6]

Summary

A study has been made of the effects of radiation upon the time of set of silicic acid gels, produced by mixing solutions of sodium silicate and acetic acid. Great care was taken that no measurable temperature change was produced by the radiation. Radiations from a Mazda lamp, a capillary mercury arc and an iron spark were used.

No significant effects of these types of radiation on the time of set were found.

A series of curves obtained with the Recording Spectrophotometer, showing the per cent. radiation transmitted by the sol are also given. The effect of age of the sol upon light transmitted is shown.

Diolefins from Allylic Chlorides. II

BY ALBERT L. HENNE AND HENRY H. CHANAN

We have shown[1] that two molecules of butadiene hydrochloride react with magnesium in ether to give a mixture of 1,5-diolefins, the composition of which remains the same whether the primary form of the halide, its secondary form, or the equilibrated mixture of both forms is used as the starting material. These results were in agreement with some of Young's observations[2] on allylic equilibria.

This method of synthesizing 1,5-diolefins is now extended to five allylic chlorides grouped in a variety of pairs. Allyl and methallyl chlorides which exist in only one form (CH_2=$CHCH_2Cl$ and CH_2=$C(CH_3)CH_2Cl$) were purchased. Piperylene hydrochloride which also exists in only one form ($CH_3CHClCH$=$CHCH_3$) was made by adding dry hydrogen chloride to commercial piperylene. Butadiene and isoprene hydrochlorides were made similarly from commercial butadiene or isoprene; they both exist in two forms, namely, $CH_3CHClCH$=$CH_2 \rightleftarrows CH_3CH$=$CHCH_2Cl$; and $(CH_3)_2C$=$CHCH_2Cl \rightleftarrows (CH_3)_2$-$CClCH$=$CH_2$. All materials were supplied to us by a Research project of the American Petroleum Institute, directed here by Dr. C. E. Boord.

Experimentally, the condensations were carried out substantially as previously[1] described. Two different allylic chlorides were mixed in equimolecular proportion, and the mixture was added to magnesium turnings covered with dry ether. After completing the condensation and working up the products, a hydrocarbon fraction was obtained which amounted to about 35% of the quantity possible if pure allylic halides had been used and had condensed completely. It was, however, found more expedient to use the extremely impure materials obtained from a stream of hydrogen chloride through the commercial dienes and to discard from the condensation products all impurities, unreacted halides and resinified materials. From thirty to fifty moles

of each halide was used to secure a quantity of hydrocarbons ample for adequate separation. Before subjecting them to repeated distillations through a 30-plate, helix-packed, total reflux-partial take-off, adiabatic column, the hydrocarbons were treated with sodium in liquid ammonia[3] until the disappearance of the Beilstein flame test indicated that they were free of halides. For physical measurements, only the centers of the distillation fractions were used. In the following list of results, the percentages of the various compounds refer only to the distilled product.

Experimental Results

Let each chloride be designated by its initial with a superscript (when needed) to denote a primary, secondary or tertiary isomer when two allylic isomers are possible. Thus A, M and P will designate allyl chloride, methallyl chloride and piperylene hydrochloride, while B^1 or B^2 will designate the two forms of butadiene hydrochloride, and I^1 or I^3 those of isoprene hydrochloride.

The results of the condensations are represented in Table I, where the relative amounts of the dienes obtained by condensation are given on a molar basis.

Quite a number of possible combinations were absent. In line with our previous observation[1] condensations between different molecules predominated over condensations between two identical molecules or two forms of the same molecule. In the fourth, fifth and sixth pairs, the ratio of the total number of I^1 groups to the total number of I^3 groups was consistently close to $I^1:I^3 = 5:1$. For the butadiene group, the ratio $B^1:B^2$ proved to be about 4:5 in the third pair, and about 1:1 in the sixth pair. In our preceding paper it had been found close to unity in the condensation of butadiene hydrochloride on itself, while it was about 5:3 in the condensation of butadiene hydrochloride with allyl chloride. The experimental data do not permit more precise generalizations.

The observed physical properties of the hydrocarbons, and the analyses of the new compounds, together with the symbols representing the diolefins appear in Table II.

Identifications

Most of the diolefins were new compounds. They were first analyzed as reported in the table, then hydrogenated to the corresponding paraffins to establish their carbon skeleton. Most of these paraffins were known. Where the paraffins were new compounds, it proved possible to show that their physical constants were measurably different from possible alternate formulas. Finally the position of the double bonds was determined by ozone oxidation, using procedures previously described.[4,5] In the following paragraphs, the observed data refer to the freezing point, the corrected boiling point at 760 mm, the density d^{20}_4 and the refractive index $n^{20}D$, in that order.

B reduced to 4-methylheptane,[6] glass, 117.6°, 0.7042, 1.3980. Ozonization gave formaldehyde, acetic acid and methylsuccinic acid, m. p. 110–

111°. C reduced to a new paraffin (S in table) measurably different from the possible known isomers. Ozonization gave acetaldehyde, acetic acid and a dicarboxylic acid m. p. 178–190° with a molecular weight of 147.4. This acid was regarded as a mixture of *dl*- and α,β-dimethylsuccinic acid. The pure *meso*-acid is said to melt[7] at 198° and 208° with decomposition, while the *dl*-mixture melts[7] at 127°; they can be separated by treatment with a benzene–ether mixture, in which the *dl*-form is more soluble than the *meso*-form. This treatment was applied to the dicarboxylic acid, and raised the m. p. to 188–189.5°. Further purification was deemed not to be indispensable, in view of the fact that the isomeric diacids melt much lower, *i. e.*, ethylsuccinic acid at 100°, and α,α-dimethylsuccinic at 141°. E reduced to 2,4-dimethylheptane,[8] glass, 133.1°, 0.7153, 1.4031. Ozonization gave formaldehyde, acetic acid and a keto-acid whose semicarbazone had m. p. 178° and analyzed correctly for $C_7H_{13}N_3O_3$ (calcd. C, 44.9; H, 7.0; N, 22.4. Found: C, 44.9; H, 7.0; N, 22.3). The keto acid was interpreted as being α-methyl-γ-ketovaleric acid, whose semicarbazone is said to melt[9] at 191° and also at 181°. H reduced to a new paraffin (T in table) measurably different from the known isomers. Ozonization gave formaldehyde, acetic acid and α,β-dimethylsuccinic acid m. p. 190° (*cf.* compound C) I reduced to 3,3-dimethylhexane,[6] glass, 112.2°, 0.7096, 1.4000. Ozonization gave formaldehyde and α,α-dimethylsuccinic acid m. p. 139°. J reduced to 2-methylheptane,[6] −109.6°, 117.6°, 0.6978, 1.3950. Ozonization gave formaldehyde, acetone with a 2,4-dinitrophenylhydrazone m. p. 125° and succinic acid m. p. 186°. K reduced to a new paraffin (U in table) measurably different from the known possible isomers. Ozonization gave formaldehyde and α,α-dimethylsuccinic acid m. p. 141°. L reduced to 2,7-dimethyloctane,[10] −50.7°; 160.0°; 0.7250; 1,4087. Ozonization gave acetone detected by the nitroprusside test, and succinic acid m. 187°. M reduced to 2,4,4-trimethylhexane,[11] −117.7°, 130.8°, 0.7231, 1.4068. Ozonization gave formaldehyde and α,α-dimethyl-γ-ketovaleric acid, with a semicarbazone, m. p. 196°. N reduced to 2,6-dimethylheptane,[12] −103.6°, 135.2°, 0.7102, 1.4009. Ozonization gave formaldehyde, acetone (color test) and levulinic acid with a semicarbazone m. p. 184.5° (calcd., N, 24.2. Found: N, 23.9). P reduced to 2.5-dimethylheptane,[13] glass, 136.2°, 0.7175, 1.4042. Ozonization gave formaldehyde, acetone (color test) and methylsuccinic acid, m. 110°. Q could not be isolated from K. The mixture was hydrogenated and the paraffins were separated. The paraffin ratio was taken to represent the diolefin ratio in the mixture. R could not be isolated from O. This ratio was computed from the relative quantities of paraffins, after hydrogenation.

Summary

Five allylic chlorides have been condensed in six different pairs to give a series of 1,5-diolefins, which were purified sufficiently to permit the listing of their physical properties and the determination of their relative abundance.

Conjugated Diolefins by Double Bond Displacement. II

BY ALBERT L. HENNE AND HENRY H. CHANAN

The preceding paper[1] has described the rearrangement of seven 1,5-diolefins to conjugated dienes by passage over alumina heated to 365°. A new series of rearrangements has now been carried out at lower temperatures with a more efficient catalyst made of chromia deposited on alumina.

The use of chromia was proposed by Levina.[2] As chromia is a fine powder which packs and channels easily, it proved more convenient to use a mixed catalyst consisting of 5 mole per cent. of chromia on alumina, prepared by the method of Grosse and Ipatieff.[3] The equipment and the rearrangement procedure were substantially as described in our preceding paper, with refinements in temperature control to ensure uniform regulation within 2°, and increase in dimensions of the catalyst column to a width of 2 cm. and a length of 120 cm. The optimum temperature for rearrangement was determined in pilot experiments by passing 1,5-hexadiene (diallyl) over the catalyst at the rate of one drop in three seconds, at temperatures varied in 25° intervals, and separating the resulting 2,4-hexadiene (dipropenyl) by fractional distillation. As the temperature rose, the yield of dipropenyl went from 49% at 200° to 64% at 250°, 65% at 275° and 64% at 300°, but the amount of polymerization increased simultaneously from 7% to 9%, 12% and 14%. Consequently, a temperature of 250° was adopted as a standard for the whole study.

The progress of the rearrangement was followed by hourly readings of the refractive index. These readings which rose rapidly to a constant level due to the formation of the conjugated dienes, began in time to drop off markedly, showing that the catalyst was losing its efficacy. To regenerate the catalyst, the resinous deposit was first burned out by means of a stream of air at 450°. This treatment changed the color from the original blue-green to a bright orange, and at this stage a test for chromate ions was positive. After displacing the air with nitrogen, a stream of hydrogen was passed through at the same temperature for four hours; the catalyst, now green again, was then allowed to cool in a hydrogen atmosphere. This treatment restored the original efficacy, but became needed at increasingly shorter intervals.

All rearrangements were performed on freshly prepared or freshly regenerated catalysts. The diolefins tested were all of the 1,5-diene type; their synthesis was reported in another paper.[4]

TABLE I

TABLE OF EXPERIMENTAL RESULTS

Original diene	Rearrangement Products: Low boiling, %	Intermediates, %	Polymers, %	Orig. diene recov., %	Chief product	Yield, %	F. p., °C.	B. p., °C.	d^{20}_4	$n^{20}D$

before[1] for the first three lines of the table and more precise than those in the literature for the third[5] and the fourth[6] line of the table.

Since the carbon skeleton of the molecules is not altered during the rearrangements, as shown before[1] by hydrogenation to known paraffins, the problem of identification is merely one of locating the double bonds. This was done by oxidation with ozone, using experimental procedures described previously.[7,8] The ozonization results are listed in the notes of the table.

Comments

For double bond displacement chromia-coated alumina proved considerably more efficient than plain alumina. It permitted operation at 250° instead of 365° and reduced polymer formation.

The ease of rearrangement was found contradictory. In agreement with our first experiments, terminal bonds shifted inwards with ease, particularly well over a methyl group in *iso*-position; yet two compounds so constructed failed to rearrange.

Summary

Twelve dienes of the 1,5-type were subjected to double bond shift at 250° over a catalyst made of chromia and alumina. Seven were transformed to conjugated diolefins, while five failed to rearrange to any appreciable extent.

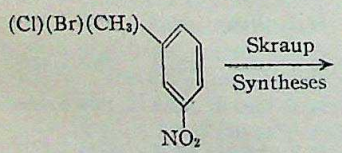
Derivatives of 1,10-Phenanthroline[1]

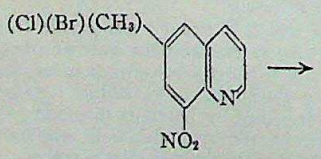
BY FREDERIC RICHTER[2] AND G. FREDERICK SMITH

Although the application of the Skraup synthesis to 1,2-phenylenediamines suitably substituted in either the 4- and/or 5-positions might appear to be the most direct approach to the synthesis of 5 (6)-substituted (1,10)-phenthrolines the side reactions encountered practically preclude the isolation of the desired products.[3]

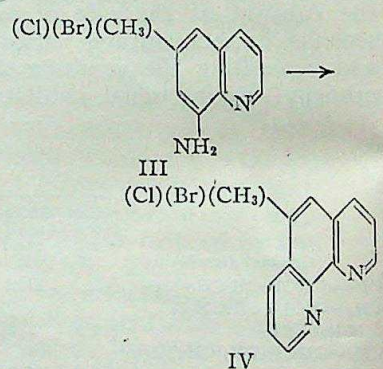
Application of the method of Skraup to suitably substituted 2-nitroanilines (I) followed by reduction of the resulting 8-nitroquinolines (II) and application of a second Skraup synthesis to the 8-aminoquinolines so formed (III) is the basis for the present series of syntheses



I



II



III IV

From the standpoint of orientation, at least, 2-nitroanilines substituted in either the 4- or 5-positions could be employed because these positions later become equivalent in 1,10-phenanthroline. In the present series only 4-substituted 2-nitroanilines were employed.

The 5(6)-chloro(1,10)-phenanthroline obtained by the above scheme agreed in melting point and other properties with that obtained by Kuczynski and Sucharda[4] who heated a mixture of 8-nitroquinoline, glycerol and hydrochloric acid under pressure. It is of interest to note that the chlorophenanthroline obtained by this method is probably formed through 8-amino-5-chloroquinoline

VII VIII

The first step is postulated as involving N-chlorination of (V). This is followed by rearrangement to (VII) and finally conversion to the phenanthroline. Under no condition would one expect the chlorine atom of (VI) to migrate to the 6-position (meta rearrangement). In the present series the chloro phenanthroline is obtained through 8-amino-6-chloroquinoline (III) and the fact that both products appear to be identical is good evidence for the equivalence of the 5- and 6-positions in 1,10-phenanthroline. This in turn points to a symmetrical structure for the base.

The synthesis of a 5(6)-bromo(1,10)-phenanthroline by a Skraup reaction on 4-bromo-1,2-phenylenediamine was previously claimed[5] and the melting point reported as 215° whereas the bromo derivative (IV) was found to melt at 119°. The analysis of our product and the correlation between the absorption spectra of the ferrous complexes of (IV) and the parent base, together with the difficulties encountered in attempting a synthesis from a 1,2-phenylenediamine indicate that the previously claimed[5] synthesis of 5(6)-bromo-(1,10)-phenanthroline is incorrect.

Attempts to obtain a 5(6) carboxylic acid by oxidation of the methyl derivative (IV) failed even under the mildest conditions, presumably because of the rupture of the 5,6-double bond. This is entirely analogous to the case of the corresponding methylphenanthrene where oxidation readily takes place at the 9,10-double bond to produce 2,2′-biphenyldicarboxylic acid.

The 5(6)-methyl derivative was found to undergo nitration with greater ease than the unsubstituted base. Under the same conditions, *viz.*, nitrating mixture, temperature and time, the methylphenanthroline gave a 20–25% higher yield of its nitration product than did the parent compound. This result was to be expected in view of the analogous case of toluene and benzene, the former undergoing the usual substitution reactions more readily than the latter. Nitration of either the methyl derivative or the parent compound undoubtedly takes place in the 5- or 6-position since one would hardly expect substitution to occur in the pyridine rings under the conditions employed.

Excellent correlation was found between the absorption spectra of the ferrous complexes of (IV) and that of the parent base over the wave length region of 400–670 millimicrons.

Experimental

Because of the difficulties encountered in the preliminary stages of this investigation in controlling the Skraup reactions a general procedure was developed. It was found that the directions usually given[6] include a ratio of sulfuric acid to glycerol which is too high and which usually results in excessive carbonization with consequent loss of yield. The best mass relations found were: one mole of the aromatic amine, four moles of glycerol (dried by passing dry air through the liquid for three hours at 170–180°), three-fourths mole of arsenic pentoxide and a weight of sulfuric acid (sp. gr. 1.84) equal to about 50–60% of the weight of glycerol employed. The use of stronger sulfuric acid, *e. g.*, 10–20% oleum, did not present any advantage.

In general, the amine, glycerol and arsenic oxide were weighed into a three-necked flask. This was then equipped with a glycerol-sealed stirrer, thermometer dipping into the liquid and a Pyrex water-cooled condenser with a calcium chloride tube for eliminating atmospheric moisture. The sulfuric acid was added through the condenser with vigorous stirring, and at such a rate as to maintain the temperature below 130°. The temperature was then held at 130–135° for one hour and finally the mixture was kept in active reflux for six additional hours. Longer heating did not improve the yields.

After cooling, the tarry reaction mixture was poured into water, neutralized in the cold with aqueous ammonia and the quinoline or phenanthroline recovered by filtration or extraction with boiling benzene. The nitroquinolines were employed without further purification. The reduction of the 6-chloro- and 6-bromo-nitroquinolines was accomplished with stannous chloride in hydrochloric acid solution; the nitromethylquinoline was reduced with ammonium sulfide formed *in situ* by passing hydrogen sulfide into an ammoniacal ethanol solution of the base.

8-Nitro-6-chloroquinoline.—Yield of dry, crude product 47–48 g. from 43.1 g. (0.25 mole) of 4-chloro-2-nitroaniline. A portion was recrystallized from ethanol, m. p. 159°.

5(6)-Chloro-(1,10)-phenanthroline.—Needles from benzene–petroleum ether, m. p. 123°; yield 24.0 g. (56%) from 35.7 g. (0.2 mole) of 8-amino-6-chloroquinoline.

Acknowledgment.—The authors gratefully acknowledge the valuable suggestions offered by Professor C. S. Marvel in the course of this work.

Summary

1. A procedure for the synthesis of 5(6) derivatives of 1,10-phenanthroline has been described.

2. The previously reported synthesis of 5(6)-bromo-1,10-phenanthroline has been proved erroneous.

3. Evidence for the equivalence of the 5- and 6-positions in 1,10-phenanthroline has been presented. This in turn indicates a symmetrical structure for 1,10-phenanthroline.

Tryptic Digestion of Bovine Serum and Other Proteins in the Presence of Ethyl Alcohol

BY EDWIN A. RISLEY, ANN C. BUFFINGTON AND L. EARLE ARNOW

In connection with some problems under investigation in this Laboratory, it became desirable to prepare tryptic digests of bovine serum. The chief difficulties encountered revolved around the slow digestion of relatively concentrated serum solutions and the development of putrefaction after a few days of digestion. It was found that both of these difficulties could be overcome if suitable amounts of ethyl alcohol were included in the digestive mixtures.

The effect of alcohol on tryptic digestion has not been investigated extensively. In 1896 Chittenden and Mendel[1] found that the digestion of fibrin by pancreatic extracts was inhibited by increasing concentrations of alcohol. However, appreciable digestion still occurred in 20% alcoholic solution. Vernon[2] stated that extracts of pancreas prepared with 25% alcohol were slightly less active in digesting fibrin than were similar extracts prepared with saline solution. Gizelt,[3] using egg white in Mett tubes as a substrate and pancreatic juice as a source of enzyme, found that alcohol in concentrations less than 20% inhibited enzymatic activity. Concentrations of 20% or higher abolished all enzymatic activity. Bayliss[4] suspended crude trypsin in 80% alcohol. This suspension was reported to digest gliadin slowly. Since most of the tryptic activity could be removed from the suspension by simple filtration, Bayliss concluded that trypsin in an insoluble form must still be active. Edie[5] concluded that the action of crude trypsin on fibrin was inhibited to some degree by concentrations of alcohol higher than 3%. Some digestion took place in 25% alcohol, but none was detected at 50%. On the other hand, no appreciable inhibition of digestion of casein was noted until the alcohol concentration was raised to 10% and, indeed, digestion in 25% alcohol was almost as efficient as in non-alcoholic media. Some digestion of casein occurred even in the presence of 50% alcohol. Abderhalden and Reich[6] studied the influence of various alcohols on the rate of tryptic digestion of *d,l*-leucylglycyl-*d,l*-leucine. No significant inhibition of digestion in concentrations of ethyl alcohol of 10% or lower was detected. Twenty per cent. alcohol markedly inhibited digestion of the peptide.

Experimental

The bovine serum used in these experiments was supplied to us in spray dried form through the courtesy of Dr. David Klein of the Wilson Laboratories. Difco trypsin, 1:250, was used as a source of enzyme. The alcohol employed was 95% ethyl alcohol. A micro-Kjeldahl method was used for nitrogen determinations. Amino nitrogen determinations were done with the Koch[7] modification of the Van Slyke[8] micro-apparatus.

Van Slyke[9] pointed out many years ago that the presence of alcohol causes the formation of excess gas in the amino nitrogen apparatus. Provided the concentration of alcohol is not too high, the excess gas can be removed by increasing the shaking time during absorption. In all the analyses reported in this paper, the solutions were diluted and, in the great majority of instances, contained approxi-

mately 2% alcohol. In a few cases, the alcohol concentration in the diluted solution was as high as 10%. The following experiment indicates that analyses can be carried out accurately at these concentrations of alcohol. A tryptic digest of beef serum was diluted with water and with suitable alcohol water mixtures, and the various solutions thus formed were analyzed for total and amino nitrogen. The data are given in Table I.

TABLE I

ANALYSIS OF A DILUTED SERUM DIGEST IN THE PRESENCE AND IN THE ABSENCE OF ALCOHOL

Final alcohol concn., %		0	10	20
Nitrogen, mg. per cc.	Total	1.23	1.23	1.23
	Amino	0.32	0.32	0.33

Comparative Digestion of Bovine Serum and Casein in 20% Solution.—The following digestive mixtures were prepared: (1) 5 g. of bovine serum and 120 mg. of trypsin were suspended in sufficient 1% methyl *p*-hydroxybenzoate solution to make a volume of 25 cc. The mixture was well stirred. The methyl ester served as a preservative, although it was found to be ineffective for digestion periods of more than a few days. (2) 5 g. of serum, 120 mg. of trypsin, 5 cc. of alcohol, and sufficient water to make 25 cc. were mixed and well stirred. (3) Mixtures identical with the above two, except that casein was substituted for the dry serum, were prepared. All four mixtures were incubated at 37°. At the times indicated in Table II, aliquots were filtered and the filtrates were analyzed for total and amino nitrogen. The results obtained are given in Table II.

TABLE II

COMPARATIVE DIGESTION OF BOVINE SERUM AND CASEIN BY TRYPSIN

Time in hours	0[a]		24		48	
Substrate	TN[b]	AN%[c]	TN	AN%	TN	AN%
Bovine serum	12.5	7	23.0	16	21.0	26
Bovine serum + alcohol	10.6	10	20.1	30	24.1	32
Casein	0.7	4	22.7	39	23.2	44
Casein + alcohol	0.6	4	26.2	33	26.6	39

[a] Filtered at room temperature. [b] TN represents total nitrogen in mg. per cc. of filtrate. [c] AN% represents amino nitrogen as % of total nitrogen.

Under these experimental conditions, it is apparent that digestion of the beef serum proceeds more rapidly in the presence of the alcohol than in its absence. This difference in rate is most striking at twenty-four hours. The absolute values for amino nitrogen do not differ significantly in the presence or absence of alcohol when casein is the substrate, although somewhat more nitrogen goes into solution in the mixture containing alcohol.

Effect of Concentration of Trypsin on Digestion of Serum in the Presence of Alcohol.—Ten grams of dried serum was dissolved in 150 cc. of water with rapid stirring. After solution was complete, an additional 10 cc. of water was added. This serum solution was divided into 4 aliquots of 40 cc. each. To each aliquot were added 10 cc. of alcohol and the quantity of trypsin indicated in Table III. After stirring, all four mixtures were placed in the incubator at 37°. At various times, samples were removed and filtered, and the filtrates were analyzed for total and amino nitrogen. The results obtained are given in Table III.

As might have been anticipated, these data indicate that both the rate and extent of hydrolysis increase as the concentration of trypsin is increased. Incubation of serum with alcohol, but without added trypsin, resulted in precipitation of material containing nitrogen. The soluble material remaining after ninety-six hours of incubation was rich in amino nitrogen as compared with the original serum,

[a] See footnotes after Table II.

and it is apparent that some slight digestion occurred. Probably this was due to the presence of enzymes in the serum.

Effect of Concentration of Alcohol on Digestion of Serum.—Mixtures containing 5% serum, 0.3% trypsin, and varying concentrations of alcohol were prepared and incubated at 37°. Total and amino nitrogen determinations were made on filtrates at intervals. The results are given in Table IV.

The data in this table indicate that the rate and extent of hydrolysis were decreased in the presence of alcohol concentrations exceeding 30%, although appreciable hydrolysis occurred even in the presence of 60% alcohol. Digestion proceeded steadily for long periods of time in concentrations of 10 to 30% alcohol. Five per cent. alcohol was not sufficient to prevent the development of putrefaction.

Digestion of Various Proteins in the Presence of Alcohol.—In addition to the use of alcohol, we have also frequently utilized digestion at 60° as a means of preventing putrefaction. Comparative figures for tryptic digestion of several proteins, with and without 20% alcohol, and at 37 and 60°, are given in Table V. The digestive mixtures employed contained 5% protein and 0.3% trypsin, and were adjusted to *p*H 7.6 (the *p*H of the serum solution). Where alcohol was not present, 1% methyl *p*-hydroxybenzoate was added as a preservative.

At the intervals indicated in Table V, filtered samples of each mixture were analyzed for total and amino nitrogen. The figures for one hundred forty-eight hours cannot be compared directly with the other data, since they were obtained in a separate experiment carried out at a later date.

These data indicate that, in general, digestion at 37° is as efficient in the presence of alcohol as in its absence except in the case of serum during early phases of digestion. In the case of soy bean protein considerably more nitrogen went into solution when alcohol was present. When the digestion was allowed to proceed at 60°, the presence of the alcohol decreased the rate and extent of digestion of all the proteins tested. This effect was most marked in the case of egg albumin.

Discussion

The experimental data recorded in this paper make it evident that efficient tryptic digestion at 37° can be obtained in the presence of ethyl alcohol in concentrations of 30% or less. When 5% dried serum in 8 *N* sulfuric acid was heated under reflux for twenty-four hours, the soluble amino nitrogen was found to be 82% of the total soluble nitrogen. Under the conditions used in our experiments, then, 70 to 80% of the potential amino groups were liberated after one or two weeks of incubation with a single charge of trypsin.

Putrefaction was not observed when the concentration of alcohol was 10% or higher. It would appear that alcohol should be a useful reagent for preventing putrefaction during the lengthy

digestion periods required for certain experimental procedures and for the commercial preparation of some types of peptone.

It has been known for years that an antitrypsin is present in blood sera. A purified preparation of this material has been described by Schmitz.[10] The same worker has suggested that the trypsin (or trypsin-like protease) normally present in plasma is combined with its antiprotease.[11] The data in Table II indicate that concentrated (*i. e.*, 20%) solutions of dried bovine serum are resistant to tryptic digestion in the absence of alcohol. It is possible that this resistance is caused by the presence of serum antiproteases. If this is true, the role of the alcohol would appear to be the inactivation of (or the release of trypsin from) these antiproteases. This explanation of the action of the alcohol in our experiments is made more probable by reports indicating that the antitryptic power of serum is removed by treatment with acetone, phenol or chloroform.[12]

The probable importance of serum proteases and antiproteases both in physiological and pathological processes has become increasingly evident in recent years. Much of the important work in this field has been reviewed by Grob.[13] The possible roles of serum antiprotease and protease in the blood-clotting mechanism have been stressed by Ferguson.[14] Marked changes in the antitryptic power of the blood associated with anaphylaxis were observed by Burdon.[15] There is good evidence that serum antiproteases inhibit the growth of bacteria.[13] Holmes, Keefer and Myers[16] have made the interesting suggestion that the antiproteases in body fluids are of importance in the prevention of damage to tissue by proteases liberated from the leukocytes that accumulate in regions of suppuration. It is possible that some of the beneficial effects produced by the parenteral administration of blood, plasma, and serum may be related to the proteases and antiproteases present in these fluids.

Summary

1. Concentrated (20%) solutions of dried bovine serum are resistant to the action of trypsin.

This resistance can be overcome by the use of digestion mixtures containing 20% alcohol. It is suggested that the effect of the alcohol may be due to an inhibition of antiproteases present in the serum.

2. Tryptic digestion of serum proceeded smoothly in concentrations of 10 to 30% alcohol for as long as two weeks, at which time approximately 70 to 80% of the potential amino groups had been liberated.

3. Concentrations of alcohol higher than 30% inhibited tryptic digestion of serum, but appreciable hydrolysis occurred even in 60% alcohol.

4. Efficient digestion of several other proteins (casein, lactalbumin, soy bean protein, egg albumin) was obtained in the presence of alcohol (20%).

5. Digestion at 60°, instead of the more usual 37°, was less rapid and complete when alcohol (20%) was present in the digestion mixture.

6. It is suggested that ethyl alcohol is a useful reagent for preventing putrefaction during tryptic digestion.

α,β-Diamino Ketones. II.[1] Reactions of Thalline and Open Chain Secondary Amines with α-Bromo-β-aminoketones

By Norman H. Cromwell, John A. Caughlan[2] and Gordon F. Gilbert

A wide variety of mixed diamino ketones may be prepared from α-bromo-α,β-unsaturated ketones. Since tetrahydroquinoline had been shown to react with α-bromo-β-aminoketones to give excellent yields of mixed diamino ketones[3] it seemed important to prepare for chemotherapeutic investigations the analogous tetrahydro-6-methoxyquinolino (thallino) compounds. Thalline for these investigations was prepared by a high pressure reduction of 6-methoxyquinoline using hydrogen and a copper chromite catalyst. The 6-methoxyquinoline was prepared by a modified Skraup reaction.

β-Piperidino- and β-morpholino - α - bromobenzylacetophenone and the corresponding benzylacetones reacted readily with thalline to give good yields of the mixed diamino ketones.

The only diamino ketone which had been prepared by treating an α-bromo-β-amino ketone with an open chain type of secondary amine was α,β-di-N-methylbenzylaminobenzylacetophenone.[4] Since this product was obtained in such low yields it seemed of interest to establish whether or not such low yields are to be expected generally when an open chain secondary amine is used in these reactions.

It was found that β-piperidino-α-bromobenzylacetophenone and β-piperidino-α-bromobenzylacetone reacted with N-methylbenzylamine, di-

benzylamine and N-methylethanolamine[5] to give from fair to poor yields, of the mixed diamino ketones.

It has been shown previously[3b] that these reactions give the best yields of the mixed diamino

ketones when the amine used is a weaker base than the amine used to form the α-bromo-β-amino ketone. In all of these present cases this condition has been met, but a major portion of the reaction seems to have proceeded in such a manner as to form the colored α-piperidinobenzalacetophenone and α-piperidinobenzalacetone (B).

This difference in the nature of the reactions of α-bromo-β-aminoketones with heterocyclic secondary amines as compared with the reactions with open chain secondary amines can possibly be explained on the basis of the relative steric effects of these two types of amines on the relative rates of the two competing reactions. The formation of the mixed diamino ketones from the quaternary ammonium salt (A) comes about through an attack of the amine, >NH, at the β-carbon atom. Open chain secondary amines might be expected to be more hindered in their approach to the β-carbon atom than the heterocyclic secondary amines such as thalline, etc. Moreover, the α-piperidino-α,β-unsaturated ketones (B) are formed from (A) by loss of a proton from the α-carbon atom of (A) followed by rearrangement to the products (B). This latter reaction to form (B) is more dependent on the basic strength and less dependent on the structure of the amine, >NH, than the former reaction that leads to the mixed diamino ketone. Thus the rate of formation of the mixed diamino ketone is slowed so as to allow more of (A) to be converted into (B), when open chain secondary amines are used in these reactions. The very low yields of the mixed diamino ketones experienced when N-methylethanolamine was used were probably due to a combination of the steric factor and the considerable strength of this base.

TABLE I

PHYSICAL AND ANALYTICAL DATA

Mixed diamino ketones	No.	M. p., °C., dec.	Yield, %	Formula	Percentage composition Calcd. C	Calcd. H	Found C	Found H

solved in 150 g. (1.63 mole) of dry glycerol was then added and the flask contents thoroughly mixed. To this mixture was then slowly added 69.8 ml. of 95% sulfuric acid with good stirring. The mixture was refluxed over a direct flame for twenty hours. The reaction solution was then diluted with one half its volume of water and cooled to 0° to precipitate some unchanged *p*-nitroanisole which was filtered off.

The filtrate was steam distilled to remove the last traces of *p*-nitroanisole, cooled and made alkaline with strong sodium hydroxide. The mixture was again steam distilled until the distillate was clear. The distillate was extracted with benzene and the benzene extract evaporated to give an oil which was diazotized with saturated sodium nitrite solution in an acid mixture of 20 ml. of concd. sulfuric acid and 150 ml. of water. After allowing the diazotized mixture to stand for one hour at 0° it was steam distilled for about two hours. The residual solution was then made alkaline and the 6-methoxy-quinoline steam distilled, and extracted from the distillate with benzene. The product was distilled under reduced pressure to give 35 g. of a light yellow oil, b. p. 182–184° (34 mm.) (yield 53% based on *p*-anisidine). This product was quite pure, m. p. 18–20°.[8]

Tetrahydro-6-methoxyquinoline (Thalline).—A solution of 88.5 g. (0.555 mole) of 6-methoxyquinoline dissolved in 175 ml. of absolute alcohol, and 9 g. of copper chromite catalyst[9] were placed in the bomb of a high pressure hydrogenator. This mixture was reduced under a pressure of 1800 lb./sq. in., and at a temperature of 180°, the theoretical amount of hydrogen being absorbed in fifteen minutes. The product was purified by vacuum distillation to give 84.1 g. (93% yield) of a pale yellow oil, b. p. 127–130° (1 mm.). The oil solidified on cooling, m. p. 42–43°[8]; n_{50}, 1.5718. The bright yellow picrate, which is not very stable in air was prepared, m. p. 164–165°.[10]

Mixed α,β-Diaminobenzylacetophenones and Mixed α,β-Diaminobenzylacetones

α-Piperidino-β-thallinobenzylacetophenone (I).—A suspension of 11.2 g. of α-bromo-β-piperidinobenzylacetophenone[11] in 18 ml. of absolute alcohol was treated with 9.7 g. of thalline. The mixture was warmed on a water-bath to 70° for one hour with frequent shaking. The clear orange solution was then cooled in the ice chest for five hours to give a yellow precipitate. The precipitated material was filtered, washed with 95% alcohol, water, then 95% alcohol and dried, to give 10.6 g. of a bright yellow solid, m. p. 151–153°. This crude product was recrystallized successively from chloroform and alcohol, and from benzene and petroleum ether and dried under vacuum at 90° for two hours, m. p. 159–160°.

The other new mixed diamino ketones prepared by essentially this same procedure were: (II) from α-bromo-β-morpholinobenzylacetophenone[12] and thalline; (VI) from α-bromo-β-piperidinobenzylacetone,[4] and thalline; and (VII) from α-bromo-β-morpholinobenzylacetone[13] and thalline.

α-Piperidino-β-N-methylbenzylaminobenzylacetophenone (III).—α-Bromo-β-piperidinobenzylacetophenone[11] (23.5 g., 0.063 mole) was made pasty with a 25% absolute alcohol–75% dry ether solution, and 15.3 g. (0.126 mole) of N-methylbenzylamine[14] added. After the mixture had stood at room temperature for twelve hours, it was placed in the ice chest for two days. The yellow precipitate was filtered off and purified in the previously described manner, to give 9.3 g. of light yellow needles, m. p. 138–140°.

The other new mixed diamino ketones prepared by essentially this same procedure were (V) from α-bromo-β-piperidinobenzylacetone[4] and N-methylethanolamine[5]; (VIII) from α-bromo-β-piperidinobenzylacetone and N-methylbenzylamine; and (X) from α-bromo-β-piperidinobenzylacetone and N-methylethanolamine, the product, however, was recrystallized from alcohol and water.

Hydrolysis of (III).—This diamino ketone (III) (5.0 g.) was heated on the steam-bath with 30 ml. of 15% sulfuric acid for two hours. The precipitated benzaldehyde was extracted with ether. Neutralization of the residual acid solution gave an oily precipitate which was removed by ether extraction. The ether extract was evaporated and the residual oil taken up in a small amount of methyl alcohol to which was added 8.5 g. of potassium hydroxide and 4.35 g. of hydroxylamine hydrochloride in 50 ml. of methyl alcohol and 9 ml. of water. After this reaction mixture had stood at room temperature for two days it was neutralized with dilute hydrochloric acid to give a white precipitate. Several recrystallizations of this product from alcohol and water gave 1.5 g. of white plates, m. p. 112–115°. This product was identical with a mixture of the high and low melting forms of the oxime of ω-piperidinoacetophenone, prepared from ω-piperidinoacetophenone.

Anal. Calcd. for $C_{13}H_{18}N_2O$: C, 71.52; H, 8.31; N, 12.83. Found: C, 71.69; H, 8.50; N, 12.59.

α-Piperidino-β-dibenzylaminobenzylacetophenone (IV).—Freshly prepared α-bromo-β-piperidinobenzylacetophenone[11] (6.0 g., 0.0161 mole) was suspended in 15 ml. of absolute alcohol, and 6.35 g. (0.0322 mole) of dibenzylamine added. After standing at room temperature for twelve hours, the mixture was cooled in the icebox for forty-eight hours. A bright yellow precipitate formed. The solution was filtered and the precipitate washed with chloroform. The insoluble amine hydrobromide remained. The chloroform was partially evaporated from the diamino ketone and alcohol was added. A yellow precipitate was obtained which weighed 1.0 g., m. p. 167–169°, dec. This was recrystallized from benzene and petroleum ether to give bright yellow needles, m. p. 173–175°, dec.

α-Piperidino-β-dibenzylaminobenzylacetone (IX).—Freshly prepared α-bromo-β-piperidinobenzylacetone[4] (23.0 g., 0.074 mole) was made pasty with a 37% absolute alcohol–63% dry ether solution, and 29.5 g. (0.150 mole) of dibenzylamine added. After standing at room temperature for thirty minutes the mixture was cooled in the ice chest for four days to give a white precipitate. The solution was filtered and the precipitate was suspended in warm chloroform and again filtered. The insoluble amine hydrobromide remained. The chloroform was evaporated from the diamino ketone and the resulting oil taken up in ether, washed with three 25-ml. portions of water and dried over anhydrous sodium sulfate. This was filtered and the ether partially evaporated and petroleum ether added. A white precipitate was obtained which weighed 1.2 g., m. p. 144–148°, dec. This was recrystallized from 95% alcohol to give white crystals, m. p. 158–160°, dec.

Summary

1. A method of preparing tetrahydro-6-methoxyquinoline (thalline) has been described.

2. The preparation of ten new mixed diamino ketones has been outlined, and the general nature of the reaction of open chain secondary amines with α-bromo-β-amino ketones discussed.

Some Derivatives of *cis*-3,6-Endomethylene-Δ^4-tetrahydrophthalic Acid

BY MARCUS S. MORGAN,[1] R. STUART TIPSON, ALEXANDER LOWY[2] AND W. E. BALDWIN

The compound *cis*-3,6-endomethylene-Δ^4-tetrahydrophthalic anhydride (I), formed by the addition of cyclopentadiene to maleic anhydride, was first described[3] in 1928. Although it has since been investigated extensively as regards reactions of its double bond,[4] very little has been reported on reactions involving its dicarboxylic anhydride grouping.

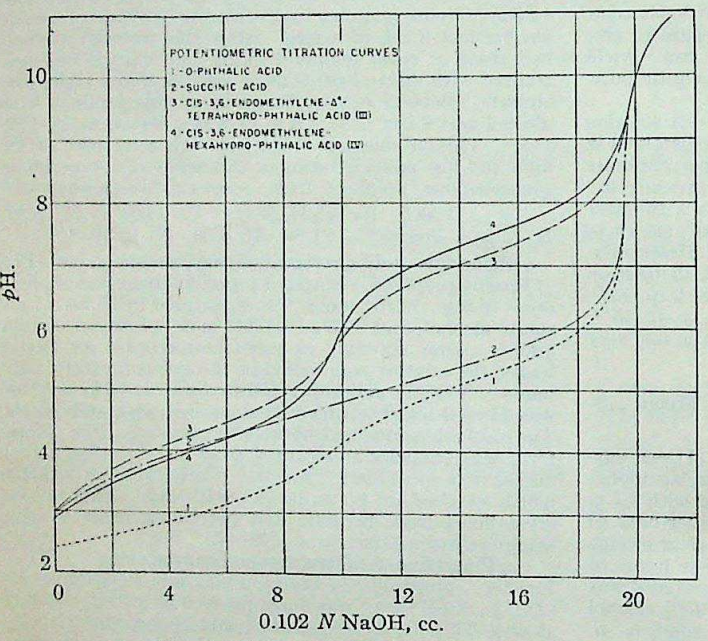

Fig. 1.—Potentiometric titration curves.

The present study was therefore initiated to obtain information on this aspect of the chemistry of compound I and its dihydro derivative II. Known reactions of phthalic anhydride served as a guide for the experimental procedures employed but modifications in mode of preparation and isolation of the products were usually necessary since compounds I and II were found to behave differently, in many respects, from phthalic anhydride.

Diels and Alder[3] had prepared compound II by converting I to the free acid III, thence to the sodium salt which was hydrogenated (palladium catalyst) under low pressure; the free saturated acid IV was then liberated and transformed to the saturated anhydride II. This method is tedious for the preparation of II in large quantities and we have now found that hydrogenation of I to give II can be accomplished directly, in one step and in quantitative yield, by catalytic hydrogenation (Raney nickel catalyst) under high pressure.

The potentiometric titration curves for the two dibasic acids, III and IV, determined by means of a glass-electrode titration assembly, are given in Fig. 1. For comparison, the potentiometric titration curves for succinic and *o*-phthalic acids were determined under identical experimental conditions and the four curves have been superimposed on the same set of coördinates. The magnitude of the inflection at the midpoint of each curve is proportional to the value of K_1/K_2, calculated for acids III and IV from the figures for K_1 and K_2 determined by Bode.[5]

Certain di-esters of the unsaturated acid III were prepared using *p*-toluenesulfonic acid as catalyst (since it was found to have no effect on the sensitive double bond at position 4). The monomethyl ester, monoamide, monoamide monoammonium salt, ammonium salts, and certain imides (V) of acids III and IV have been prepared. It is seen that, with the exception of the unsubstituted imide, the melting point of each saturated compound is higher than that of its unsaturated analog. Attempts to isolate an anilic acid derivative of III or IV invariably resulted in the anil (V, R = C_6H_5).

hydroxide. Similarly, the dimethyl ester of III was unaffected by treatment with a saturated solution of ammonia in methanol, during several days at room temperature. This resistance to ammonolysis may be contrasted with the reactivity of the corresponding phthalic acid derivatives.

Anhydride II reacts readily with benzene in the presence of anhydrous aluminum chloride (Friedel–Crafts) to form the expected 3-benzoylnorcamphane-2-carboxylic acid (VI). However, formation of the corresponding derivative of anhydride I by this reaction could not be detected. On heating VI with concentrated sulfuric acid at 100°, ring closure to a quinone structure did not appear to take place.

Experimental

Dicyclopentadiene was obtained by purification of the commercial material[6] by distillation at atmospheric pressure to give the monomer and repolymerization to the dimer which was fractionally distilled at diminished pressure (about 10 mm.). **Cyclopentadiene** was prepared, as needed, by distillation of the purified dimer at atmospheric pressure in an atmosphere of nitrogen. The fraction boiling at 40.5 to 41° at 760 mm. was retained, and stored in a receptacle cooled in solid carbon dioxide–acetone.

***cis*-3,6-Endomethylene-Δ^4-tetrahydrophthalic anhydride** (I) was prepared as described by Diels and Alder[3] and recrystallized from dry benzene. It had m. p. 165°.

***cis*-3,6-Endomethylene-hexahydrophthalic Anhydride** (II).—The unsaturated anhydride (250 g.) was dissolved in 500 cc. of dry dioxane, 30 g. of Raney nickel catalyst was added and the suspension shaken, in an atmosphere of hydrogen at 45° and an initial pressure of 2,050 pounds per square inch, during ninety minutes. The suspension was then cooled, filtered and the filtrate evaporated to small volume; yield of crude product, 245 g. (97% of theoretical). It was recrystallized from dry benzene and then had m. p. 167.5–168°.

Potentiometric Titration.—Acids III and IV were prepared and purified as described by Diels and Alder.[3] A dry sample of the dibasic acid (0.001 mole) was dissolved in 75 ml. of carbon dioxide-free water. The *p*H of the original solution was measured and sodium hydroxide solution (0.102 *N*) then added in small increments of such size as to yield *p*H readings which were about 0.3 *p*H unit apart. All measurements were made under equilibrium conditions. The *p*H values corresponding to the volume of alkali added are summarized in the titration curves shown in Fig. 1.

Alkyl Esters: Monomethyl.—A solution of 6 g. of the appropriate anhydride (I or II) in 30 cc. of absolute methanol was boiled under a reflux condenser (closed by a calcium chloride tube) during ninety minutes. It was then cooled and evaporated to dryness under diminished pressure at 25°, giving a quantitative yield of crystalline product.

The Δ^4-compound was purified by washing with three successive 5-cc. portions of pentane. It had m. p. 76–78.5°.

Anal.[7] Calcd. for $C_{10}H_{12}O_4$: C, 61.21; H, 6.17; neut. equiv., 196.1. Found: C, 61.23; H, 6.14; neut. equiv., 200.7.

The saturated compound was recrystallized from hexane. It had m. p. 77–79°. The melting point of an intimate 50:50 mixture of the two esters was 60–62°.

Anal. Calcd. for $C_{10}H_{14}O_4$: C, 60.59; H, 7.12; neut. equiv., 198.2. Found: C, 60.96; H, 6.58; neut. equiv., 201.5.

Dimethyl.—A mixture of 32.8 g. of the unsaturated anhydride with 0.5 g. of *p*-toluenesulfonic acid was dissolved in 60 cc. of absolute methanol and the solution boiled under a reflux condenser during ten hours. It was then cooled, evaporated to small volume and dissolved in 96% ether. The solution was washed successively with water, dilute sodium bicarbonate solution and water, dried with anhydrous calcium sulfate, filtered and the filtrate evaporated to dryness. The sirupy product was purified by distillation under diminished pressure: yield, 29 g. (69%) boiling at 136–137° at 12.5 mm. It was redistilled at 9 mm. (b. p. 129–130°) and then had $n^{20}D$ 1.4852, d^{21}_4 1.164 and neutral equiv., zero.

Anal. Calcd. for $C_{11}H_{14}O_4$: sapon. equiv., 105.1. Found: sapon. equiv., 106.5.

A solution of 5.4 g. of the dimethyl ester in absolute methanol saturated with dry ammonia at 0° was kept in the refrigerator during three days. The dimethyl ester was recovered unchanged on evaporation of the alcohol and ammonia in a vacuum desiccator over concentrated sulfuric acid. The refractive index was practically identical with that of the dimethyl ester and the nitrogen content was zero.

Diethyl.—The unsaturated anhydride (32.8 g.) was treated with 60 cc. of absolute ethanol, as for the dimethyl ester, giving 28 g. (59%) of product boiling at 136–140° at 7 mm. It was redistilled at 8 mm. (b. p. 138–140°) and then had $n^{20}D$ 1.4761, d^{21}_4 1.100 and neutral equiv., zero.

Anal. Calcd. for $C_{13}H_{18}O_4$: sapon. equiv., 119.1. Found: sapon. equiv., 118.5.

Di-*n*-butyl.—A mixture of the unsaturated anhydride (20 g.) with 0.5 g. of *p*-toluenesulfonic acid was dissolved in 50 g. of *n*-butanol and the solution boiled under reflux during ten hours, in an apparatus having a water-trap between the condenser and the flask. Most of the water formed during the reaction collected in this trap. The product was then isolated as for the dimethyl ester, giving 30.6 g. (85%) of material boiling at 187–188° at 12.5 mm. It was redistilled at 8 mm. (b. p. 174–176.6°) and then had $n^{20}D$ 1.4721, d^{21}_4 1.044, and neutral equiv., zero.

Anal. Calcd. for $C_{17}H_{26}O_4$: sapon. equiv., 147.1. Found: sapon. equiv., 148.6.

Imides—Unsubstituted Imides: (a) Using Ammonium Carbonate.—An intimately ground mixture of anhydride I (16.4 g.) and dry ammonium carbonate (18.0 g.) was heated slowly in an oil-bath until no more vapors were evolved (maximum reaction temperature, 200°). The product was extracted with hot 95% ethyl alcohol. On cooling, the extract yielded 7.3 g. of imide, m. p. 183–185°. With a maximum reaction temperature of 250° a dark red product, from which no imide could be readily isolated, was obtained.

(b) Using Dry Ammonia.—Dry ammonia was passed over the molten anhydride (I or II) in an oil-bath at 170° until the gas was no longer absorbed.

(Δ^4) Imide.—As the ammonia was absorbed, the product solidified to an almost colorless substance (except for a yellowish color on the surface, due to oxidation). Recrystallization from hot water resulted in a yield of 13.7 g. (84% of theoretical) of crystalline imide, m. p. 186.5–187°. On admixture with a sample of the product from (a) the m. p. was 185–186.5°.

Anal. Calcd. for $C_9H_9O_2N$: C, 66.23; H, 5.56; N, 8.59. Found: C, 66.30; H, 5.53; N, 8.58.

(Sat.) Imide.—On cooling, the product solidified to a colorless mass, m. p. 143–149°. A portion of the crude imide (9 g.) was extracted with pure, dry ethyl acetate in a Soxhlet extractor. On evaporation at room temperature, the extract yielded a colorless, crystalline product weighing 7.5 g. and having m. p. 168–174°.

The following method of recrystallization gives an analytically pure, crystalline product. The imide (5 g.) was dissolved in dilute ammonium hydroxide (30 cc. of 2:1)

(6) Kindly presented by the Carnegie-Illinois Steel Corporation Fellowship at Mellon Institute.

(7) All carbon and hydrogen determinations were performed microanalytically by Dr. Carl Tiedcke, New York, N. Y.

Digitized by Arya Samaj Foundation Chennai and eGangotri

and refluxed during thirty minutes. On slowly cooling the solution to 5°, colorless, hexagonal-shaped crystals, m. p. 174–175.5°, separated in quantitative yield.

Anal. Calcd. for $C_9H_{11}O_2N$: N, 8.48. Found: N, 8.47.

Substituted Imides. (Δ^4) N-Phenyl-imide.—A solution of 5 ml. (slight excess) of aniline in 20 ml. of dry benzene was added to a warm solution of 8.2 g. of anhydride I in 40 ml. of benzene. The resulting precipitate was filtered off and washed successively with benzene, hydrochloric acid (1:1) and cold water. It was recrystallized by dissolving in hot glacial acetic acid and adding water to the warm solution almost to turbidity, resulting in the crystalline anil, m. p. 144°.

Anal. Calcd. for $C_{15}H_{13}O_2N$: N, 5.85. Found: N, 5.59.

(Sat.) N-Phenyl-imide.—Aniline (4.4 ml.) was slowly added to a solution of 8.3 g. (slight excess) of anhydride II in 25 ml. of chloroform. An exothermic reaction took place with the formation of a heavy, colorless precipitate. This was filtered off, washed with chloroform and air-dried. The yield was 12 g. of product having m. p. 175–176° (dec.). If the anhydride (II) exhibits all the properties typical of a dicarboxylic anhydride,[8] this material is the anilic acid derivative. However, all attempts to purify the "anilic acid" resulted in the anil. (a) Recrystallization from either hot glacial acetic acid or hot ethyl alcohol (95%) (to each of which water was added almost to turbidity) resulted solely in the crystalline anil, m. p. 152–153°. A mixed m. p. with the analytically pure anil described in (b) showed no depression.

(b) An attempt to isolate the sodium salt of the anilic acid resulted in the anil. The substance (3 g.) with m. p. 175–176° (dec.) was suspended in 100 ml. of 50% ethyl alcohol (at 25°) and the suspension rendered slightly alkaline with 10% sodium carbonate solution (15 ml.). Evaporation of the solution at room temperature (vacuum desiccator) to half its original volume gave 2.3 g. of beautiful, needle-like crystals, m. p. 151.5–152.5°. On recrystallization from ethyl alcohol–water (5:3), the crystalline anil had m. p. 152–153°.

Anal. Calcd. for $C_{15}H_{15}O_2N$: C, 74.65; H, 6.27; N, 5.81. Found: C, 74.58; H, 6.50; N, 5.81 (Dumas); N, 5.55 (Kjeldahl).

(Δ^4)-N-*p*-Tolyl-imide.—A solution of 5.4 g. of *p*-toluidine in 20 ml. of dry benzene was added to a solution of 8.2 g. of anhydride I in 30 ml. of dry benzene. On standing, a heavy colorless precipitate (11.2 g.) was formed. This was filtered off and washed successively with benzene, dilute hydrochloric acid and water. Crystallization from either hot glacial acetic acid or ethanol, each diluted with water almost to turbidity, resulted in the N-*p*-tolyl-imide, m. p. 156.5–157°.

Anal. Calcd. for $C_{16}H_{15}O_2N$: N, 5.53. Found: N, 5.52 (Dumas); N, 5.20 (Kjeldahl).

N-Benzyl Imides.—A solution of sodium ethoxide was prepared by dissolving 0.15 g. of oxide-free sodium in absolute ethanol (25 ml.) under a reflux condenser (anhydrous calcium sulfate tube). The imide (1.12 g.) was then added and the mixture refluxed during twenty minutes. A solution of benzyl chloride in 10 ml. of absolute ethanol was now added to the suspension and refluxing was continued during one hour. The ethanol suspension was filtered while still hot and water added to the hot filtrate, almost to turbidity. This solution gave the crystalline N-benzyl-imide on rapid cooling and agitation with a glass rod or, preferably, on evaporating under diminished pressure at 40°.

Unsaturated: m. p. 82.5–83.5°.

Anal. Calcd. for $C_{16}H_{15}O_2N$: C, 75.87; H, 5.97; N, 5.53. Found: C, 75.31; H, 5.87; N, 5.46.

Saturated: m. p. 101–103°.

Anal. Calcd. for $C_{16}H_{17}O_2N$: N, 5.49. Found: N, 5.47.

Amides—A. Monoamide Monoammonium Salts.—The finely powdered anhydride (0.05 mole) was added in small portions to 20 ml. of concentrated ammonium hydroxide in a mortar and the mixture intimately ground after each addition. Finally, 10 ml. of ethyl alcohol was added, the insoluble salt filtered off and dried to constant weight in a vacuum desiccator over sulfuric acid.

Unsaturated: m. p. 172° (dec.).

Anal. Calcd. for $C_9H_{14}O_3N_2$: N, 14.14. Found: N, 14.00.

Saturated: m. p. 177° (dec.).

Anal. Calcd. for $C_9H_{16}O_3N_2$: N, 13.99. Found: N, 13.20.

B. Amidic Acids.—Concentrated hydrochloric acid (5.8 ml.) was added dropwise, with continuous stirring, to a suspension of the monoamide monoammonium salt in water (55 ml.) until just acid to congo red, while maintaining the temperature between 0 and 5°. The resulting colorless precipitate was filtered off and washed with successive small portions of cold water until the last washing was not acid to congo red. The product was lixiviated with two 20-ml. portions of acetone, giving a dry, colorless product. Owing to its instability, recrystallization was not attempted. (When a solution of the monoamide monoammonium salt was treated in the cold with an excess of concentrated hydrochloric acid and allowed to stand at 5° for twenty-four hours before filtering, the resulting product proved to be the dibasic acid.)

Unsaturated: m. p. 136° (dec.).

Anal. Calcd. for $C_9H_{11}O_3N$: N, 7.73. Found: N, 7.93.

Saturated: m. p. 165–166° (dec.).

Anal. Calcd. for $C_9H_{13}O_3N$: N, 7.65. Found: N, 7.74.

Ammonium Acid Salts.—The amidic acid (0.8 g.) was suspended in carbon dioxide-free water (10 ml.) and the acid was dissolved by boiling the suspension under a reflux condenser on a steam-bath during forty minutes. The colorless solution was then evaporated to dryness in a vacuum desiccator. After washing the crystalline residue with 20 ml. of purified acetone (dried with anhydrous potassium carbonate and distilled), it was dried in a vacuum desiccator over phosphorus pentoxide.

Unsaturated: m. p. 148° (dec.).

Anal. Calcd. for $C_9H_{13}O_4N$: N, 7.03. Found: N, 6.91.

Saturated: m. p. 149–150° (dec.).

Anal. Calcd. for $C_9H_{15}O_4N$: C, 53.72; H, 7.51; N, 6.96. Found: C, 53.82; H, 7.58; N, 6.96.

Diammonium Salt.—An excess of concentrated ammonium hydroxide (6 ml.) was added to a suspension of 5 g. of the dibasic acid (III) in 80 ml. of water, with constant stirring. The resulting solution was evaporated in a vacuum desiccator over concentrated sulfuric acid. On removal of most of the solvent the product set to a solid mass of colorless crystals. It was filtered off and dried thoroughly at room temperature.

Unsaturated: m. p., indefinite.

Anal. Calcd. for $C_9H_{16}O_4N_2$: C, 49.99; H, 7.46; N, 12.97. Found: C, 49.83; H, 7.06; N, 12.51.

Attempted Preparation of the Diamide.—A solution of the saturated unsubstituted imide (1.5 g.) in concentrated ammonium hydroxide (6 ml.) was refluxed during twenty minutes. On cooling, a crystalline product was obtained which, after drying, weighed 1.3 g. and had m. p. 175–176°. After sublimation at 160° under reduced pressure it had m. p. 174.5–175°.

Anal. Calcd. for $C_9H_{14}O_2N_2$ (diamide): N, 15.38. Calcd. for $C_9H_{11}O_2N$ (imide): N, 8.48. Found: N, 8.47.

3-Benzoyl-norcamphane-2-carboxylic Acid (VI).—One-tenth mole (16.6 g.) of II was dissolved in 100 ml. of dry,

(8) W. J. Hickinbottom, "Reactions of Organic Compounds," Longmans, Green and Co., New York, N. Y., 1936, p. 198.

Digitized by Arya Samaj Foundation Chennai and eGangotri

thiophene-free benzene, and anhydrous aluminum chloride (30.5 g.; 0.23 mole) added in one portion with continuous stirring and cooling. The temperature of the reaction mixture was now raised slowly to 45° during thirty minutes and maintained at 45° for thirty minutes.

After cooling the reaction mixture in an ice-bath, 100 g. of chopped ice was added slowly, followed by 20 cc. of concentrated hydrochloric acid and enough water to bring the final volume to about 250 ml. The excess benzene was then removed by steam distillation. The colorless reaction product was filtered, washed with cold water, dissolved in 75 ml. of aqueous sodium carbonate solution (10%) and the solution boiled during three hours. After filtering, the solution was rendered acid to congo red by addition of concentrated hydrochloric acid (10 ml.) and the resulting colorless precipitate was filtered off, and washed with cold water. The yield of dry, crude 3-benzoyl-norcamphane-2-carboxylic acid was 20.3 g. (87% of theoretical), m. p. 150–158°.

The compound is soluble in benzene, ether, glacial acetic acid, hot ethyl acetate, acetone or chloroform. It is insoluble in water or petroleum ether.

A portion (12 g.) of the acid was recrystallized by dissolving in 300 ml. of hot, dry benzene and adding 50 ml. of petroleum ether to the warm solution. On cooling, a crystalline precipitate was obtained which, after filtering and drying, weighed 6.7 g. and had m. p. 170–173°. The filtrate was evaporated until the volume was about 50 ml., whereupon an equal volume of petroleum ether was added, resulting in a second crop of crystalline product (5.2 g.) having m. p. 170–171°.

Anal. Calcd. for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60; neut. equiv., 244.2. Found: C, 74.12; H, 6.84; neut. equiv., 247.0.

Attempted Cyclization of VI to the Substituted Anthraquinone.—A small portion of the acid (VI) was dissolved in 1 ml. of concentrated sulfuric acid and heated on the steam-bath during forty-five minutes. On pouring the resulting yellow-colored solution into 10 ml. of water, a colorless precipitate was formed. It was filtered off and washed free of acid. On examining the product for the presence of the quinone structure, the tests were negative, indicating that cyclization to the substituted anthraquinone had not occurred.

Summary

1. *cis*-3,6-Endomethylene-hexahydrophthalic anhydride (II) has been prepared by direct catalytic hydrogenation (under high pressure) of *cis*-3,6-endomethylene-Δ^4-tetrahydrophthalic anhydride (I).

2. A number of new alkyl esters, imides, amides and ammonium salts of the two acids corresponding are described.

3. The synthesis of 3-benzoyl-norcamphane-2-carboxylic acid (VI) by a Friedel–Crafts reaction is given.

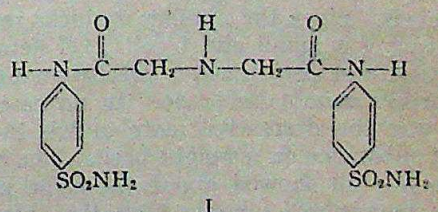
N⁴-Substituted Sulfonamides

BY JACOB FINKELSTEIN*

In 1938, Fourneau and co-workers[1] showed the formyl and acetyl sulfanilamides were considerably less active than sulfanilamide against streptococcal infections. However, in a rather thorough study of the effect of various acyl groups on the activity of sulfanilamide, Miller, Rock and Moore[2] found that the caproyl derivative was as effective as the parent drug and yet, less toxic. During that time, we have prepared several N⁴-substituted derivatives of the several widely used sulfa drugs. Among these compounds are several already recorded in the literature. However, they are included in this report because the work has been extended to include their action against other pathogenic organisms and to present a more complete basis for comparison with related substances.

The chloroacetyl compounds were prepared by two methods. In one, the required chloroacetyl chloride was added dropwise to an ice-cooled suspension of the drug in an inert solvent, and in the other, the chloroacetyl chloride was added to an aqueous solution of the sulfa drug in dilute sodium hydroxide. The aminoacetyl compounds were obtained by dissolving the chloroacetyl derivatives in aqueous ammonia, warming at 40° for twenty-four to forty-eight hours, followed by evaporation of the solvent. These compounds were difficult to purify because of their unfavorable solubility properties.

The preparation of N⁴-aminoacetylsulfanilamide was reported by Pollak, *et al.*,[3] who recorded a melting point of 259°, whereas our product melted at 216–218°. Therefore, we repeated their work using liquid ammonia in place of aqueous ammonia, and obtained a product which melted at 256–258°. The analysis of this compound indicated the empirical formula $C_{16}H_{19}N_3S_2O_6$ and it most likely is (I) α,α'-iminobis-(N⁴-



I

acetylsulfanilamide), which the above authors erroneously reported as glycyl sulfanilamide, in spite of the fact that their recorded analytical values agree with those of the desired compound.

The substances here discussed were tested at the Merck Institute for Therapeutic Research by

[a] Mietzach, *et al.*, U. S. P. 2,289,029; July 7, 1942. [b] After six recrystallizations. [c] Pollak, *et al.*[3] [d] Raiziss, *et al.*, *J. Lab. Clin. Med.*, **27**, 1276 (1942). [e] All recorded analyses were performed by Messrs. Hayman, Reiss, Clark and Boos.

Dr. A. O. Seeler and Dr. Harry Robinson against malaria and pathogenic organisms.

Dr. Robinson reported that "preliminary toxicity experiments in mice suggest that the acute oral toxicity of these derivatives is similar to that of sulfadiazine, sulfapyridine, and sulfathiazole. This apparent low acute toxicity may be due in part to the poor absorption from the gastrointestinal tract. Efficacy experiments in mice indicate that these compounds afford good protection against severe experimental infections produced by the intraperitoneal injection of *Streptococcus hemolyticus, Staphylococcus aureus, Diplococcus pneumonia* Type I and *Salmonella schottmülleri*. However, more accurate evaluations will be based upon blood level determinations."

These compounds were tested for activity against the schizonts of *Plasmodium lophurae* in Pekin ducklings. Fifty-gram ducklings were inoculated intravenously with 2,000,000 parasitized erythrocytes. Administration of the drugs was begun on the day of inoculation and was continued for six days. In order to maintain a reasonably constant blood level, the drugs were mixed into the diet in such fashion that the birds would consume their daily dose throughout the twenty-four hours. The relative activity was estimated by comparing the effects on the parasite count when the drugs were given at the same dose levels. Since the number of ducks receiving each drug was small and blood level determinations were not performed, a precise quantitative comparison cannot be made. In no case, however, was the derivative more active than the parent substance on a weight basis. The caproyl compounds all showed about the same activity as the parent sulfonamides and the chloracetyl derivatives seemed uniformly less active.

The solubility determinations of the compounds were performed by Mr. Walter A. Bastedo, Jr., of these Laboratories. All derivatives are soluble in 100 ml. of water at 37° to the extent of less than four-tenths of mg. except glycylsulfanilamide (157 mg./100 ml.) and glycylsulfathiazole (0.7 mg./100 ml.).

Acknowledgments.—The author wishes to acknowledge his indebtedness to Drs. R. T. Major and K. Folkers for their advice and interest, and to express his appreciation to Dr. A. O. Seeler and Dr. Harry Robinson of the Merck Institute for Therapeutic Research for their evaluation of the products as therapeutic agents.

Experimental

Preparation of N^4-Chloroacetyl Derivative

Method I.—To a well-stirred solution of 24.9 g. of sulfapyridine in 80 cc. of 1.25 *N* sodium hydroxide, 18 g. of chloroacetyl chloride was added slowly and dropwise. There was only a slight rise in temperature. One hour after the addition was completed, the white insoluble product was filtered and washed with water. After several recrystallizations from dioxane, the pure product was obtained.

Method II.—To a well-stirred suspension of 10 g. of sulfadiazine in 3.2 g. of dry pyridine and 60 cc. of dry chloroform cooled in an ice–salt mixture, 4.6 g. of chloroacetyl chloride was added slowly and dropwise. The reaction mixture was kept at room temperature for some time and the insoluble product filtered. It was stirred for a short time with 40 cc. of 2.5 *N* hydrochloric acid, collected by filtration and, after washing with water, recrystallized from boiling absolute alcohol.

Preparation of N^4-Aminoacetyl Derivatives

The preparation of the glycyl derivatives may be illustrated as follows. A solution of 50 g. of N^4-(chloroacetyl)-sulfanilamide was prepared by adding small amounts to 600 cc. of concentrated aqueous ammonia with stirring. The solution was placed in a pressure bottle and heated in a water-bath at 40° for two days. The solution was filtered from a small amount of insoluble material and evaporated in a shallow dish until a colorless, crystalline product separated. After three recrystallizations from water, there was obtained pure N^4-aminoacetylsulfanilamide.

The caproyl derivatives of sulfapyridine, sulfathiazole and sulfadiazine were prepared according to the method of Miller, Rock and Moore.[2]

Summary

A series of chloroacetyl and aminoacetyl derivatives of sulfonamides has been prepared for study as agents to combat infectious organisms. Many of these drugs were found to be very effective against such organisms as streptococcus, pneumococcus (type I), *Staphylococcus aureus* and *Salmonella schottmülleri*.

1,*n*-Alkyl-cyclopentanols and their Derivatives[1,2]

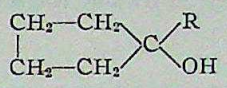
By C. R. McLellan[3] and W. R. Edwards, Jr.

As a series, the 1,*n*-alkyl-cyclopentanols have not previously received comprehensive study. Different authors[4] have reported the preparations of the first seven members of the series; but most of these have been characterized incompletely. Existing data concerning their physical properties were not obtained under uniform conditions; some contradictions appear in them; and few derivatives have been made from these alcohols, either for identification purposes or with a view toward their possible practical value. The peculiar structures of these compounds, in which the cyclopentyl ring fills the dual role taken by two distinct radicals in most tertiary alcohols, make prediction of their properties by analogy unreliable. The purposes of the present work were to prepare a number of these alcohols; to characterize them more completely and uniformly; to compare some of their properties with the corresponding properties of other relevant series; and to prepare and study some of their derivatives.

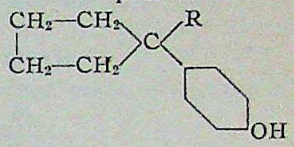
To accomplish these purposes, ten compounds of Type (I) were prepared; those in which R contained 1, 2, 3, 4, 6, 7, 8, 10, 12 and 14 carbon atoms, respectively. Compounds of Type (II) were prepared from the first seven of these.

Other derivatives prepared from Type (I) included the *p*-nitrobenzoates of five of them and the 3,5-dinitrobenzoates of all ten. Dibromo derivatives were prepared from three compounds of Type (II). With the exception of the first six alcohols of Type (I), these were new compounds.

Type (I)
1,*n*-alkyl-cyclopentanols



Type (II)
p-(1,*n*-alkyl-cyclopentyl)-phenols



Apparently no condensations of phenols with such alicyclic tertiary alcohols have been reported previously, regardless of the size of the alicyclic ring.

The 1,*n*-alkyl-cyclopentanols were prepared by the Grignard reaction from cyclopentanone and the appropriate alkyl bromides. Their purifications presented some difficulty, due chiefly to the formation of alkanes during the syntheses, and to ready dehydration of the products themselves at distillation temperatures. Data serving to characterize the members of this series appear in Tables I and III; properties of crystalline esters are included in Table II. Table IV contains data pertaining to compounds of Type II.

In Fig. 1, the boiling points of the 1,*n*-alkyl-cyclopentanols are plotted against their molecular weights, along with the boiling points of compounds of several other series. Between the curve

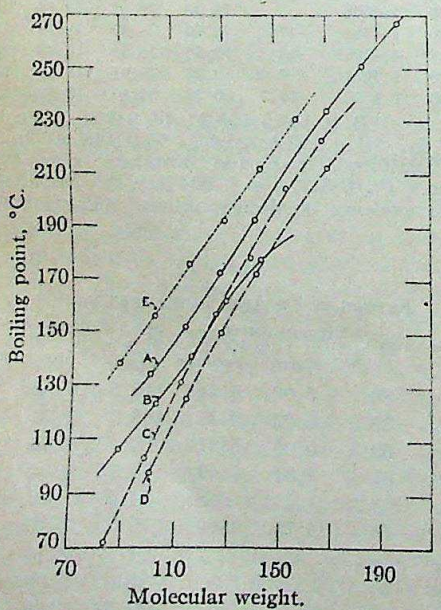

Fig. 1.—A, 1,*N*-Alkyl-cyclopentanols; B, *N*-alkyl-dimethylcarbinols; C, *N*-alkyl-cyclopentanes; D, *N*-alkanes; E, normal primary alcohols.

for the 1,*n*-alkyl-cyclopentanols and the one given by a series of non-cyclic tertiary alcohols, there is a relationship approximately similar to the relationship between the curves for *n*-alkylcyclopentanes, and for *n*-alkanes, respectively. The quantitative difference produced by the ring is slightly greater in the case of the alcohols. The difference in boiling point which may be ascribed to the presence of a cyclopentyl ring is seen (by reference to curves A, B and E) to be small compared to the difference between primary and tertiary alcohols of non-cyclic type.

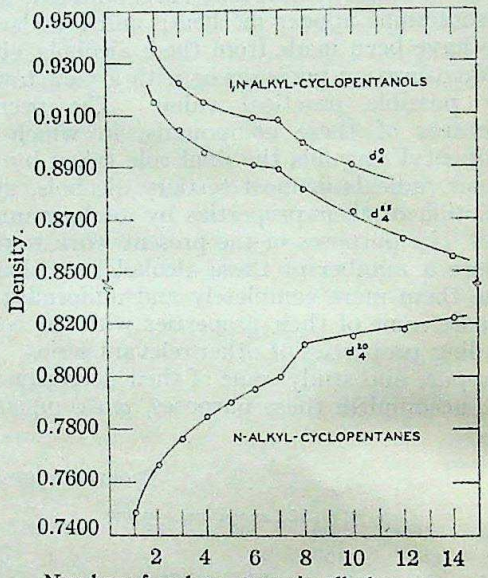

Fig. 2.

Figure 2 shows a remarkable break at the heptyl in the curve given by the densities. The densities of the *n*-alkylcyclopentanes taken from the literature[4,5] show a similar break in the same region. This appears to be due to the relationship between the sizes of the alkyl groups and of the cyclopentyl ring, and to the distinct difference in their configurations, a difference which includes the relative elasticity of the alkyl groups as compared to the rigidity of a five-membered ring. When the alkyl group is small, the cyclopentyl group is dominant, in the sense that it presents the chief obstacle to closer packing of the molecules; therefore it is chiefly responsible for the molecular volume. The curve from the methyl to the heptyl compound reflects this condition. At the point where the alkyl group has so increased in size as to become the dominant group, the situation changes sharply. Above this point, the alkyl-cyclopentanols constitute what is actually a different series as far as densities are concerned. An abrupt change in the slope of the density curve

(5) Schmidt and Gemassmer, *Ber.*, **73**, 359 (1940). The value for the density of *n*-hexylcyclopentane was taken from Plate (ref. 4). Use of the much lower value reported at an earlier date by Zelinski (ref. 4) would have caused the break to appear at this point rather than at the heptyl.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

results, at the point at which dominance shifts from one group to the other.

An analogous series of *n*-alkyl-cyclohexanols is now being investigated, to determine whether or not they exhibit the same phenomenon.

Condensation of 1,*n*-alkyl-cyclopentanols with phenol to form *p*-(1,*n*-alkyl-cyclopentyl)-phenols resulted in somewhat smaller yields than usual for this type of reaction. The octyl compound was never thoroughly purified; and an attempted preparation of the decyl compound was unsuccessful. Tests of the bacteriostatic strengths of these substituted phenols showed the first four to be rather effective toward the Gram-positive *Staphylococcus aureus*, but wholly ineffective toward the Gram-negative *E. coli*. The higher members of the series were ineffective toward both organisms.

Experimental

Cyclopentanone.—Cyclopentanone was prepared from adipic acid[6] by the method of Thorpe and Kon,[7] and purified by the modification of Wagner.[8]

1,*n*-Alkyl-cyclopentanols.—These compounds were prepared from cyclopentanone and the appropriate alkylmagnesium bromides, by the method of Zelinsky and Namjetkin.[4] All but the lauryl and myristyl compounds were purified by repeated fractional distillations, at pressures ranging from atmospheric to 1 mm. All were colorless liquids, except the methyl compound which was a crystalline solid, and the lauryl which possessed a faint yellow color. They had peppermint-like odors. The methyl compound was slightly soluble in water; this solubility diminished regularly with increase in size of the alkyl group. They were all soluble in the usual organic solvents; yields were 50% for the methyl, 35–40% for ethyl through decyl, and 20% for lauryl and myristyl.

The 1,*n*-heptyl-cyclopentanol presented a special problem, since the tetradecane formed during its synthesis boils very close to the alcohol at all pressures between a few millimeters and one atmosphere. Consequently, although the crude alcohol was redistilled several times until an almost constant-boiling product was obtained, it seems unlikely that this impurity was eliminated completely.[9]

Purification of 1,*n*-Lauryl-cyclopentanol-1 and 1,*n*-Myristylcyclopentanol-1.—As these compounds decomposed on distillation even at 1 mm., they were purified by recrystallization at low temperatures. At the conclusion of the preparation by the Grignard reaction, the ethereal extract containing crude 1,*n*-lauryl-cyclopentanol-1 was washed with water and dried; the ether was then removed by evaporation on a steam-bath, gradually reducing the pressure to 4 mm. The oily residue was dissolved in three times its volume of 95% ethanol and chilled in an ice–salt-bath. Solid impurities consisting chiefly of tetracosane precipitated, and were removed by filtration. The filtrate was concentrated on a steam-bath, at a pressure of 2.5 mm. The oily residue was dissolved in an equal volume of anhydrous ether, and chilled in dry-ice. Crystals of the product precipitated. These were filtered on a Buchner funnel packed with dry-ice, washed once with ether previously chilled, and quickly transferred to a suitable container. Upon reaching room temperature, these crystals melted, forming an oily liquid with a faint yellow color; this was taken to be 1,*n*-lauryl-cyclopentanol-1. Further recrystallizations yielded a smaller amount of product having the same physical characteristics. Minor differences in details were observed in purifying the myristyl compound.

1,*n*-Alkyl-cyclopentyl-*p*-nitrobenzoates and -3,5-dinitrobenzoates.—These esters were prepared from the 1,*n*-alkyl-cyclopentanols by the method of Conn, Collett and Lazzell,[10] allowing several days for each reaction. They were recrystallized from ether, or petroleum ether, or a mixture of the two.

***p*-(1,*n*-Alkyl-cyclopentyl)-phenols.**—These were prepared by condensation of the 1,*n*-alkyl-cyclopentanols with phenol, employing two different methods; that of Huston and Hedrick,[11] and that of Welsh and Drake,[12] a method which had given particularly good yields with certain tertiary alcohols containing aromatic rings. In the present work, however, there was little to choose between results of the two methods. The products were purified by fractional distillation at reduced pressures, followed by recrystallization from petroleum ether; the methyl member of the series was purified solely by successive recrystallizations; yields ranged from 27 to 39%.

For analytical purposes, the *p*-(1,*n*-alkyl-cyclopentyl)-phenols were titrated with 0.13 *N* potassium bromide–potassium bromate solution, using the method of Francis and Hill.[13]

The *p*-(1,*n*-alkyl-cyclopentyl)-phenols were colorless crystalline solids, possessing faint phenolic odors. They were soluble in most of the ordinary organic solvents, the solubility in petroleum ether increasing appreciably with increase in the size of the alkyl group. The methyl member of the series was slightly soluble in water; water solubility decreased with increase in the size of the alkyl group.

2,6-Dibromo-4-(1,*n*-alkyl-cyclopentyl)-phenols.—The *p*-(1,*n*-alkyl-cyclopentyl)-phenols were dissolved in chloroform or ligroin, and the calculated amount of a dilute solution of bromine in the same solvent added. Reaction was practically instantaneous. The solvent was removed by evaporation on a steam-bath, and the products recrystallized from ethanol–water mixtures.

Determination of Boiling Points of 1,*n*-Alkyl-cyclopentanols.—These were determined with a modified Cottrell boiling point apparatus,[14] which is drawn to scale in Fig. 3. The diameter of the tube was 3 cm. Quantities as small as 3 cc. gave satisfactory results. Short-stemmed Allihn thermometers were used. Boiling points were determined at five pressures, except when prevented by (a) thermal decomposition of the three highest alcohols; or (b) difficulty in condensing the two lowest ones at very low pressures.

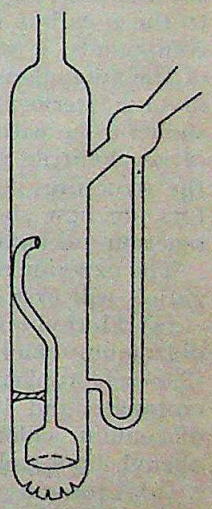

Fig. 3.—Boiling point apparatus.

Determination of Melting Points.—Melting points of the 1,*n*-alkyl-cyclopentanols were determined by the method of cooling curves, readings being taken every thirty seconds. Tubes containing the samples undergoing such treatment were separated from the cooling baths by an air jacket, so that slow and uniform cooling was achieved. The methyl member of the series was an exception; its melting point was determined in the usual way, as were the melting points of the various esters and phenols.

Acknowledgment.—The authors thank Dr. E. Emmet Reid for his interest in the problem, and

for the gift of most of the alcohols from which the bromides were prepared.

Summary

1. The 1,*n*-alkyl-cyclopentanols have been characterized as a series, through the preparation and study of four new members, together with a more complete and uniform study of six previously prepared members.

2. Some of the data thus obtained have been plotted, and compared with similar curves representing other relevant series. The unusual form of the density curves has been discussed.

3. Esters of *p*-nitrobenzoic acid have been prepared from five of these alcohols, and esters of 3,5-dinitrobenzoic acid have been prepared from all ten, and the melting points of these esters have been determined.

4. Seven *p*-(1,*n*-alkyl-cyclopentyl)-phenols have been prepared by condensation of these alcohols with phenol, and characterized. Their bacteriostatic strengths have been determined. Four of them were found to be effective toward *Staph. aureus*.

5. Three 2,6-dibromo-4-(1,*n*-alkyl-cyclopentyl)-phenols have been prepared, and their melting points determined.

The Coupling of α,β-Unsaturated Compounds with Diazonium Salts[1]

BY C. F. KOELSCH AND VIRGIL BOEKELHEIDE

In a previous paper[2] it was shown that the reaction between acrylonitrile and diazonium chlorides in buffered solutions and in the presence of cupric chloride led to the formation of α-chlorohydrocinnamonitriles. Since Meerwein, Buchner and van Emster[3] had considered that in similar reactions the aryl group always became attached to the α-carbon of β-substituted α,β-unsaturated compounds, it was believed that an explanation of the anomalous results with acrylonitrile might involve steric hindrance. This belief is now shown to be without foundation, for the behavior of acrylonitrile is not anomalous. Also some of the structures advanced by the earlier investigators are now shown to be incorrect, and a new reaction mechanism is proposed.

The experimental results of the present investigation will first be summarized.

(a) Methyl crotonate and 2,4-dichlorobenzenediazonium chloride yielded methyl α-chloro-β-(2,4-dichlorophenyl)-butyrate.[4] Similarly ethyl crotonate and benzene- (and *p*-chlorobenzene-) diazonium chloride yielded ethyl α-chloro-β-phenyl- (and *p*-chlorophenyl-) butyrate.

(b) Crotonic acid and *p*-nitrobenzenediazonium chloride gave α-chloro-β-(*p*-nitrophenyl)-butyric acid.[5]

(c) Methyl cinnamate and *p*-chlorobenzenediazonium chloride yielded methyl β-chloro-α-(*p*-chlorophenyl)-hydrocinnamate.[6]

(d) Cinnamalacetic acid and benzenediazonium chloride gave 1,4-diphenylbutadiene.

(e) Methyl cinnamalacetate and benzene- (and *p*-chlorobenzene-) diazonium chloride gave methyl α-phenyl- (and *p*-chlorophenyl)-cinnamalacetate.

(f) Sorbic acid and benzenediazonium chloride gave 1-phenylpentadiene-1,3.

It is clearly seen that the volume occupied by the group on the β-carbon atom of the unsaturated compound is not a factor in determining the point of entry of the aryl group. A methyl group occupies at least as large a portion of the space in the immediate vicinity of the β-carbon atom as does a vinyl group, yet crotonic acid and its derivatives undergo β-coupling, whereas α-coupling takes place with the vinyl compounds listed in paragraphs d, e and f.

The following mechanism appears to account for the products obtained.

$$C_6H_5N_2^+ + CH_3COO^- \rightleftharpoons C_6H_5N{=}NOCOCH_3 \longrightarrow C_6H_5\cdot + N_2 + CH_3COO\cdot \quad (1)$$

$$C_6H_5\cdot + RCH{=}CHR' \longrightarrow C_6H_5CHR{-}C\cdot HR' \text{ (I)} \quad (2)$$

$$\text{(I)} + Cu^{++} \longrightarrow Cu^+ + C_6H_5CHR{-}C^+HR' \text{ (II)} \quad (3)$$

$$Cu^+ + CH_3COO\cdot \longrightarrow Cu^{++} + CH_3COO^- \quad (3a)$$

$$\text{(II)} + Cl^- \longrightarrow C_6H_5CHR{-}CHClR' \quad (4)$$

$$\text{(II)} \longrightarrow H^+ + C_6H_5CR{=}CHR' \quad (4a)$$

Equation 1 shows the function of the buffer; the diazonium salt cannot, but the homopolar diazoacetate can decompose easily into a free phenyl radical.[7] Equation 2 represents the "electron pairing"[8] attack of the free radical on the unsaturated compound. The structure of I is determined by considerations analogous to those advanced by Mayo and Walling[9] to account for the orientations observed in Kharasch's peroxide

directed addition of hydrogen bromide to olefins; coupling takes place to yield the more stable of the two possible products. If R is saturated and R′ contains C=O (or C≡N), the free radical I will be stabilized by resonance of the odd electron into R′. But if R is phenyl or vinyl, then the more stable free radical (I) will be the one with the odd electron on the carbon attached to R,[10] since the resonance in the more symmetrical system $\overset{\curvearrowleft}{C}=C-\overset{\curvearrowleft}{C}\cdot$ will be greater than the resonance $\cdot\overset{\curvearrowright}{C}-C=\overset{\curvearrowright}{O}$.

Equations 3 and 3a show the function of the cupric salt, while equations 4 and 4a indicate how two characteristic products of the reaction are formed. It is of some interest that if in II R is COOH and α-coupling has taken place (*e. g.*, cinnamic acid, cinnamalacetic acid and sorbic acid), then decarboxylation of II follows, as would be predicted; whereas if in II R′ is COOH and β-coupling has taken place (*e. g.*, crotonic acid), then the ion II retains the carboxyl group and acquires an anion (Cl^-), again as would be predicted.

The foregoing equations do not show all of the processes involved in the reaction. For example, the rate of nitrogen evolution from a reaction mixture is highly dependent on the particular unsaturated compound used, and this must indicate that a complex is formed between the unsaturated compound and a nitrogen-containing reactant. However, the structure of this complex cannot now be determined. Furthermore, the yields of pure products are always low; the by-products are non-volatile tarry substances.

Experimental

Orienting experiments were made in the following way. A mixture of 0.1 mole of an aromatic amine with 10 ml. of water and 20 ml. of hydrochloric acid was warmed until homogeneous and then cooled in ice. Ten grams of ice was added, and then a concentrated solution of 7 g. of sodium nitrite was dropped in. The resulting solution was filtered and added dropwise and with stirring to a mixture (at 0°) of 0.1 mole of the unsaturated compound in 75 ml. of acetone with 0.1 mole of sodium acetate and 3 g. of cupric chloride in a minimum amount of water. The reaction mixture was warmed to a temperature (3 to 30°) at which gas was evolved evenly and not too rapidly, and stirring was continued until approximately the theoretical amount of nitrogen had been collected (two to six hours). The gases evolved were passed through sulfuric acid, then through a weighed Ascarite tube, and finally collected over water. When the reaction was complete, two liquid phases were present, a green aqueous layer containing mainly inorganic salts, and a brown oily layer which contained most of the product.

Ethyl Crotonate and *p*-Chlorobenzenediazonium Chloride.—An experiment was carried out using 1 mole of each of the reactants in 500 ml. of acetone, etc. The reaction required five hours at 20°. The product (108 g., 41%), isolated by ether extraction and distillation, was a pale red oil, b. p. 100–150° at 6 mm. A second distillation through a short column gave 88 g. (34%) of **ethyl α-chloro-β-(*p*-chlorophenyl)-butyrate**, a pale yellow oil, b. p. 125–140° at 2–3 mm.

Anal. Calcd. for $C_{12}H_{14}Cl_2O_2$: C, 55.2; H, 5.4; Cl, 27.2. Found: C, 55.3; H, 5.1; Cl, 27.7.

When 6.8 g. of this ester was allowed to stand for twelve hours with 12 g. of potassium hydroxide in 75 ml. of methanol, it furnished 3.2 g. (62%) of *p*-chloro-β-methylcinnamic acid, colorless crystals from ligroin, m. p. 134° (reported,[11] 133.5°). The acid formed a liquid-crystalline melt that became clear at 138.5°. For comparison the acid was synthesized from 30 g. of *p*-chloroacetophenone, through ethyl *p*-chloro-β-hydroxy-β-methylhydrocinnamate[12] (yield, 52%; b. p. 160–162° at 11 mm.), which was dehydrated with formic acid[11] to ethyl *p*-chloro-β-methylcinnamate (yield, 93%); the latter ester was hydrolyzed with 10% sodium hydroxide, giving the desired acid in 93% yield; it melted at 134° to a turbid liquid that became clear at 138.5°, and a mixture with the acid from the coupling showed the same behavior. Furthermore, each product was partly rearranged to a stereoisomer, m. p. 92–99° (reported[11] 94°) when it was warmed in concd. sulfuric acid for a few minutes.

That the coupling reaction yielded no ethyl β-chloro-α-(*p*-chlorophenyl)-butyrate was shown in the following way. Forty-one grams of once-distilled material from another experiment was boiled for ten minutes with 200 g. of diethylaniline, giving 33 g. of crude unsaturated ester. This was saponified, and 22.5 g. of the resulting crude acid was dissolved in 250 ml. of 5% sodium hydroxide and shaken with hydrogen at 40 lb. in the presence of Raney nickel. Gas absorption stopped after twenty-four hours, and titration then showed the presence of 0.14 mole of chloride ion (calcd. 0.11 mole). There was isolated 12.8 g. of an oily acid, b. p. 126–128° at 3 mm., neut. equiv., 164 (calcd. for phenylbutyric acid 164). Twelve grams of this acid in 40 ml. of benzene was treated with 18 g. of phosphorus pentachloride and then with 10 g. of aluminum chloride. This reaction yielded 4.4 g. (40%) of 3-methylindanone, b. p. 128–131° at 16 mm. (identified through its oxime and by comparison with an authentic sample), and 2 g. of a neutral substance, b. p. 144–148° at 16 mm. The higher boiling fraction was not ethyldesoxybenzoin, for it gave no solid oxime under conditions which were found to yield this oxime, m. p. 127–129°, when an authentic sample of the ketone was used.

Ethyl Crotonate and Benzenediazonium Chloride.—A one-mole experiment required three and one-half hours at 20–35° for completion of the nitrogen evolution. There was obtained 26.5 g. (11.5%) of once-distilled product, b. p. 110–150° at 11 mm., and this furnished 17 g. (7.5%) of a refractionated ester, b. p. 100–104° at 4 mm. Analysis indicated that the expected **ethyl α-chloro-β-phenylbutyrate** lost some hydrogen chloride on distillation.

Anal. Calcd. for $C_{12}H_{15}ClO_2$: C, 63.6; H, 6.6. Found: C, 65.1; H, 6.7.

When 3.8 g. of the chloro ester was allowed to stand for twelve hours with 4.5 g. of potassium hydroxide in 30 ml. of methanol, it gave 1.75 g. (65%) of β-methylcinnamic acid, which melted at 97–98° (reported[13] 97–98°) after it had been made sterically homogeneous by boiling it for three hours with excess 5% sodium hydroxide. The acid was identified by comparison with an authentic sample synthesized[11,12] from acetophenone.

Methyl Crotonate and 2,4-Dichlorobenzenediazonium Chloride.—A solution of 20.3 g. (0.13 mole) of 2,4-dichloroaniline in 100 g. of hydrochloric acid was diazotized and then partly neutralized by adding 26.2 g. (0.65 mole) of sodium hydroxide in 100 ml. of water at −5°. The solution was mixed with 12.5 g. of methyl crotonate in 200 ml. of acetone, then with 23.3 g. of sodium chloroacetate in 50 ml. of water, and finally with 5.3 g. of cupric

(10) It is to be noted that the present results indicate that the normal mode of addition of hydrogen bromide to cinnamic acid may be reversed by peroxides. It has been stated (ref. 9, p. 363) that this reversal cannot be achieved, but actually a conclusive experimental test of the matter has not been made (*cf.* Michael, *J. Org. Chem.*, **4**, 128 (1939)).

Digitized by Arya Samaj Foundation Chennai and eGangotri

chloride in 10 ml. of water. Nitrogen was evolved rapidly at 5°, and the reaction was complete after two and one-half hours. There was obtained 7 g. (20%) of methyl α-chloro-β-(2,4-dichlorophenyl)-butyrate,[4] b. p. 155–170° at 3 mm. (reported[3] 130–140° at 0.1 mm.).

Treatment of 5 g. of the ester with potassium hydroxide in methanol yielded **2,4-dichloro-β-methylcinnamic acid**, which formed colorless crystals (1.2 g., 30%) from ligroin, m. p. 126–127°.

Anal. Calcd. for $C_{10}H_8Cl_2O_2$: C, 52.0; H, 3.5. Found: C, 52.5; H, 3.6.

When 0.62 g. of the unsaturated acid was dissolved in a solution of 0.4 g. of sodium hydroxide in 30 ml. of water and shaken with Raney nickel under hydrogen at atmospheric pressure, it absorbed 230 ml. of the gas (calcd. 210 ml.) in ninety minutes. The resulting β-phenylbutyric acid was identified by comparison with an authentic sample, and by conversion into its amide (yield 50%), which melted at 105–106° (mixed m. p.) in agreement with the reported figure.[14]

Crotonic Acid and *p*-Nitrobenzenediazonium Chloride.—A diazonium salt solution prepared from 69 g. of *p*-nitroaniline, 138 g. of hydrochloric acid, and 35 g. of sodium nitrite was stirred into a mixture containing 43 g. of crotonic acid, 600 ml. of acetone, 100 g. of sodium chloroacetate, 20 g. of cupric chloride, and 100 ml. of water. Gas was evolved rapidly at 0°, and after one hour the reaction was complete. Extraction of the mixture with ether and of the ether with aqueous sodium bicarbonate furnished 16 g. of a nearly black oily acidic material, which could not be distilled, and from which no crystalline material could be obtained.[15] Fifteen grams of the oil was boiled for four hours with 40 ml. of methanol containing 5 g. of hydrogen chloride. There was obtained 11.3 g. of **methyl α-chloro-β-(*p*-nitrophenyl)-butyrate**, a pale red oil that distilled at 175–180° at 3 mm. with some loss of hydrogen chloride.

Anal. Calcd. for $C_{11}H_{12}ClNO_4$: C, 51.3; H, 4.7. Found: C, 53.5; H, 4.7.

When 10.7 g. of the ester was boiled for fifteen minutes with 60 g. of diethylaniline, it was dehalogenated, giving 7.2 g. (76%) of methyl β-methyl-*p*-nitrocinnamate, b. p. 156–160° at 3 mm., m. p. 120–121° (reported[13] 121–122°). Saponification of this product with 5% sodium hydroxide gave β-methyl-*p*-nitrocinnamic acid in 52% yield, m. p. 167–168° (reported[13] 168–169°). The melting points of the cinnamic ester and of the acid were unchanged when the substances were mixed with the corresponding compounds synthesized by the methods of Schroeter and Wulfing.[13]

Methyl Cinnamate and *p*-Chlorobenzenediazonium Chloride.—A solution prepared from 25.6 g. (0.2 mole) of *p*-chloroaniline, 54 g. of hydrochloric acid and 14 g. of sodium nitrite was stirred slowly into a mixture of 32.4 g. of methyl cinnamate, 150 ml. of acetone, 26 g. of pyridine, 20 g. of acetic acid, 6 g. of cupric chloride, and 100 ml. of water. Gas evolution began at 30° and ended after two hours. The volatile constituents were removed by distillation from a steam-bath, and the remaining oil was extracted with 500 ml. of benzene. From this extract there was obtained 12.8 g. of pure methyl β-chloro-α-(*p*-chlorophenyl)-hydrocinnamate,[6] colorless crystals from methanol, m. p. 121–122° (reported[3] 124–124.5°).

When 2.2 g. of the ester was allowed to stand for twelve hours at room temperature with 3.5 g. of potassium hydroxide in 30 ml. of methanol, it yielded 1.65 g. (86%) of α-(*p*-chlorophenyl)-cinnamic acid, m. p. 180–181°. And when a solution of 0.75 g. of this acid in 35 ml. of 1% aqueous sodium hydroxide was shaken with hydrogen under atmospheric pressure and in the presence of Raney nickel, it yielded 0.52 g. (84%) of α-phenylhydrocinnamic acid, m. p. 95–96° alone or mixed with a sample prepared by reducing α-phenylcinnamic acid.

(14) Kohler and Reimer, *Am. Chem. J.*, **33**, 353 (1905).

(15) Meerwein, Buchner and van Emster reported that this procedure gave 3.5 g. of an acid $C_{10}H_9NO_4$, m. p. 173.5–174.5°.

Cinnamalacetic Acid and Benzenediazonium Chloride.—A mixture of 0.1 mole of each of the reactants (but containing 0.2 mole of sodium acetate and 160 ml. of acetone) evolved gas at 10°. The reaction was complete after five hours, and 1.4 g. of carbon dioxide was collected. Only 0.9 g. of acidic product was obtained, and this was unchanged cinnamalacetic acid. Crystallization of the neutral products from benzene–ligroin gave 5.7 g. (28%) of 1,4-diphenylbutadiene, m. p. 149–150° alone or mixed with a sample synthesized by the method of Thiele and Schleussner.[16]

Methyl Cinnamalacetate[17] and Benzenediazonium Chloride.—A mixture of one mole of each of the reactants prepared in the usual way, but containing 0.17 mole of pyridine acetate in place of sodium acetate, began to evolve nitrogen at 15°, and the reaction was complete after five hours. Distillation of the products gave 4 g. of unchanged methyl cinnamalacetate and 5 g. (19%) of the expected coupling product, a pale red oil, b. p. 180–190° at 2 mm. Since some decomposition had accompanied its distillation, the substance was treated directly with 10% potassium hydroxide in methanol. No chloride ion was formed, but there was obtained 2.5 g. (10%) of pure α-phenylcinnamalacetic acid, faintly yellow crystals from benzene–ligroin, m. p. 186–187° alone or mixed with a sample prepared by the method of Thiele.[16]

Methyl Cinnamalacetate and *p*-Chlorobenzenediazonium Chloride.—A mixture containing 0.17 mole of each of the reactants, 0.16 mole of sodium acetate, 5 g. of cupric chloride, and the necessary solvents began to evolve gas at 15°, and the reaction was complete after two hours. There was obtained 53 g. of a dark oily product from which no pure substance could be isolated directly. Eighteen grams of this oil was allowed to stand with 15 g. of potassium hydroxide in 120 ml. of methanol, and the potassium salt which had separated after thirty minutes was removed. This salt yielded 4.4 g. of cinnamalacetic acid. The solution was allowed to stand for twelve hours and then acidified. The resulting sticky acid was dissolved in 50 ml. of hot concd. aqueous sodium carbonate. The sodium salt which separated when the solution was cooled was washed with ether, then dissolved in water and decomposed, giving 1.7 g. of **α-(*p*-chlorophenyl)-cinnamalacetic acid**, faintly yellow needles from acetic acid, m. p. 233–234°.

Anal. Calcd. for $C_{17}H_{13}ClO_2$: C, 71.8; H, 4.6. Found: C, 72.0; H, 5.0.

Sorbic Acid and Benzenediazonium Chloride.—A solution prepared from 0.125 mole of aniline, 0.375 mole of hydrochloric acid, and 0.125 mole of sodium nitrite was added to a mixture containing 0.1 mole of sorbic acid,[18] 0.2 mole of sodium acetate, 5 g. of cupric chloride, and 160 ml. of acetone. Nitrogen was evolved at 0°, and the reaction was complete after two and one-half hours. Steam distillation gave 3.8 g. (26%) of 1-phenylpentadiene-1,3, b. p. 118–124° at 24 mm.; $n^{30}D$ 1.6002; $n^{25}D$ 1.6025 (reported[19] b. p. 116° at 16 mm.; n^{13} 1.6111). A sample of the hydrocarbon obtained in 57% yield by the method of Klages[20] boiled at 118–120° at 24 mm. and had a refractive index ($n^{25}D$) of 1.6010. Both samples of the hydrocarbon yielded an adduct with maleic anhydride, m. p. 157–158° (reported[21] 157–158°), alone or mixed.

Summary

It is suggested that aryl radicals arising from the decomposition of diazo acetates attack the C–C double bond of an α,β-unsaturated compound in such a way that the new radical formed will have

The Dissociation of Hexaarylethanes.[1] XV. Methoxyl Substituents

BY C. S. MARVEL, JOHN WHITSON AND H. W. JOHNSTON

Substitution of methoxyl groups for hydrogen atoms in the aryl rings of a hexaphenylethane has been reported[2] to lead to compounds which dissociate to a much greater extent than does the parent hydrocarbon. In all of these reports the degrees of dissociation were determined by cryoscopic molecular weight methods. In this paper we are reporting figures on the degrees of dissociation of certain methoxyl substituted hexaarylethanes determined by the magnetic susceptibility method.[3] Our values are much lower than those previously reported. All of the methoxyl substituted hexaarylethanes were found to be relatively unstable, and the change in magnetic susceptibility with the age of the solution showed that these radicals decompose quickly. The molecular weight determinations undoubtedly show too high values for the radical because of the presence of disproportionation products in the aged solution of the ethanes.

The ethanes which have been prepared and whose dissociations have been measured by the magnetic susceptibility method are listed in Table I. The dissociations reported are on benzene solutions and are calculated for 0.1 *M* solutions from the actual data measured at other concentrations.

TABLE I

DISSOCIATIONS OF VARIOUS METHOXYL SUBSTITUTED HEXAPHENYLETHANES

Ethane	α at 0.1 *M*, %	Reported dissociation, %	Ref.
Tetraphenyldi-*o*-anisyl	3.8 ± 1	26	2a
Tetraphenyldi-*m*-anisyl	2.6 ± 1		
Tetraphenyldi-*p*-anisyl	4.4 ± 1	24	2b
Diphenyltetra-*o*-anisyl	7.3 ± 1	40	2d
Hexa-*o*-anisyl	42 ± 5	100	2d
Hexa-*m*-anisyl	8.5 ± 1.5		

The ethanes with ortho- and para-methoxyl groups used in our work were made from triarylchloromethanes described by the earlier workers and the physical properties checked those reported and the analyses indicated the chlorides were pure. In general we used new reactions to produce our intermediates and brief descriptions of our processes are given. The *m*-methoxyl substituted ethanes are new but the carbinols have been described.[4] We have also used different methods for the preparation of these compounds but have found the properties to be identical with those previously reported.

The degrees of dissociation for these ethanes which we have determined by the magnetic susceptibility method are much nearer those which would be expected by comparison with other substituted ethanes studied in this Laboratory than were the older values. It has been rather generally observed that an ortho substituent has the most marked effect on dissociation and hexa-*o*-anisylethane is highly dissociated. The very low value for the dissociation of tetraphenyl-di-*o*-anisylethane is surprising yet the relative interference value of the methoxyl group as measured by the ease of racemization of ortho-substituted diphenyls[5] indicates that it has much less steric effect than a methyl group.

Experimental

Ethyl *m*-Methoxybenzoate.—One hundred grams of *m*-methoxybenzoic acid (m. p. 106°), 600 cc. of absolute ethyl alcohol, 150 cc. of thiophene-free benzene especially dried by distillation and 3 cc. of concentrated sulfuric acid were placed in a 1-liter round-bottomed flask. A 200-cc. Soxhlet extractor filled with anhydrous potassium carbonate was inserted between the flask and a reflux condenser whose top was connected to a calcium chloride tube. The contents of the flask were refluxed for twenty-four hours. After this the reaction mixture was filtered and the product was then distilled until all solvents boiling below 82° were removed. The residue, which contained the ester, was washed with 10% sodium hydroxide. The mixture formed an emulsion which was extracted with benzene. The benzene extract was washed with water and distilled from a modified Claisen flask. The yield was 75 g. (60%) of product which boiled at 130–135° (15 mm.).

Preparation of Triarylcarbinols.—The triarylcarbinols were prepared from the appropriate Grignard reagents and carbonyl compounds by the usual procedures using the forced conditions of Bachmann and Kloetzel.[6] The crude carbinols were obtained as viscous liquids and in some cases steam distillation was employed to purify the product of the reaction. In cases where the viscous oil could not be caused to crystallize it was converted directly into the corresponding chloromethane. All of these carbinols have been prepared previously but by more complex methods.

o-Anisyldiphenylcarbinol.—From 26 g. of magnesium, 172.5 g. of bromobenzene, and 45 g. of methyl *o*-methoxybenzoate there was obtained 53 g. (68%) of product; m. p. 128–129° recrystallized from absolute alcohol. Baeyer reported a melting point of 128–129°.[4a]

This compound was also prepared from the reaction of 8 g. of magnesium with 63 g. of *o*-bromoanisole, and the subsequent addition of 61 g. of benzophenone; the yield was 92 g. (95%).

Phenyldi-*o*-anisylcarbinol.—From 25.7 g. of magnesium, 200 g. of *o*-bromoanisole and 75 g. of ethyl benzoate there was obtained 105 g. (66%) of product; m. p. 115–116°, recrystallized from a mixture of ligroin and ethyl acetate. Baeyer reported a melting point of 115°.[4a]

Tri-*o*-anisylcarbinol.—From 40.5 g. of magnesium, 323 g. of *o*-bromoanisole, and 59 g. of diethyl carbonate there was recovered 157.5 g. (90%) of product. The carbinol was highly insoluble in organic solvents; glacial acetic acid was the most suitable solvent for recrystallization; m. p. 181°. Baeyer and Villiger reported the melting point as 181°.[4b]

m-Anisyldiphenylcarbinol.—From 28 g. of magnesium, 185 g. of bromobenzene and 72 g. of ethyl *m*-methoxybenzoate there was obtained 110 g. (95%) of product which melted at 88° after recrystallization from a mixture of ligroin and ethyl acetate. Baeyer reported a melting point of 88°.[4a]

Tri-*m*-anisylcarbinol.—From 25.7 g. of magnesium, 200 g. of *m*-bromoanisole and 39.3 g. of diethyl carbonate there was obtained 57.5 g. (56%) of product having a melting point of 119° after recrystallization from benzene followed by a second recrystallization from absolute ethanol. Baeyer and Villiger reported a melting point of 119.5°.[4b]

p-Anisyldiphenylcarbinol.—From 15 g. of magnesium, 118 g. of *p*-bromoanisole and 91 g. of benzophenone there was obtained 101 g. (70%) of product. The carbinol was difficult to crystallize. Crystallization was induced by dissolving the oily product in ether and adding low-boiling petroleum ether to the point of turbidity. After several recrystallizations the carbinol had a melting point of 60°. Baeyer and Villiger have reported a melting point of 58–61°[4b] and later also reported a melting point of 84°.[7] Kauffmann and Pannwitz obtained a melting point of 84°[8] and Gomberg and Buchler reported 82°.[9] The compound can evidently exist in two crystalline modifications.

Triarylchloromethanes.—The chloromethanes were prepared from the pure crystalline carbinols. The carbinol was dissolved in dry benzene, excess acetyl chloride[10] was added, and the solution refluxed for several hours. The excess acetyl chloride was removed under reduced pressure and the crude chloromethane crystallized out on standing at 5°. The chloromethanes were hydrolyzed readily by moisture and the usual precautions were observed to avoid decomposition of the products in moist air. All of the crude chloromethanes were recrystallized to constant melting point and the emphasis of each experiment was on obtaining a pure compound rather than maximum yield. The new chloromethanes are listed in Table II and the appropriate solvent used for recrystallization of the crude product is indicated.

TABLE II

METHOXYSUBSTITUTED TRIPHENYLCHLOROMETHANES

Magnetic Susceptibility Measurements.—The hexaarylethanes were prepared in the apparatus previously described,[3,11] for magnetic susceptibility measurements. Dissociation measurements were made on 0.1 *M* benzene solutions except in certain experiments in which the ethane was found to be insoluble in 0.1 *M* benzene. More dilute solutions were used and the dissociation values were calculated back to 0.1 *M* by use of the mass law.[12] Measurements were made over varying periods of time to check stability of the ethanes. Ethanes carrying methoxy groups were found to undergo slow decomposition on standing twenty-four hours. A decomposition of 40% was estimated for diphenyl-tetra-*o*-anisylethane over a twenty-four hour period. It was interesting to note that solutions of tri-*o*-anisylchloromethane when cooled to −70° during the preparation of the ethane solidified to a purple ice. The original colorless benzene solution was obtained upon warming to room temperature. Other chloromethanes of this series did not show this phenomenon. The chloromethane and the corresponding ethane were insoluble in 0.1 *M* benzene solution and heat was necessary to dissolve the chloromethane in benzene to make up a 0.05 *M* solution.

The experimental data are summarized in Table III.

TABLE III

EXPERIMENTAL DATA ON MAGNETIC SUSCEPTIBILITY

Ethane	% in benzene	Molarity	$-\chi$ Sol. 10^6	α% (observed)
Tetraphenyldi-	6.199	0.1	0.6938	3.8
o-anisyl	3.118	.05	.6988	5.32
Tetraphenyldi-	6.18	.1	.7001	2.1
m-anisyl	6.14	.1	.6959	3.1
Tetraphenyldi-	6.20	.1	.6900	5.2
p-anisyl	3.06	.05	.6982	5.8
	6.21	.1	.6944	3.8
Diphenyltetra-	6.9	.1	.6842	6.8
o-anisyl	7.0	.1	.6806	8.0
	6.9	.1	.6835	7.0
Hexa-*o*-anisyl	1.9	.025	.6638	60
	3.75	.05	.6332	52
Hexa-*m*-anisyl	3.8	.05	.6920	9.4
	7.5	.1	.6750	10

Peroxides.—Exposure of the fresh solutions from the magnetic susceptibility measurement to air produced the peroxides except in the case of diphenyltetra-*o*-anisylethane. In this case we isolated a product which melted at 114–116°, whereas the diphenyl-di-*o*-anisylcarbinol melts at 115° and a mixed melting point was found to be 113–115°. Bowden has reported[2e] the peroxide as melting at 110°. It is possible that our chloromethane hydrolyzed for some reason and that our dissociation value on this ethane is too low.

The *m*-anisyl derivatives gave new peroxides which were isolated and purified in the standard manner.

Summary

Redetermination of the degrees of dissociation of methoxyl substituted hexaarylethanes by the magnetic susceptibility method has shown that the values in the literature determined by cryoscopic molecular weight values are too high due to the instability of these ethanes. The new values show that the *o*-methoxyl group is much less effective than the *o*-methyl group in causing dissociation. In the *m*- and *p*-positions the methoxyl groups are also somewhat less effective than methyl groups but the difference is less marked.

The Action of Formaldehyde on *m*-Hydroxybenzoic Acid. I

BY C. A. BUEHLER, TROY A. POWERS[1] AND JULIAN G. MICHELS[2]

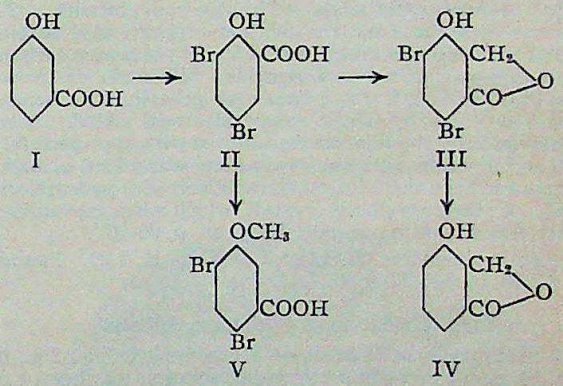
This study is one of a series[3] dealing with the action of formaldehyde on substituted phenols in hydrochloric acid solution. At room temperature *m*-hydroxybenzoic acid produces chiefly two compounds melting at 175 and 254°. The latter is the subject of this investigation. This compound, of formula $C_8H_6O_3$, contains a hydroxyl group since it gives unsaponifiable methoxy and ethoxy derivatives, and an acetyl derivative. In addition, the presence of a phthalide ring is indicated by the fluorescence which develops with resorcinol and sulfuric acid.

Of the possible structures, 4-hydroxy- or 6-hydroxyphthalide, for the condensation product, the latter is ruled out since the melting points of our product and of its methoxy and ethoxy derivatives do not agree with those of the known 6-hydroxyphthalide and its known methoxy and ethoxy derivatives. Indirectly, then, the structure of our compound corresponds to that of 4-hydroxyphthalide.

Direct methods for proving the structure were:

1. Oxidation of the methoxy derivative with dilute potassium permanganate produced the known 3-methoxyphthalic acid, which in turn with methyl alcohol and hydrogen chloride gave the known dimethyl 3-methoxyphthalate.

2. It was found possible to synthesize 4-hydroxyphthalide by blocking the reactive positions (those *o*- or *p*- to the hydroxyl) with the exception of 2-, then introducing the phthalide ring and finally removing the blocking groups. This synthesis was accomplished by brominating *m*-hydrobenzoic acid, I, in glacial acetic acid solution to give 4,6-dibromo-3-hydroxybenzoic acid, II. Although the structure of this acid was arrived at by analogy by Coppadoro,[4] we confirmed its structure by conversion into the known 4,6-dibromo-3-methoxybenzoic acid, V. On treatment of II with methylal, hydrochloric and sulfuric acids, 4-hydroxy-5,7-dibromophthalide, III, was obtained. The latter could not be debrominated with sodium and ethyl or amyl alcohols, or with zinc and alcoholic potassium hydroxide, but on hydrogenation under pressure with Raney nickel at a temperature of 150–200°, it gave 4-hydroxyphthalide, IV, identical with the original condensation product.



It is interesting to note that the orientation in this condensation is similar to that which occurred at low temperatures in the case of *m*-nitrophenol,[5] in that the entering group takes the position ortho to the two substituents.

Experimental

I. Preparation of 4-Hydroxyphthalide.—*m*-Hydroxybenzoic acid, m. p. 200–201°, 25 g., was dissolved in 500 cc. of 40% U. S. P. formaldehyde, and 500 cc. of concentrated hydrochloric acid and 25 cc. of concentrated sulfuric acid were added. The solution was stirred at 30–40° in a three-necked, round-bottomed flask, equipped with a mercury-sealed stirrer, a thermometer, and a glass tube with an opening of about 1 mm. in diameter leading to the bottom of the flask for introducing dry hydrogen chloride. Any excess of hydrogen chloride was removed through an exhaust tube, in the side arm of the flask opposite to the one containing the inlet, attached to an aspirator pump. After the introduction of hydrogen chloride gas for two hours, followed by cooling in the refrigerator, the precipitate which had formed was filtered off and crystallized once from water to give 6 to 8 g. of white crystals, m. p. 254°. Dilution of the filtrate with water to twice its volume and then standing overnight in the refrigerator gave more crystals, which when crystallized twice from water weighed 6 to 8 g. and melted at 175°.

The first crystals produced a fluorescence when heated with resorcinol and sulfuric acid, but there was no color

with ferric chloride, no precipitate with alcoholic silver nitrate, no indication of the presence of a dioxane ring with phloroglucinol and sulfuric acid, and attempts to esterify with several alcohols were unsuccessful.

Anal. Calcd. for $C_8H_8O_3$: C, 64.00; H, 4.03; neut. equiv., 150. Found: C, 63.94, 63.68; H, 4.24, 4.14; neut. equiv. (indirect), 151, 150.

(a) **4-Methoxyphthalide.**—The hydroxyphthalide, 3 g., was treated in the usual manner with an excess of 10% sodium hydroxide solution and an excess of dimethyl sulfate. After warming for thirty minutes, the solution was acidified with hydrochloric acid and cooled. The solid, which separated, was crystallized three times from water to give 1.3 g., m. p. 127°.

Anal. Calcd. for $C_9H_8O_3$: C, 65.85; H, 4.91; OCH_3, 18.91; mol. wt., 164. Found: C, 65.58, 65.75; H, 4.80, 4.67; OCH_3, 18.54, 18.55; mol. wt. (cryoscopic, benzene), 166, 166.

(b) **4-Ethoxyphthalide.**—4-Hydroxyphthalide, 2 g., in 100 cc. of 10% sodium hydroxide solution was treated with 5 cc. of diethyl sulfate in the usual manner. The product, thrice crystallized from ethanol–water, weighed 1.8 g., m. p. 170°.

Anal. Calcd. for $C_{10}H_{10}O_3$: C, 67.40; H, 5.66; neut. equiv., 178. Found: C, 67.52, 67.40; H, 5.72, 5.60; neut. equiv. (indirect), 179, 179.

(c) **4-Acetoxyphthalide.**—The hydroxyphthalide, 2.3 g., was acetylated by the method of Pratt and Robinson[6] in which it was mixed with 2.5 g. of potassium carbonate and 6.4 cc. of acetic anhydride. When the first reaction had subsided, 1.3 g. more of potassium carbonate and 5 cc. more of acetic anhydride were added. After thirty minutes the mixture was diluted with approximately 100 cc. of water, potassium carbonate was added in slight excess and then the solution was acidified with hydrochloric acid. Cooling produced crystals, which when crystallized three times from water gave 1.4 g., m. p. 96–97°.

Anal. Calcd. for $C_{10}H_8O_4$: C, 62.50; H, 4.20. Found: C, 62.50, 62.54; H, 4.50, 4.48.

II. Oxidation of 4-Methoxyphthalide

3-Methoxyphthalic Acid.—4-Methoxyphthalide, 2 g., in 200 cc. of *N* potassium hydroxide solution was heated to 60–70° for one hour and then potassium permanganate solution (2 g. in 200 cc. of water) was added gradually during one and one-half hours. The reaction mixture was held at 75° for another hour and one-half, after which the excess permanganate was removed with sodium bisulfite. Filtration removed the manganese dioxide and the filtrate, upon being acidified with hydrochloric acid and evaporated to one-third its volume, was extracted with ether. The solid obtained on evaporation was taken up in water and the solution was made basic with sodium bicarbonate and then filtered. The filtrate was again acidified, evaporated to dryness, and the residue was leached with ether. Evaporation gave a product which was crystallized twice from benzene–ethanol solution (10:1), norite having been used the first time, to yield 0.5 g., m. p. 167–168° (Bentley, Robinson and Weizmann[7] give 173–174°).

Anal. Calcd. for $C_9H_8O_5$: C, 55.11; H, 4.10. Found: C, 55.11, 55.34; H, 4.29, 4.22.

Dimethyl 3-Methoxyphthalate.—A solution of the acid, 1 g. in 10 cc. of ethanol and 140 cc. of ether was cooled to 5° and diazomethane was added until a yellow color appeared. The ester was recovered in the usual manner, washed with sodium bicarbonate solution, then with water and finally crystallized from ethanol several times by the addition of water. The pure product, 0.8 g., melted at 73–74° (Onnertz[8] gives 71°).

Anal. Calcd. for $C_{11}H_{12}O_5$: C, 58.92; H, 5.39. Found C, 59.40, 59.52; H, 5.32, 5.40.

III. Synthesis of 4-Hydroxyphthalide

3-Hydroxy-4,6-dibromobenzoic Acid (II).—This acid was prepared by the method of Robertson.[9] Sixty-nine g. (0.5 mole) of *m*-hydroxybenzoic acid dissolved in a minimum amount of glacial acetic acid at 50° was treated with 77 cc. (1.5 moles) of bromine and the solution was allowed to stand at 50° for two hours. Cooling in the refrigerator gave crystals, which when crystallized from water amounted to 36 g. Three additional crystallizations from water gave a product melting at 198–199° (Robertson gives 201–202°).

Anal. Calcd. for $C_7H_4Br_2O_3$: Br, 54.01. Found: Br, 53.93, 53.98.

3-Methoxy-4,6-dibromobenzoic Acid (V).—The acid, 10 g., was dissolved in 10% sodium hydroxide solution of such an amount that the resulting solution was decidedly alkaline. Dimethyl sulfate in excess was added in the customary manner over a half hour period. About 10 cc. of 25% sodium hydroxide solution was then introduced and the solution was boiled for fifteen minutes. Acidification and cooling in the refrigerator gave a white, gelatinous mass. Solution in the minimum amount of boiling methanol, followed by the addition of water of an amount just short of that necessary to cause precipitation at the boiling point, and then slow cooling yielded white, fluffy crystals. Repetition of the above process twice more gave 6 g. (57%) of the acid, m. p. 205° (Hodgson and Beard[10] give 202–203°).

Anal. Calcd. for $C_8H_6Br_2O_3$: Br, 51.57; neut. equiv., 310. Found: Br, 51.34, 51.34; neut. equiv., 301, 304.

4-Hydroxy-5,7-dibromophthalide (III).—The dibromo acid, 26.8 g., dissolved in 250 cc. of methylal, was treated with 400 cc. of concentrated hydrochloric acid and 12 cc. of concentrated sulfuric acid. Hydrogen chloride was bubbled through this solution at 50–55°, with stirring, for six hours, after which the reaction mixture was diluted to two liters with water and cooled. The white crystalline product which formed was crystallized three times as described above by solution in the minimum amount of methanol followed by the addition of water. Final product, 16.9 g. (60%), m. p. 146°, gave a fluorescence with resorcinol and sulfuric acid, but it reacted negatively toward ferric chloride and alcoholic silver nitrate.

Anal. Calcd. for $C_8H_4Br_2O_3$: Br, 51.90. Found: Br, 52.18, 52.00, 51.86.

4-Hydroxyphthalide (IV).—The dibromophthalide, 1 g., in absolute ethanol with 0.5 g. of Raney nickel was shaken with hydrogen at 150–200° and 500 lb. pressure for three hours. The product recovered on evaporating the ethanol was crystallized twice from water to give 0.2 g. (41%), m. p. 254°. A mixed melting point with the original condensation product showed no depression.

Anal. Calcd. for $C_8H_6O_3$: C, 64.00; H, 4.03. Found: C, 63.78, 63.99; H, 4.35, 4.32.

Summary

At room temperature one of the products of the condensation of formaldehyde and *m*-hydroxybenzoic acid in acid medium is 4-hydroxyphthalide.

Although the structure of this phthalide may be inferred by indirect means, it has been established by oxidative and synthetic methods.

Isolation of Partheniol, Parthenyl Cinnamate, and Other Constituents from Guayule Resin[1]

BY E. D. WALTER

In the program conducted in this Laboratory on the isolation and improvement of quality of rubber from guayule, *Parthenium argentatum* Gray, retting by aerobic microbiological decomposition to reduce the resin content received considerable attention. For the retting experiments it was of interest to know the chemical constituents of the resin and whether they were altered by retting. This paper describes some of the constituents isolated from the acetone extracts (considered to be resin) of the whole shrub, the foliage, the rubber from the unretted and the retted shrub and also from the resin exuded from the shrub.

A crystalline ester, which hyrolyzes to give cinnamic acid, and a crystalline sesquiterpene alcohol were obtained from the exuded resin and from an acetone extract of the rubber. Since the literature reveals no compounds identical with the ester or the alcohol, the name *partheniol* is proposed for the sesquiterpene alcohol and *parthenyl cinnamate* for the ester. Other constituents were obtained, in small amounts, which have not been definitely identified.

In 1911 Alexander[2] investigated the acetone-soluble constituents and ethereal oils derived from the guayule plant. He obtained an acid melting at 119°, which he thought belonged to the cinnamic series, and mentioned a private communication from R. Weil, who said he had found cinnamic acid in the saponification products of guayule resin. By prolonged steam distillation of the acetone extract of guayule wood, Alexander also obtained a crystalline substance melting at 127–28°, which he thought was a sesquiterpene alcohol. By distillation of the ethereal oils, he obtained two fractions. The first was characterized as pinene and the second was thought to be a sesquiterpene, $C_{15}H_{24}$, but efforts to identify it with any known sesquiterpene failed. Alexander mentioned that his sesquiterpene alcohol changed to a liquid on long standing. This tendency was also observed with *partheniol* and seems to be characteristic of the sesquiterpene tertiary alcohols described by Simonsen[3] under alcohols of unknown constitution, such as cedrol and ledol.

Experimental

Parthenyl Cinnamate.—The sticky balsam-like exudate from injured roots and bark of two-year old shrubs was collected with a penknife. The material was dissolved in ether and filtered, and the ether evaporated. At this stage the product resembled Canada balsam in appearance and had $n^{20}D$ 1.537, acid number 0.94, saponification number 34.5, iodine number 150. When 80% ethanol was added to this material until turbidity appeared and then allowed to stand for several days, a white crystalline substance separated. Recrystallization from acetone gave tetragonal crystals (Fig. 1), melting at 125–126°, with a yield of about 20% of the whole resin. This substance, named *parthenyl cinnamate*, is insoluble in water but soluble in organic solvents. Saponification of this substance with alkali in ethanol solution yields *partheniol* and cinnamic acid.

Anal. Calcd. for $C_6H_5CH{=}CHCO_2C_{15}H_{25}$: C, 81.81; H, 9.09; mol. wt., 352. Found: C, 81.97, 81.97; H, 8.97, 8.92; mol. wt. (Rast), 353 (saponification equivalent, 354); $[\alpha]^{24}D$ 61.6° ($CHCl_3$, c = 4.752).

This substance also was isolated from concentrated acetone extract of guayule rubber, supplied by the Rubber Laboratory, Navy Yard, Mare Island, California. After the extract had stood for about a month, crystals of parthenyl cinnamate (Fig. 1) were found throughout the sticky mass. On centrifuging, the yield of crystals contaminated with mother liquor was about 20% of the total. Pure crystals were obtained by clarification with Nuchar followed by recrystallization from acetone solution, the yield being about 5% of the extract.

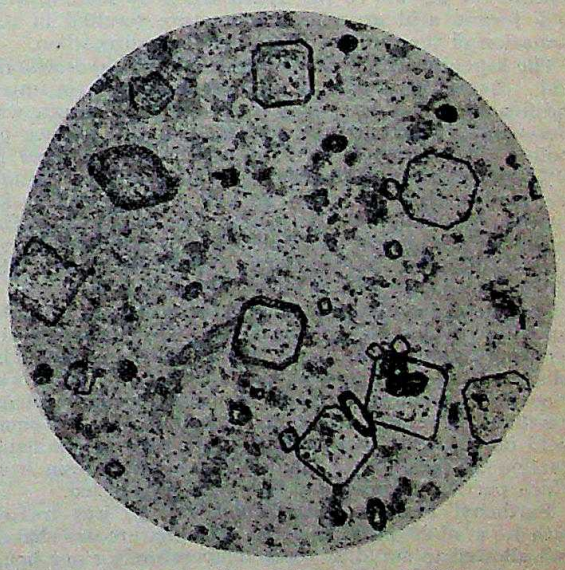

Fig. 1.—Parthenyl cinnamate (×30).

Partheniol.—The crystalline ester (0.56 g.) was saponified with 25 cc. of a saturated solution of potassium hydroxide in 95% ethanol. The excess alcohol was distilled, and the mixture was diluted with water and extracted with petroleum ether. The petroleum ether was removed, and the residue, when heated on the steam-bath in a beaker covered with a watch glass, yielded long silky crystals subliming and festooning the inside of the beaker. Repeated tufts of crystals were collected over a period of several days. The resublimed crystals (Fig. 2) melted at 131°; yield, 0.06 g. of partheniol from 0.56 g. of ester. It had a delicate terpene odor and was slightly soluble in hot water and very soluble in organic solvents. It may

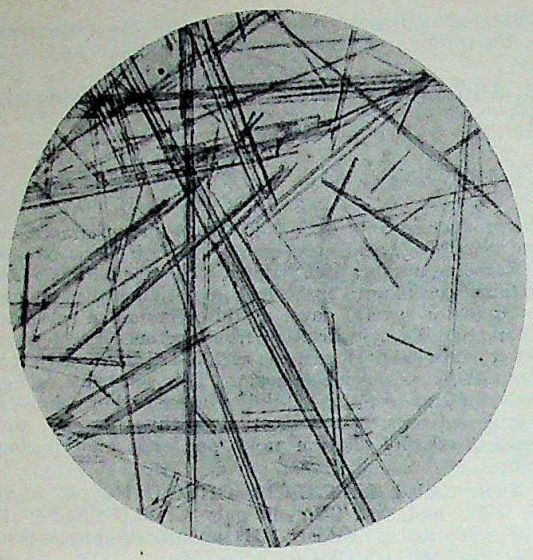

Fig. 2.—Partheniol (×100).

be obtained by steam distillation of the saponification mixture and crystallization in the aqueous distillate.

Anal. Calcd. for $C_{15}H_{26}O$: C, 81.08; H, 11.71; hydroxyl, 7.65; mol. wt., 222. Found: C, 81.17, 81.48; H, 11.39, 11.10; hydroxyl, 7.62, 7.65; mol. wt. (Rast), 233; $[\alpha]^{24}D$ 88.7 ($CHCl_3$, c = 1.566).

Attempts to prepare the phenylurethan or the 3,5-dinitrobenzoate were unsuccessful. An attempt to dehydrate the alcohol to the hydrocarbon by shaking with 90% formic acid at room temperature resulted in the formation of the formate instead of the hydrocarbon.

The saponified fraction was acidified with hydrochloric acid. A tarry substance, as yet uncharacterized, separated and floated. This was partly filtered, and the filtrate was concentrated until crystals appeared on the surface on cooling. The crystals were separated and dissolved in 50% ethanol and clarified with Nuchar. When recrystallized and dried, they melted at 133°. The phenacyl derivative was prepared, and this melted at 140.5°. The conclusion that it was cinnamic acid was confirmed by an X-ray diffraction pattern from the powdered crystals, which agreed with that of known cinnamic acid.

Partheniol and cinnamic acid also were isolated from the saponification products of the acetone extracts of the rubber from retted shrubs, from whole shrubs, and from the foliage. The yield of partheniol from the rubber was about 2.5%, from the shrub about 2%, and from the foliage less than 1%, respectively, of the acetone extract. A small yield of partheniol was isolated from the unsaponifiable fraction of the mother liquor of the exuded resin from which parthenyl cinnamate had been crystallized.

Parthenyl Formate.—Partheniol, 0.7 g., was treated with 1.5 g. of 90% formic acid. The mixture was shaken and allowed to stand at room temperature for one hour. The acid was neutralized with sodium hydroxide, and the ester was extracted with ether. The alkali was removed by shaking the mixture with water and draining it off in a separatory funnel. The ether solution was dried with calcium chloride, and then the ether was evaporated. The product was a brown liquid, yield 0.6 g.; d^{25} 0.941; b. p. 215° (dec.) at 755 mm.; $n^{25}D$ 1.503.

Anal. Calcd. for $HCO_2C_{15}H_{25}$: C, 76.80; H, 10.40; mol. wt., 250. Found: C, 76.65, 76.49; H, 10.11, 9.93; mol. wt. (saponification equivalent), 250.

Crystallographic Optical Properties

When crystallized from the concentrated acetone extract from guayule rubber parthenyl cinnamate (Fig. 1) appears as tetragonal tablets and bipyramids. In convergent polarized light (crossed nicols), uniaxial interference figures are common. When crystallized from 80% ethanol the crystals appear more fragmented but the same interference figures are observed. The optic sign is positive. On fragments showing a well-centered uniaxial figure, $n\omega$ = 1.550. On fragments showing red interference color, $n\epsilon$ > 1.64 (the substance was soluble in the higher index liquids available).

Sublimed crystals of partheniol appear as very long orthorhombic lathlike prisms (Fig. 2). In parallel polarized light (crossed nicols) the extinction is parallel; the elongation is negative. All crystals extinguish rather sharply and no clear interference figures are found in convergent polarized light. Lengthwise $n\alpha$ = 1.538; across the elongation $n\gamma$ = 1.590; $n\beta$ = indet.

Wax-like Substance.—The air-dried foliage (1500 g. of leaves and flowering stems) was ground in a Ball and Jewell mill to $^1/_{16}$-inch size and extracted with warm acetone in a Soxhlet type extractor for thirty-two hours. The extract was cooled before being concentrated and on standing overnight deposited fine crystalline material. Recrystallization from either ethanol or acetone gave tiny white crystals melting at 76°; yield, 3.73 g. or about 0.25% of the foliage or about 3 to 4% of the acetone extract (resin). It was soluble in organic solvents, but insoluble in water and in concentrated sulfuric acid. It dissolved slowly in fuming sulfuric acid, forming a brown solution. It did not absorb bromine.

Anal. Found: C, 80.18; H, 13.25; saponification number, 74.4; mol. wt. (Rast), 597.

The same substance was obtained in lower yields from acetone extracts of the whole shrub and from rubber from both retted and unretted shrubs. Attempts to identify it with any known substance have not been successful.

Volatile Oil.—Steam distillation of acetone extract of guayule rubber gave a volatile oil, $n^{25}D$ 1.4938, $[\alpha]^{25}D$ −17.92°, b. p. 244–245° at 750 mm. Attempts to prepare a nitrosochloride or a bromide of this material failed. It is probably a mixture of sesquiterpenes.

Products of Vacuum Distillation of Acetone-Extracted Resin.—Distillation of 650 g. of resin in a Fenske column yielded about 80 g. of liquid between 28° and 17 mm. and 162° and 26 mm. A greenish solid was collected between 170° and 25 mm. and 202° and 4 mm. The major part of this fraction proved to be cinnamic acid.

The liquid fraction was redistilled in a short Fenske column at a pressure of about 1 mm. No constant boiling temperature was attained, but cuts were made between 70 and 78°, 78 and 81°, and 82 and 90°. The lower boiling fraction had $n^{24}D$ 1.4850 and $[\alpha]^{22}D$ −10.5° (1-dm. tube). The intermediate fraction had $n^{24}D$ 1.4952 and $[\alpha]^{22}D$ −9.17° (1-dm. tube); b. p. 244–245° at 755 mm. The higher boiling fraction had $n^{24}D$ 1.4995 and $[\alpha]^{22}D$ −6.84; b. p. 246–247° at 755 mm. *Anal.* of the higher boiling fraction: Calcd. for $C_{15}H_{24}$: C, 88.23; H, 11.76; found: C, 87.59, 87.40; H, 11.17, 11.09. Since no partheniol was obtained in these distillates and cinnamic acid was obtained, it appears that the alcohol was dehydrated in the process and appeared in these fractions as the sesquiterpene, $C_{15}H_{24}$, the higher boiling fraction being the least contaminated.

Discussion

Since parthenyl cinnamate, partheniol, and cinnamic acid were isolated from the whole shrub, from the foliage, and from rubber from both the retted and the unretted shrub, it is obvious that the acetone extracts from all of these are qualitatively similar. The foliage extract, of course, contains more chlorophyll and more wax-like material than that from the whole shrub or

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

from the rubber. No wax-like material was found in the exuded resin, and since this is practically free of chlorophyll it might be considered as the true guayule resin. About 20% of the exuded resin was parthenyl cinnamate. The acetone extract of the rubber also yielded roughly 20% of crude parthenyl cinnamate.

Acknowledgment.—The author is indebted to the Rubber Laboratory, Navy Yard, Mare Island, California, for a supply of acetone extract of guayule rubber and to Dr. C. L. Ogg and assistants of the Microanalytical Laboratory for the analyses reported.

Summary

1. *Partheniol*, a new sesquiterpene alcohol, and *parthenyl cinnamate* were isolated from guayule resin, and some of their properties, including crystallographic optical properties, are described.

2. A crystalline waxlike substance and several fractions of volatile oils, probably sesquiterpenes, were prepared from acetone extracts of whole shrub, guayule foliage, and guayule rubber.

3. Retting of the shrub appears to make no change in the relative proportions of the constituents isolated from the resin.

Allylic Rearrangements. XIV. The Hydrolysis of Butenyl Chlorides[1]

BY WILLIAM G. YOUNG AND LAWRENCE J. ANDREWS

Recent work[2] on nucleophilic replacement reactions of allylic systems of the type  or  indicates that bimolecular or S_N2 reactions produce unrearranged products (Equation 1). Unimolecular or S_N1 type reactions, involving an unfree carbonium ion intermediate, lead to a mixture of allylic isomers (Equation 2)

(1) 
(2) 
The relative contributions of types (1) and (2) in a given reaction are readily influenced by the experimental conditions. With this in mind it was desirable to examine critically the apparently conflicting reports in the literature concerning the hydrolysis of alkenyl halides.[3] For example, halides of the type are reported to give primary alcohol, mixtures of alcohols or the pure allylic isomer,  . Although reaction (1) would account for the production of pure normal product and reaction (2) would give a mixture due to the formation of a resonating carbonium ion intermediate, neither (1) nor (2) should give a pure secondary alcohol from a pure primary halide.

The present investigation has been undertaken to show that under controlled conditions it is possible to account for the products of hydrolysis of the butenyl chlorides[4] in terms of the mechanisms given above. Reaction conditions were varied from those favorable to S_N1 type hydrolysis to those suitable for a bimolecular type (S_N2) reaction of the organic halide with hydroxide ion. From a consideration of the composition of the alcohols produced in these reactions (Table I) it was possible to compare the relative contributions of the S_N1 and S_N2 type processes to the hydrolysis of the two halides. The correctness of the estimated contributions of the mechanisms to these hydrolyses has been demonstrated by an investigation of the kinetics of the reactions.

The Products of Hydrolysis of the Butenyl Chlorides.—The reactions with silver oxide were studied to determine the composition of

	Secondary	97	60.9		39.1		43

[a] All reactions were carried out at room temperature. [b] The designations primary and secondary are used for the crotyl and methylvinylcarbinyl radicals, respectively. [c] Yields are based on butenyl chloride assuming complete reaction. [d] This crotyl alcohol contains some *cis* isomer.

alcohols to be expected from the solvolytic (S_N1) type reaction. In this case both chlorides gave a predominance of secondary alcohol, 55% from the primary chloride and 66% from the secondary chloride. It might be expected that the same mixture of alcohols should be obtained from both chlorides in an S_N1 type process. This difference in composition of alcohols arising from the unfree carbonium ion[2a] probably should be attributed to the polarizing influence of the chloride ion on the carbon atom from which it is being removed rather than to contributions of a bimolecular type. The low solubility of silver oxide would leave little opportunity for a bimolecular reaction with hydroxide ion, and the rate of reaction was far too rapid to allow for bimolecular reaction of the organic halide with solvent.

The other experiments were designed to increase the opportunity for a bimolecular reaction with hydroxide ion either by raising the hydroxide ion concentration or by decreasing the solvating power of the medium. In every case the composition of the butenols from the secondary chloride was close to that obtained in the runs with silver hydroxide. Aqueous sodium carbonate gave 65% secondary alcohol; aqueous sodium hydroxide gave 62% secondary alcohol. It thus appeared that the secondary chloride was not affected by conditions designed to promote the S_N2 reaction and instead reacted by an S_N1 process The primary chloride responded readily to conditions favoring the bimolecular reaction giving larger amounts of unrearranged product than obtained with silver oxide.

Additional evidence that a bimolecular reaction was being brought into play during the hydrolysis of the primary chloride arose through the fact that the crotyl chloride used must have contained some *cis* isomer. The S_N1 type hydrolysis of either the primary or the secondary chloride gave only *trans*-crotyl alcohol from the resonating carbonium ion. Similarly it has been observed that only *trans*-crotyl alcohol is formed when the secondary alcohol is rearranged by strong acid to produce primary alcohol by means of the intermediate carbonium ion.[5] However, when the conditions favored the bimolecular hydrolysis of the primary chloride, both *cis* and *trans* primary alcohols were formed (see Table I). The formation of *cis*-crotyl alcohol must be attributed to a bimolecular reaction of *cis*-crotyl chloride with hydroxide ion. This is the first evidence that the primary chloride contains some of the *cis* isomer[6]; however previous investigators did not prepare their chloride by chlorination of butene mixtures.

The Rate Expressions for Organic Halide Hydrolysis.—The rate of hydrolysis of an organic halide may be expressed by equation (3)

$$\frac{dx}{dt} = k_1(a - x) + k_2(a - x)(b - x) \qquad (3)$$
$$\text{I} \qquad \text{II}$$

where a is the original concentration of organic halide, b the original concentration of hydroxide ion, and x the concentration of halide ion at time t. Term II represents the second order and bimolecular (S_N2) contribution to the rate. Term I does not necessarily represent only the S_N1 contribution to the reaction but also may account for any bimolecular reaction between the solvent and the halide which may occur. If term I disappears from the rate expression, a constant κ_2 equal to k_2, the specific second order rate constant, may be calculated by equation (4).

$$\kappa_2 = \frac{1}{t(a - b)} \ln [b(a - x)]/[a(b - x)] \qquad (4)$$

Similarly when only a first order reaction proceeds, κ_1 equal to k_1, the specific first order rate constant, is calculated by equation (5).

$$\kappa_1 = \frac{1}{t} \ln \frac{a}{a - x} \qquad (5)$$

(5) Young, Warner and Andrews, unpublished work.

(6) Gredy, *Bull. soc. chim.*, [5] 2, 1029 (1935), found only the *trans* isomer by measurement of the Raman spectrum of crotyl chloride prepared from methylvinylcarbinol and phosphorus trichloride.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

In the event that first and second order reactions occur simultaneously values calculated for κ_1 and κ_2 during a run will show serious drifts.

Kinetic Studies of Butenyl Chloride Hydrolysis.—To verify the assumptions that the secondary chloride was hydrolyzed only by the S_N1 type reaction while the primary chloride could react by both S_N1 and S_N2 processes the kinetics of the hydrolysis of the butenyl chlorides were studied. The rate runs were made at 25.00° using dilute solutions of the halide and sodium hydroxide in approximately fifty volume per cent. aqueous ethanol.

As was expected, the rate of reaction of methylvinylcarbinyl chloride was independent of hydroxide ion over a range of 0.0 to 0.2 *N* hydroxide ion concentration. A typical run is summarized in Table II. During any given run using primary chloride in the presence of hydroxide ion values of κ_1 drifted downward while those of κ_2 drifted upward. This indicates that both first and second order reactions contribute to the total rate as was expected. Values of k_1 and k_2 were obtained by plotting x against t to obtain values of dx/dt at any time t. A plot of $(dx/dt)/a - x$ against $b - x$ gives a straight line according to equation (3). The slope of this line is k_2, and the intercept at $b - x$ equals zero is k_1. The values of k_2 and k_1 obtained from several runs in which the halide and sodium hydroxide concentrations were varied are in good agreement. The small variations in the rate constants may be the result of salt effects. The values of k_1 are also in good agreement with that obtained from a run in which no sodium hydroxide was used and the rate constant was calculated from equation (5). The rate constants for the hydrolysis of the primary and secondary chlorides are summarized in Table III.

It appears that the primary chloride reacts by a bimolecular process much more readily than does the secondary chloride. To demonstrate further this difference in reactivity of the primary and secondary chlorides toward S_N2 type replacements a few rate runs were carried out with alcoholic sodium ethoxide in a manner similar to that previously described.[2a] The rate constants calculated from equation (4) are summarized in Table IV.

THE REACTION OF BUTENYL CHLORIDES IN ALCOHOLIC SODIUM ETHOXIDE SOLUTION

Butenyl chloride	Temp., °C.	(Butenyl chloride) = a a	(NaOEt) = b b	κ_2 hours^{-1} g. mole^{-1} l.
Secondary	40.00	0.1984	0.2110	0.0225
Secondary	40.00	.1984	.0937	.0276
Secondary	25.00	.1979	.2073	.00363
Primary	25.00	.2051	.2694	.201

At 25° the ratio of κ_2 for the primary chloride to that of the secondary chloride is 55/1. The effect of halving the sodium ethoxide concentration in the runs at 40° with the secondary chloride was to cause a 23% increase in the rate constant. This may be due to salt effects.

The Nature of the Solvolytic Reactions of the Butenyl Chlorides.—It is interesting to note that the first order constant for the hydrolysis of the primary chloride ($k_1 = 0.0532$) is slightly higher than that for the secondary chloride ($k_1 = 0.0411$). Similarly the first order constant for the solvolysis of the primary chloride in absolute ethanol at 25° ($\kappa_1 = 2.20 \times 10^{-4}$ hr.$^{-1}$) was found to be of the same magnitude as that for the secondary chloride at 40° ($\kappa_1 = 2.11 \times 10^{-4}$ hr.$^{-1}$). These facts are contrary to the usual observation that primary chlorides react much more slowly by an S_N1 type process than do secondary chlorides. It seemed quite possible, therefore, that the first order reaction of the primary chloride might be in part a bimolecular reaction with solvent giving rise to normal product, as represented by equation (6).

$$\begin{array}{l} R{-}\underset{\displaystyle H}{\underset{|}{O}} + Cl{-}CH_2{-}CH{=}CH{-}CH_3 \longrightarrow \\ \qquad\qquad R{-}\overset{+}{\underset{\displaystyle H}{\underset{|}{O}}}{-}CH_2{-}CH{=}CH{-}CH_3 + Cl^- \end{array} \quad (6)$$

It seemed like that in alcoholic solution, which is a poorer solvating medium than water, the primary chloride solvolysis might be completely bimolecular. This was found to be true when the primary chloride was refluxed with 90% aqueous ethanol in the presence of calcium carbonate giving a product containing at least 95.6% crotyl ethyl ether. It is, therefore, probable that the formation of normal product in the hydrolysis of the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

primary chloride in dilute basic media must result, in part, from a bimolecular reaction with solvent.

The Validity of Previously Reported Work.—The present investigation has shown that methylvinylcarbinyl chloride is hydrolyzed in dilute basic media by a first order process giving rise to a mixture of alcohols. Crotyl chloride reacts by a mixed first and second order process to give mixtures of alcohols, but the relative amount of normal product may be increased by raising the base concentration. In agreement with these findings are several reports in the literature that primary or secondary allylic halides hydrolyze in dilute basic media to give alcohol mixtures.[3c,d,e] In view of the rapid thermal rearrangement of butenyl bromides it is questionable just how much significance can be attached to the quantitative results reported for allylic bromide hydrolysis. The report of Claisen and Tietze[3a] that crotyl bromide is hydrolyzed in 10% sodium carbonate solution to give only crotyl alcohol must be regarded as erroneous. The reported conversion of 1-bromo-3-methyl-2-butene to 3-methyl-1-butene-3-ol in 10% sodium carbonate[3b] involves a rearrangement from a primary to a tertiary carbon atom. The present results indicate that complete conversion from one allylic isomer to the other is not to be expected from the hydrolysis of primary and secondary allylic halides. Therefore this report will be checked in this Laboratory.

Acknowledgment.—The authors wish to express their appreciation to Dr. S. Winstein for the many helpful suggestions which he made in regard to this work.

Experimental Part

Crotyl and Methylvinylcarbinyl Chlorides.—Mixtures of the chlorides obtained from the Shell Development Corporation or prepared from the alcohols as previously described[2a] were separated by fractionation on a six foot column packed with glass helices. The secondary chloride used had the properties: b. p. 63.4–63.5° (751 mm.), n^{20}D 1.4151. The purity of the crotyl chloride samples was tested by measuring their rates of reaction with alcoholic sodium ethoxide.[2a] The sample used for rate work was prepared from methylvinylcarbinol and phosphorus trichloride and had the following physical properties: b. p. 45.2–45.4° (192 mm.), n^{20}D 1.4352, κ_2 (alcoholic sodium ethoxide) 0.201. Other samples (from the Shell Development Corporation or prepared by the reaction of the butenols with concentrated hydrochloric acid) had somewhat higher refractive indices and rate constants. The properties of the primary chloride obtained from the Shell Development Corporation mixture were: b. p. 83.8–84.0° (750 mm.), n^{20}D 1.4364, κ_2 0.225. It seems likely that the presence of *cis*-crotyl chloride in some of the samples is responsible for their varying physical properties.

The Hydrolysis of the Butenyl Chlorides in the Presence of Silver Hydroxide.—A mixture of freshly prepared silver hydroxide (258 g. or 1.1 moles), 250 ml. of water, and 100 g. (1.1 moles) of the chloride was stirred at room temperature, and the reaction flask was cooled by a water-bath. At the end of the reaction period the aqueous phase was filtered from the precipitate. The precipitate was washed several times with water, and the washings were added to the filtrate. The filtrate was distilled until the distillate no longer gave a bromine test for unsaturation. The alcohols were salted out from the distillate and dried over potassium carbonate. Analysis of the alcohol mixtures was accomplished by fractionation through a three foot Podbielniak type column. The refractive indices of samples of the pure chlorides in contact with silver chloride did not change over a long period of time nor did the pure butenols rearrange when in contact with silver residues taken from one of the runs.

The Hydrolysis of the Butenyl Chlorides in Dilute Basic Media.—In the aqueous sodium carbonate runs the hydrolysis medium was a solution of 58 g. (0.5 mole) of sodium carbonate in 2 liters of water. In the runs using aqueous ethanol 58 g. of sodium carbonate was dissolved in a solution of 1142 ml. of water and 858 ml. of 95% ethanol. In the runs with sodium hydroxide the medium contained 65 g. (1.63 moles) of sodium hydroxide in 2 liters of water. To these solutions were added 100 g. (1.1 moles) of the chloride, and the mixtures were stirred at room temperature until the halide layer had disappeared. The products from the runs in aqueous media were isolated and analyzed in a manner similar to that used in the runs with silver hydroxide. The products from the runs in aqueous ethanol were isolated by distillation from their solution and dried as before. The ethanol and the constant boiling mixtures of ethanol and the ethyl ethers of the primary and secondary chlorides[7] were removed from the butenols by distillation through a three foot column packed with glass helices. When all of the low boiling material was removed, the column was washed down with 50 ml. of ether. Fractionation of the combined boiler residues and ether washings was carried out on the three foot column of the Podbielniak type.

Properties of the Butenols Prepared from the Butenyl Chlorides.—The methylvinylcarbinol produced in these reactions had the following properties: b. p. 97°, n^{25}D 1.4125, m. p. of 3,5-dinitrobenzoate 54°. The crotyl alcohol obtained from the hydrolysis of methylvinylcarbinyl chloride and that obtained from the hydrolysis of crotyl chloride in the presence of silver hydroxide or in aqueous sodium carbonate solution appeared to be predominantly the *trans* isomer. Its properties were as follows: b. p. 121°, n^{25}D 1.4270, m. p. of 3,5-dinitrobenzoate 70.5°. The crotyl alcohol isolated from the reaction of crotyl chloride with aqueous sodium hydroxide and with an aqueous ethanol solution of sodium carbonate always distilled over a range of 121–122°. The refractive index of material taken at the end of these distillations was high. A sample of such material of n^{25}D 1.4302 gave a 3,5-dinitrobenzoate which melted from 54–56°. These properties indicated that this sample contained an appreciable quantity of *cis*-crotyl alcohol. The properties of *cis*-crotyl alcohol which had been prepared in this Laboratory by other methods[8] were b. p. 121°, n^{25}D 1.4330, m. p. of 3,5-dinitrobenzoate 54–56°.

Rates of Reaction of Butenyl Chlorides with 50 Volume % Aqueous Ethanol Solutions of Sodium Hydroxide.—To a 100-ml. volumetric flask was added 50 ml. of a standardized aqueous solution of sodium hydroxide and enough anhydrous ethanol to fill the flask to within about 0.5 ml. of the mark. This solution was brought to temperature in the thermostat, and the butenyl chloride was added to the mark by means of a weight pipet. Aliquot portions were withdrawn from time to time and titrated with alcoholic hydrogen chloride or in runs where no sodium hydroxide was used with aqueous sodium hydroxide to the phenolphthalein end-point.

Rate of Conversion of Butenyl Chlorides to Ethyl Ethers.—To a 100-ml. volumetric flask was added the proper volume of a standardized solution of sodium ethoxide in absolute ethanol. The flask was filled to within 5 ml. of the mark with absolute ethanol, and a 2-ml. sample of the organic halide was added from a weight pipet. The flask was filled to the mark with absolute ethanol, shaken and immersed in the thermostat. Aliquot portions were removed from time to time and analyzed as described above. All liquids were brought to thermostat temperature before they were mixed.

The Solvolysis of Crotyl Chloride in 90% Aqueous Ethanol.—A mixture of 75 g. (0.83 mole) of crotyl chloride, 200 ml. of absolute ethanol, 20 ml. of water, and 95 g. of calcium carbonate was stirred and refluxed on an oil-bath (85°) for one hundred hours. The calcium carbonate was filtered out and washed with 50 ml. of ethanol, and the washings were added to the filtrate. The alcoholic solution of the product was added to 1.5 liters of water. The mixture was extracted with a total of 400 ml. of carbon disulfide and dried briefly over potassium carbonate. Fractionation of this material was carried out on the three foot Podbielniak type column. Fractions containing other than carbon disulfide, alcohol and water were

Fr. 1	1.9 g.	48.0–76.0° (uncor.)	$n^{20}D$ 1.5030
Fr. 2	2.0 g.	76.0–98.6°	$n^{20}D$ 1.4010
Fr. 3	24.9 g.	98.6–99.0°	$n^{20}D$ 1.4049 (crotyl ethyl ether)

It was estimated that not more than 1.2 g. of methylvinylcarbinyl ethyl ether (b. p. 77.6°, $n^{21}D$ 1.3751)[2a] out of a total of 27.6 g. of ether was formed in this reaction. The yield of ether was 33%.

Summary

The hydrolysis of crotyl and methylvinylcarbinyl chlorides has been studied using a variety of experimental conditions designed to produce different ratios of S_N1 and S_N2 replacement reactions, and the compositions of butenols from these reactions have been determined. The secondary chloride appears to react only by the S_N1 type process to give a mixture of allylic isomers while the primary chloride responds readily to changes in experimental conditions, giving relatively larger amounts of normal product as the medium becomes more suitable for a bimolecular reaction.

Kinetic studies of the reaction of the isomeric chlorides in dilute solutions of sodium hydroxide in aqueous ethanol showed that the secondary chloride reaction rate was independent of hydroxide ion; the primary chloride, however, showed both first and second order kinetics. Evidence was obtained that the first order reaction of the primary chloride is in part a bimolecular reaction with solvent.

The Hydrolysis of Pantothenate: A First Order Reaction.[1] Relation to Thiamin Stability

BY DOUGLAS V. FROST AND FLOYD C. MCINTIRE

A rapid polarimetric method for following the hydrolytic decomposition of pantothenate in aqueous solution was described recently in a paper from this Laboratory.[2] Reaction rate analyses applied to the data of this earlier publication clearly show that at the temperature studied, 60°, pantothenate hydrolysis follows the pattern of a first order reaction with respect to pantothenate concentration. The effect of varying *p*H at that temperature demonstrates that pantothenate stability is good in the *p*H range 5.5–7, but that hydrolysis proceeds at an increasing rate with increase in acidity below *p*H 5.5. The present study deals with the temperature variation of the rate of pantothenate destruction at constant *p*H.

Procedure.—A *p*H of 3.7–4.0 was chosen since the formation of pantoyl lactone is rapid and complete in this range.[2] The specific rotation of 1% calcium pantothenate at *p*H 3.8 was found to be +24.2°. A standard reference curve was therefore plotted from −27.5 to +24.2° and estimations of residual pantothenate were made as previously described.[2]

Two solutions of 1% calcium pantothenate, one buffered with 3% monosodium phosphate, the other unbuffered, were studied in parallel. Addition of small amounts of concentrated hydrochloric acid was required at the start and from time to time during the experiments to maintain a *p*H of 3.8 as closely as possible. Since the necessary additions of acid were small, no corrections were made for dilution. The various temperatures of reaction were maintained constant within 0.5°. Samples were withdrawn from the reaction vessels to make the rotation measurements.

The results obtained are shown in Table I.

Discussion.—When the logarithm of the concentration of pantothenate was plotted against time, straight lines, characteristic of a first order reaction, were obtained at each of the temperatures studied. The values of k in Table I have therefore been calculated using the standard first order equation.

The rate of destruction of pantothenate was slightly greater in the buffered solutions than in the unbuffered ones. The effect of phosphate buffer, as well as other substances, in catalyzing pantothenate destruction is more pronounced at higher *p*H,[2] than at the relative low *p*H of this study. The values for the unbuffered and buffered solutions in this case are close enough to serve as a partial check against one another.

In Table II the average values for k at different temperatures are shown, together with a calculation of the half-life period for each. When the values for log k are plotted against $1/T$, the results are seen to follow the Arrhenius equation in yielding a straight line, as shown in Fig. 1. From the slope of this line an activation energy of 19,000 ± 1000 cal. may be calculated. By extrapolation of the data the value for the half-life at 0° is found to be 6030 days, while at 110 and 120° it is 0.174 and 0.096 day, respectively.

Studies also were made to determine whether

[a] Buffered solutions contained 3% monosodium phosphate. [b] Constants calculated by formula $K = 2.303/t \log C_0/C$.

the rate of pantothenate destruction at *p*H 3.7–4 depended on the buffer used. Buffers tried were 3 and 6% glycine, 3 and 6% β-alanine, 2 and 5% nicotinamide and 3% acetic acid. In all cases the amounts of destruction at 39° over a period of ninety days were about equal. Thus the rate of destruction in this acid range appears to be independent of the type of buffer.

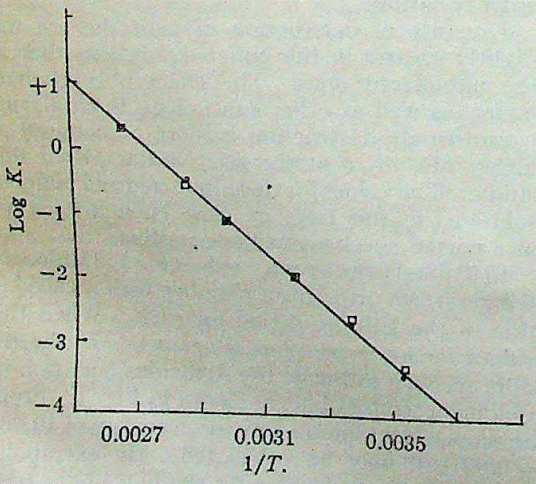

Fig. 1.—The temperature variation of the rate of hydrolysis of pantothenate: O, rate of hydrolysis unbuffered; □, rate of hydrolysis buffered with 3% monosodium phosphate.

Relative Stability of Pantothenate and Thiamin.—A solution of 0.1% thiamin hydrochloride in 3% monosodium phosphate was divided into several equal parts. The separate parts were adjusted to various *p*H values by the addition of small amounts of hydrochloric acid or sodium hydroxide. A 1% solution of calcium pantothenate was treated in like manner. The separate solutions were filtered, sealed in ampoules and immediately placed in an autoclave for fifteen minutes at 15 lb. pressure. The amounts of thiamin and pantothenate remaining after removal from the autoclave were determined by the thiochrome and rotation methods, respectively.

Figure 2 shows the percentage of original pantothenate and thiamin remaining at each *p*H studied. The maximum shift in *p*H during autoclaving was 0.2 unit. The point at which the two curves cross, *p*H 4.6, represents the condition under which destruction of the two compounds is equally rapid. In other experiments using somewhat different conditions some variation in the slope of the curves and in the point at which they cross has been noted. In general, however, the latter point falls in the *p*H range 4.5–4.8.

That stability of thiamin is favored by acid conditions has been known for some time.[3,4] More recently the thermal decomposition of thiamin was shown to be a first order reaction at a number of different acidities.[5] Reports have since appeared that the type of buffer used has a large effect on the rate of this decomposition at different acidities.[6,7]

In contrast to this, stability of pantothenate has been shown to be largely independent of the presence or type of buffer at *p*H 3.7–4. Other studies, however, have confirmed the earlier indications that buffer substances cause significant increases in the rate of destruction in the *p*H range 4–7. The positive effect of nicotinamide or phosphate in hydrolysis of pantothenate is most apparent in the range in which pantothenate is normally most stable, *i. e.*, *p*H 5–7.

Destruction of thiamine appears from the facts at hand to be considerably more complicated than that of pantothenate. Rate of hydrolysis of pantothenate is chiefly a function of *p*H, but may be catalyzed by the presence of electrolytes. Destruction of thiamin, however, appears to be subject to many influences other than *p*H and may even be inhibited by presence of certain compounds.

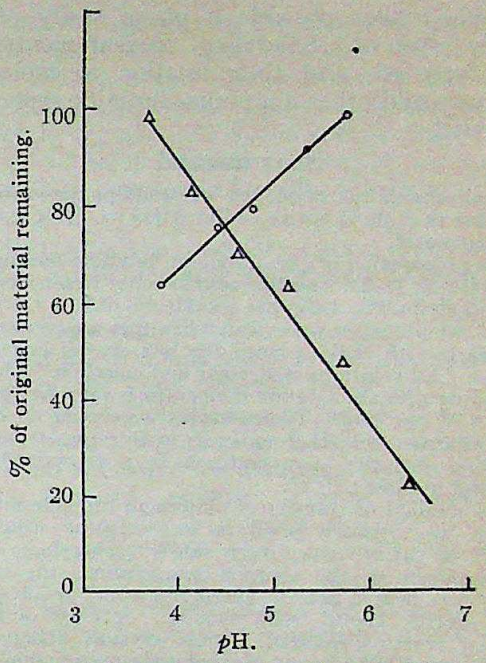

Fig. 2.—Relative rates of destruction of calcium pantothenate and thiamin hydrochloride in acid solution: O, 1% solution of calcium pantothenate; △, 0.1% solution of thiamin hydrochloride. All solutions were run in an autoclave at 15 lb. pressure for fifteen minutes.

Summary

Hydrolysis of pantothenate in acid solution follows a first order relation with respect to pantothenate concentration.

The activation energy of the reaction has been measured to be 19,000 cal., corresponding to an increment per 10° of 2.6.

The contrasting effect of acidity on rate of hydrolysis of thiamin and pantothenate has been studied and discussed.

The Solubility of Aluminum Bromide in *n*-Butane

BY JULIUS D. HELDMAN[1] AND CARL D. THURMOND

Aluminum bromide exists as the dimer in the crystal, in the molten salt, in solution in non-basic solvents, and in the vapor phase over a wide range of conditions. Although it forms highly polar double salts and complexes with organic bases, it would be expected to show normal solubility characteristics in non-polar, inert solvents, of which the paraffin hydrocarbons are good examples.

It has been shown that pure, dry aluminum bromide exerts no catalytic influence on the butanes[2] or *n*-heptane,[3] even though in the presence of a "promoter" (a hydrogen halide or substance capable of producing hydrogen bromide by reaction with the salt) aluminum bromide acts as a catalyst for paraffin conversions, notably isomerization.[2,3,4]

The stability of *n*-butane in dry aluminum

bromide makes possible a phase study of the binary system. Solubility measurements are here reported, and their relation to molecular structure and other aluminum bromide systems is discussed.

Experimental

The hydrocarbon employed was Phillips pure *n*-butane of better than 99% purity, sulfur 0.005 wt. % or less, free of unsaturates.

The preparation of the aluminum bromide and method of obtaining sealed solution sample tubes were essentially those described by Leighton and Heldman.[2]

The sample tubes were heated in either a water or glycerol bath with shaking until the last crystal had disappeared. All solutions were clear and colorless. The rate of heating near the solution temperature was never greater than 0.2° per min. Temperatures were read on one of two calibrated 0.1° thermometers, with ranges 0–50° and 50–100°. Solution temperatures were reproducible to 0.3° and usually to 0.2°.

The method of transfer of aluminum bromide into the sample tubes usually produced large crystals which dissolved in the *n*-butane very slowly. Therefore, before measurement of the solution temperature, the sample tubes were heated until all the bromide had dissolved and then quickly cooled, with shaking. A mass of finely-divided crystals resulted. These crystals dissolved so readily upon subsequent heating that presumably there was equilibrium between the solid and liquid phases at all times.

Because of the high vapor pressures of *n*-butane at the temperatures measured, the vapor volume in each sample tube at the solution temperature was estimated, in order to apply a correction. The lack of uniformity in tube size and therefore vapor volume arises from the fact that the vacuum distillation of the aluminum bromide into the many tubes sealed to the manifolds used is not easily controllable; consequently some larger tubes received less of a bromide charge than some of the smaller ones. For the same reason, the spacing of the experimental points is somewhat fortuitous, and the rather frequent close duplication of composition inherent in the sampling method.

Samples were analyzed by weighing the sealed tube and contents, freezing in liquid air and either heating the tip to suck in the glass and reaming out the opening or merely breaking open the tube, washing out the contents, and weighing the glass parts. The aluminum bromide was calculated by difference from the tare of the glass and the known weight of *n*-butane introduced.

The butane from one tube, which had been brought to its solution temperature of 67.0° twice and then purposely set aside to stand at room temperature for fifteen days, was analyzed in a dew pressure apparatus and found to be over 98% *n*-butane. Considerable isomerization would be expected if traces of water or hydrogen bromide had been present.[2,5]

Results

In Table I are given the solution temperatures and composition of the mixtures examined. The moles of aluminum bromide are calculated on the basis of the formula Al_2Br_6. The actual moles of *n*-butane in the liquid phase have been calculated by subtracting from the total butane charge the estimated moles of vapor. This quantity was approximated using the vapor pressure of *n*-butane at the solution temperature[6] and the estimated vapor volume, assuming both the perfect gas equation and Raoult's law to be valid for the system. Neither of the assumptions hold strictly, but the former can introduce no important error. The deviation from Raoult's law could have been estimated from the solubility curve and a second-order approximation of the vapor pressure made, but this procedure is not justified by the accuracy of the results.

The internal consistency of the results points to an accuracy of about 1 or 2% in determining the composition of the mixtures. If we arbitrarily fix the maximum error arising in calculating the moles of liquid *n*-butane on the above assumptions as one-fourth of the estimated moles of *n*-butane vapor, the accuracy of the calculated moles of liquid *n*-butane is usually 0.25 to 2%, and, in a few cases, 3 to 5%. The possible error in mole fraction derived from this arbitrary basis is, in general greater than the scattering of the experimental points indicates, except for the

measurement at 84.3°, which is not consistent with the rest and is presumably in error in some way.

Although it would have been desirable to obtain measurements at even greater concentrations of aluminum bromide than the highest reported here, the techniques employed do not lend themselves to the handling of the larger amounts of bromide necessary.

Discussion

The usual plot of the logarithm of the solubility expressed in mole fraction of aluminum bromide (as Al_2Br_6) *vs.* the reciprocal of the absolute temperature is shown in Fig. 1. All of the points, with the single exception noted, fall close to a smooth curve of the reverse S type commonly encountered when the solvent and solute have different internal pressures.[7]

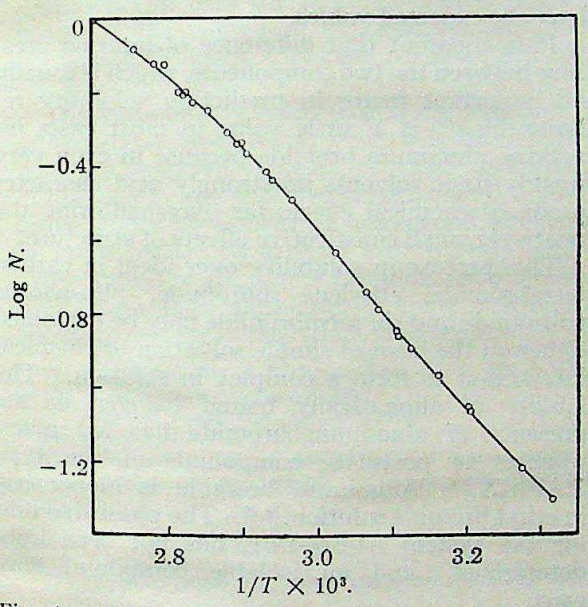

Fig. 1.—Solubility of aluminum bromide in *n*-butane (N = mole fraction Al_2Br_6).

Kendall, Crittenden and Miller[8] and Kaveler and Monroe[9] have reported a phase change in aluminum bromide just above 70° on the basis of solubility measurements. In the present case there is no change in slope of the solubility curve near 70°, nor was any change in aluminum bromide at that temperature visually observed, even with very slow heating and cooling. Kendall, *et al.*,[8a] and Crittenden[8b] claim to have authenticated the existence of two crystalline modifications of aluminum bromide by "thermal analysis" of the pure salt. No cooling curve data were presented, however. We have taken several cooling curves with pure aluminum bromide and have found them noteworthy only in the check on the melting (freezing) point obtained with the thermocouple and with the thermometer in the solubility work. Otherwise the cooling curves are completely regular. Also, the specific heat[10] and volume[11] of solid aluminum bromide are apparently smooth monotonic functions of the temperature.

Furthermore, the solubility curves from which Kendall, Crittenden and Miller, and Kaveler and Monroe, infer a phase change in aluminum bromide show no discontinuities near 70°, nor has Isbekow,[12] who has reported thermal analyses of some of the same systems, found any irregularities near 70°. Indeed, a re-plot of their data in terms of log N *vs.* $1/T$, Fig. 2, clearly shows that there is no necessity for assuming two modifications of aluminum bromide. One of the systems on which Kendall, Crittenden and Miller base their conclusions, PBr_3–Al_2Br_6, actually shows a small decrease in negative slope starting near 70°, and the internal consistency of the data for any of the systems is not great enough to justify postulating a discontinuity. It should be noted that the carbon tetrabromide used by Isbekow melted 1.9° higher than that of Kendall, *et al.*, whereas his arsenic tribromide melted 0.8° lower.

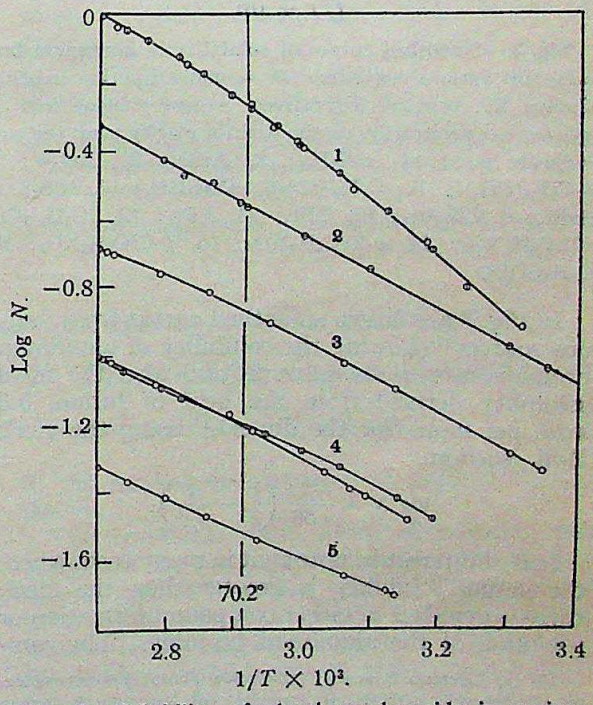

Fig. 2.—Solubility of aluminum bromide in various solvents (N = mole fraction Al_2Br_6): Curve 1, $AsBr_3$; 2, CS_2, add 1/3 to log N; 3, $SnBr_4$, add 2/3 to log N; 4, CBr_4, add 1 to log N; 5, PBr_3, add 1 1/3 to log N; ○, Kendall, Crittenden and Miller; ⊖, Kaveler and Monroe; ⊙, Isbekow.

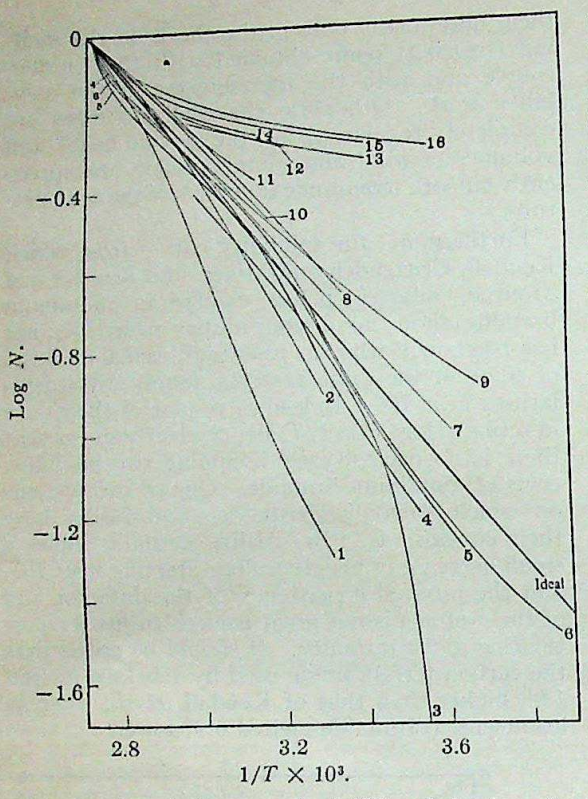

Fig. 3.—Smoothed curves of solubility of aluminum bromide in various solvents (N = mole fraction Al_2Br_6). Curves for benzene derivatives, except toluene and *p*-xylene, are arbitrarily terminated for clarity near the convergence point: 1, *n*-C_4H_{10}; 2, $AsBr_3$; 3, C_6H_6[13f]; 4, *p*-$C_6H_4(CH_3)_2$; 5, C_6H_6[13a]; 6, $C_6H_5CH_3$; 7, CS_2; 8, $SnBr_4$; 9, $C_2H_4Br_2$; 10, CBr_4; 11, PBr_3; 12, $(C_6H_5)_2CO$; 13, $C_6H_5NO_2$; 14, *p*-$BrC_6H_4NO_2$; 15, *p*-$ClC_6H_4NO_2$; 16, C_6H_5COCl.

In Fig. 3 are drawn smoothed curves from various sources[13] showing the solubility of aluminum bromide in various solvents and also the ideal solubility derived from the heat of fusion, 5.5 kcal. per mole (for the dimer),[14] using the van't Hoff isochore

$$\log N = \frac{-Lf}{4.58}\left(\frac{1}{T} - \frac{1}{Tm}\right) \qquad (1)$$

It is of interest to note that in many cases where the actual solubility is greater than the ideal, there is evidence of either compound formation or solvation of the aluminum bromide. The compounds with nitrobenzene and its derivatives are well known.[13d,15]

Benzene and its analogs give curves that are particularly interesting and somewhat puzzling, being of the unreversed S type, which is extremely uncommon in solubility work. The molecular state of aluminum bromide in benzene is that of the monomer (probably $AlBr_3 \cdot C_6H_6$) in very dilute solution and essentially the dimer at ordinary concentrations.[13f,16] The reported existence of an unstable solid compound $AlBr_3 \cdot C_6H_6$[13f] and the lack of agreement between the solubility data of Menschutkin and Plotnikow and Gratsianskiĭ indicate that the curvature may be due to non-equilibrium conditions with respect to the solid phase in Menschutkin's work.

The deep color of concentrated solutions of aluminum bromide in carbon disulfide leads us to believe that here solvation is increasing solubility over the expected values.

It is apparent that difference of internal pressure between the two components, which is usually an important factor in predicting solubility relationships,[17] is of little value in most cases involving aluminum bromide because in even very weakly basic solvents its strongly acid character produces chemical effects far overshadowing the relatively small constitutive effects of structure.

The increase in solubility over ideal in carbon tetrabromide, ethylene dibromide, phosphorus tribromide and tin tetrabromide may be explained either on the basis of simple solvation or chemical interaction to form a complex in solution. The lability of aliphatically bound halogen in the presence of aluminum bromide has led many workers to postulate compounds of the type $RAlBr_3X$.[18] Aluminum bromide is monomeric in ethyl bromide solution.[19,20] The phase diagram for the system Al_2Br_6–PBr_3 has not been fully determined,[8] and an isolable compound may exist.

In the case of *n*-butane, in which the solubility of aluminum bromide is much less than the ideal, a calculation based on the equation given by Hildebrand[21]

$$RT \ln \gamma_1 = V_1\left(\frac{N_2V_2}{N_1V_1 + N_2V_2}\right)^2\left[\left(\frac{\Delta E_1}{V_1}\right)^{1/2} - \left(\frac{\Delta E_2}{V_2}\right)^{1/2}\right]^2 \qquad (2)$$

is of interest. We can estimate the energy of vaporization of aluminum bromide at 25° from the heat of vaporization at the boiling point, 12.0 kcal. per mole at 255°, and ΔC_p of vaporization =

-18 cal. per deg. mole,[22] giving the heat of vaporization at 25° as 16.14 kcal. per mole. Subtraction of RT leaves the energy of vaporization, 15.55 kcal. per mole. It must be emphasized at the outset, however, that the uncertainty in ΔC_p leaves a margin of about 1.5 kcal. per mole in ΔE, which will be reflected in the calculation based on equation (2).

From the density of solid aluminum bromide at 25°, 3.01, and the coefficient of cubical expansion, 2.83×10^{-4},[11] the molal volume at 100° is calculated as 181 cc. At that temperature, the molal volume of the liquid is 203 cc.[23] Assuming the same percentage increase in volumes on melting the solid at 25 and 100°, we find the molal volume of molten aluminum bromide at 25° to be 198 cc. The possible error in this value can be at most 10 cc. and will not affect the conclusions to be drawn.

Hildebrand lists the required constants for *n*-butane,[24] the energy of vaporization and molal volume at 25° being 4.44 kcal. per mole and 102.0 cc., respectively.

The value of $\ln\gamma$ calculated from equation (2) on the above bases is 1.4, which is to be compared with the observed value of 1.3, taken as the ratio of the ideal to the observed (extrapolated 3°) solubility. The agreement is quite good and could be made perfect by a slight lowering of $-\Delta C_p$ of vaporization of aluminum bromide. We conclude that solutions of aluminum bromide in *n*-butane are quite regular in the Hildebrand sense.[25]

(22) Fischer and Rahlfs, *Z. anorg. allgem. Chem.*, **205**, 1 (1932). The value of $-\Delta C_p$ is surprisingly large.

(23) Biltz and Voight, *ibid.*, **126**, 39 (1923).

(24) Hildebrand, ref. 7, p. 104.

(25) Other effects, such as deviations from random mixing in solution [Rushbrooke, *Proc. Roy. Soc.* (London), **166A**, 294 (1938); Kirkwood, *J. Phys. Chem.*, **43**, 97 (1939)], and a size effect due to dimerization of the solute, which can be applied in this case [Fowler and Rushbrooke, *Trans. Faraday Soc.*, **33**, 1272 (1937)], are quite small in comparison to the Hildebrand term for regular solutions.

The system Al_2Br_6–$AsBr_3$ is apparently normal. There is good evidence for the lack of compound formation.[26]

We have throughout written aluminum bromide as the dimer Al_2Br_6. It seems to us that this is logical in view of our knowledge of its molecular state when no chemical reaction has occurred. To write it as $AlBr_3$ would be analogous to using the formula I for liquid iodine or iodine in solution. The fact that in both cases a reaction with certain solvents may occur renders it even more important to compare such solutions with others on the basis of the ideal solution, in which Al_2Br_6 (or I_2) is certainly the true molecular formula.

Summary

The solubility of aluminum bromide in *n*-butane has been measured from 28.3° to the melting point of the salt, 97.5°.

There appears to be no convincing evidence for a phase transformation in aluminum bromide near 70°, as has been reported by other workers.

The difference between the actual and ideal solubility of aluminum bromide in *n*-butane is predicted by Hildebrand's equation relating solubility to internal pressure differences. The system is regular in the Hildebrand sense.

The solubility relationships of aluminum bromide in other solvents have been briefly discussed.

Acid–Base Studies in Gaseous Systems. I. Precise Dissociation Measurements

BY HERBERT C. BROWN,[1] MODDIE D. TAYLOR AND MELVIN GERSTEIN

The rarity of simple reversible organic reactions has always been a major difficulty in the development of rational chemical theories. Because of this scarcity, the effects of structure and of substituents upon chemical behavior have been investigated largely by means of competitive reactions and reaction rate studies. Work with irreversible systems and the interpretation of the results thus obtained, however, involve great difficulties and uncertainties. Although much ingenuity has been displayed in overcoming such obstacles, and although modern physical methods for examining molecular structure have been of great service, simple reversible reactions, were they available, would still play an important role in the further development of organic chemical theory.

The reversible dissociation of addition compounds in the vapor phase has been the object of several studies in recent years.[2] These dissociations of the type $B{:}A^3 \rightarrow B{:} + A$ are simple reversible reactions are representative of a large class, the study of which should yield much valuable information. In studies of such dissociations, it is possible to make quantitative measurements from

(3) The formula of the addition compound is frequently written $B^+{:}^-A$ in order to indicate the formal charges on the bonding atoms. Since there is no evident advantage in this more complex symbolism, the simpler version will be here employed.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

which the thermodynamic quantities ΔF, ΔH and ΔS readily may be determined. The substituents in A and in B may be widely varied, and the effects of such variations on ΔF, ΔH and ΔS may then be compared. Thus it is possible to compare a particular change of the substituents in A with a similar change of the substituents in B. Moreover, the substituents in both A and B may be kept constant while the bonding atoms are varied. By comparisons of the results thus obtained, the "electrical" effects of substituent groups and the dependence of these effects on the nature of the bonding atoms may be distinguished from the "steric" effects. It is evident that the quantitative data secured from an investigation of the dissociative characteristics of a selected series of compounds offer important possibilities for broadening our understanding of the specific influences of substituent groups in organic chemistry.

The interest of such studies is considerably heightened by Lewis' suggestion that such dissociations are typical acid–base reactions.[4] The ionization of organic acids and bases in suitable solvents has hitherto been one of the few simple reversible reactions available to workers in theoretical organic chemistry. The conclusions drawn from the study of such ionizations have, however, always been open to the objection that the results may be greatly affected by complex solvent effects, the importance of which cannot yet be estimated. If Lewis' interpretations of the dissociation reaction, $B:A \rightarrow B: + A$, can be shown to be correct, the effect of structure on acid and base strength may be determined by observations made on the vapor phase, where the complexities inherent in solution work are absent. The accumulated data from solution studies may then be reëxamined in order to determine whether the customary neglect of the solvent has led to serious errors.

For these reasons, it has seemed desirable to initiate a series of studies on the dissociation of selected addition compounds in the gas phase. It was decided early that in order to derive the maximum value from the experimental data, the limits of accuracy of the measurements should be set as high as practical. The following limits were tentatively fixed: the dissociation constants should be accurate to 1–2%; the heat of dissociation should be correct to 0.1% (0.1–0.2 kcal.). The technique finally developed, and described in the present paper, is both simple and accurate—it is easily reliable to these limits. The results obtained by the application of this technique to specific problems will be discussed in later papers of this series.

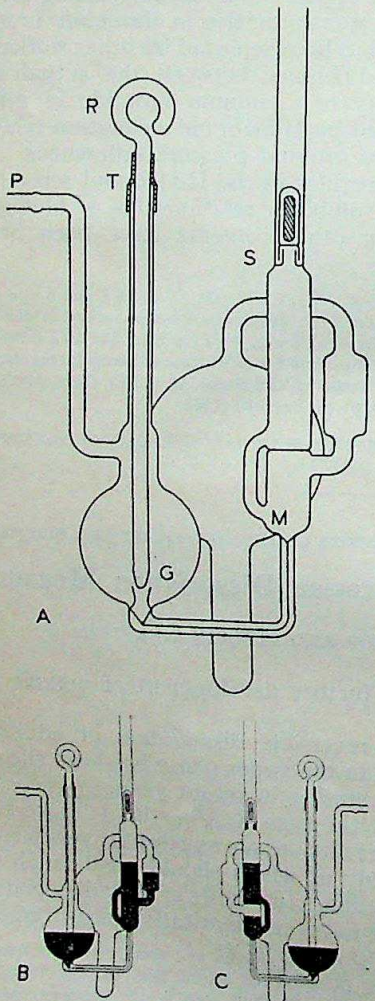

Fig. 1.—Dissociation tensimeter: A, diagram illustrating construction; B, mercury in position to read low pressures (below 20 mm.); C, mercury in position to read dissociation pressures (20–100 mm.).

The Apparatus

The apparatus used for studying the dissociations (the "dissociation tensimeter") is shown in Fig. 1.

The volumes of the two dissociation tensimeters (*ca.* 260 ml.) were matched to within 1 part in 2000. This was accomplished by comparing the pressure exerted by a given volume of gas transferred from one tensimeter to the other. Minor changes in the volumes of the tensimeter were made by adjusting the zero marks to which the mercury in the manometer was raised.

The mercury manometer was constructed of 25-mm. tubing and designed as shown to bring the upper mercury meniscus directly above the lower (Fig. 1-C). In this way the height of the mercury column could be accurately measured as a single vertical distance to within 0.01 to 0.02 mm. with the aid of a Gaertner micrometer slide (range, 100 mm.) carrying a short focus telescope. Pressures below 20 mm. could not be measured in this way. By allowing the mercury to rise in the manometer until the two menisci were side by side (Fig. 1-B), pressures below 20 mm. (*e. g.*, saturation pressure) could be read with an ordinary cathetometer with somewhat poorer precision ($\pm$0.04 mm.).

Mercury was brought into the evacuated manometer M by raising the rod R (Fig. 1-A), thus opening the ground glass closure G between the reservoir and the manometer. The mercury was lowered by connecting the mercury reservoir to a pump at the point P while the rod was lifted. The necessary vertical movement of the rod was obtained by using thin gum rubber tubing for the closure at the point T. The mercury vapor seal S was introduced to

eliminate errors resulting from the evaporation of mercury into the vacuum above the upper meniscus. In operation, the plug rested in the mercury well (Fig. 1-C), beneath the surface of the oil-bath. Thus, at equilibrium, both the bulb of the tensimeter and the space above the upper meniscus were saturated with mercury vapor. Whenever materials were introduced or removed from the tensimeter, the plug was lifted with magnets to break the seal. The tensimeter was surrounded by a thermostat maintained at a temperature constant to ±0.1° for one-hour intervals, charged with clear mineral oil and provided with a plate glass window sealed with Glyptal cement to permit observation of the manometer, this cement being resistant to the bath liquid up to 160°. Its temperature was measured by means of a mercury thermometer calibrated by the U. S. Bureau of Standards.

Procedure

A sample of component A, the amount of which had been previously measured roughly in the vacuum apparatus (±0.5%), was condensed with liquid nitrogen in one of the dissociation tensimeters. The mercury was then raised into the manometer, shutting off the tensimeter from the rest of the apparatus while component B was similarly brought into the other tensimeter. The samples used were of such a size that within the tensimeter they exerted a pressure of 20–30 mm., low enough to minimize deviations from the ideal gas laws, yet high enough to maintain the desired precision of measurement.

The sizes of the two samples were adjusted until the two pressures agreed within 0.02 mm. The adjustment was conveniently made in the following manner. The ratio between the volume of the tensimeter to the bottom of the manometer (point M) and the volume from that point to

the mercury seal S was known. Calculations based upon the measured excess pressure and the known vapor pressure of the compound at low temperatures permitted an accurate fraction of the total sample to be removed by simply cooling the flask to the calculated temperature and momentarily withdrawing the mercury from the manometer. After the manometer was closed, the small plug was lifted from the mercury seal and the material trapped in the space beneath it was distilled away. In working with a series of addition compounds in which one component was maintained constant (*e.g.*, the addition compounds of trimethylboron with aliphatic amines), it proved convenient always to have the constant component (trimethylboron) present in slight excess so that the adjustment could be made to the same component.

The two matched samples were then quantitatively brought together into one tensimeter by means of liquid nitrogen. To transfer the substances quantitatively (loss

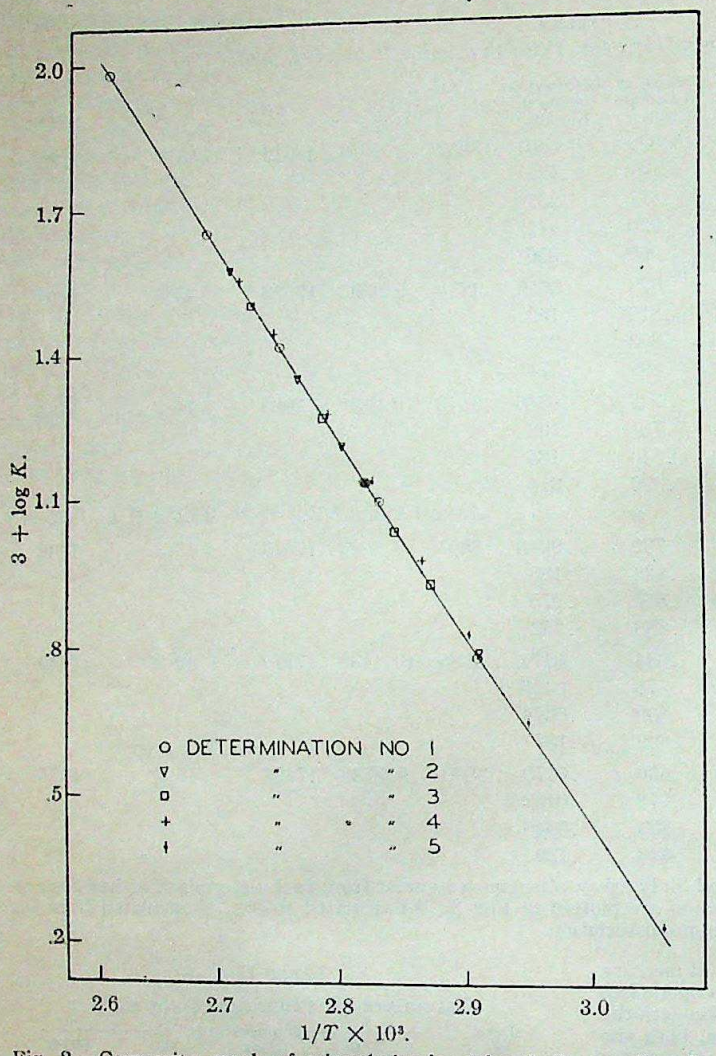

Fig. 2.—Composite graph of trimethylamine–trimethylboron dissociation data.

less than 1 part in 2000) test experiments indicated that a condensation time of close to ten minutes was necessary. Usually twenty to thirty minutes were assigned to this operation. Ordinarily the more volatile of the two components was the one transferred.

The vapor pressure of the addition compound thus synthesized from its components was measured at 0°. If this pressure agreed with that obtained for the previously prepared and purified sample of the addition compound, the heating bath was placed in position and the heating begun. The point of complete vaporization could be determined by comparison of the observed pressure with the previously measured saturation pressure. (This point could also be detected by observing the instant the glass walls of the tensimeter lost their foggy appearance and became perfectly transparent.) Usually no dissociation measurements were made for approximately 10° above this point, for the values of the dissociation constant determined near the saturation point tended to be low. The measurement of at least 8 to 10 dissociation pressures (roughly every 5°) allowed the importance of random errors in the determination of individual values to be minimized. Several check readings were also made as the bath cooled and compared with readings taken during the temperature rise in order to insure that equilibrium had been reached and to establish that no irreversible changes had occurred in the course of the experiment.

Test of Method

The reliability of the procedure described was tested by a number of studies on the dissociation of trimethylamine–trimethylboron.[5] These series of measurements were made by three different investigators who used different pairs of dissociation tensimeters and individual preparations of the components. The results are summarized in Table I (determinations 1, 2 and 3) and represented graphically in Fig. 2. To facilitate comparison between these runs, individual values of the dissociation constants for four temperatures were calculated (Table II) by means of the equation which best represented each series of measurements.[6] The agreement is excellent. The heats of dissociation calculated from these three runs agree within 0.1 kcal.; the dissociation constants agree to within 1%.

It can be shown that the value of the dissociation constant is very sensitive to small quantities of inert impurities in the components A and B used in the preparation of the addition compound. Fortunately, the nature of the addition compound and the method of its preparation offers a simple but sensitive check on the purity of the individual components and the compounds they produce. In practically all cases to which the method described is applicable, the components A and B are very volatile substances with vapor pressures of the order of 0.1 to 4 atmospheres to 0°. These components may easily be individually purified to the point where the absence of any impurities of markedly different volatility is assured. On the other hand, the addition compound B:A is, ordinarily, only slightly volatile; in most cases its saturation pressure is below 0.3 mm. at 0°. An inert impurity present to the extent of 0.2% in A would leave uncombined an equal quantity of B. If 25-mm. samples of A and B each are used, the saturation pressure of the addition compound B:A would be 0.1 mm. above the true value. A discrepancy of this magnitude is detected easily. Reactive impurities, that is, those which react with the other component to form addition compounds, are less easy to detect; their absence may be demonstrated by the constancy of the saturation pressure of the complex. That the requisite purity can be attained is indicated by the agreement between determinations 1, 2 and 3.

The effect of deviations from the perfect gas laws on the accuracy of the results remains to be considered. To obtain experimental evidence on the importance of such deviations, a run was made at a considerably lower pressure than in the three determinations already mentioned. At this low pressure the specially designed manometer and the slide cathetometer could not be used. Accordingly, the two-limb manometer and an ordinary cathetometer were used. As a check, a run was made with the same appa-

(5) Previous work on this compound and its physical properties will be described in the second paper of this series. This addition compound was selected for testing the experimental method because from its previous study, it was known that its degree of dissociation was in a moderately difficult region, $\alpha = 0.70$ to 0.95. Its study, therefore, furnished a relatively severe test of the reliability of the experimental method.

(6) The dissociation data from a number of runs were studied both by standard statistical methods and by graphical methods; the results obtained by both procedures agreed very closely. The agreement was much better than the limits of accuracy set for the results. It was, therefore, decided that the simpler graphical method should be adopted as the standard procedure for working up the experimental data.

Digitized by Arya Samaj Foundation Chennai and eGangotri

ratus at the usual pressure. The results are given in Tables I and II, determinations 4 and 5. It is apparent that within the lower precision of these results, there is no significant difference between the constants thus obtained and those observed in runs 1, 2 and 3. It may be concluded that the accuracy of the constants is not seriously affected by deviations from the perfect gas laws. Although errors due to this factor might be reduced by using an extrapolation procedure, the sensitivity of the dissociation data obtained in the lower pressure range to variations in the initial pressures[7] suggests that very little would be gained by recourse to such a method.

Summing up, then, it appears that the method described in this paper for measuring the dissociation of addition compounds yields dissociation data with the desired accuracy: the dissociation constants are estimated to be reliable to 2% and the heat of dissociation to 0.1%. The optimum pressure range (initial pressure of each component) is 20–30 mm. Operating below this range (*e. g.*, 10 mm.) does not noticeably affect the experimental values of the constants, but it greatly increases the probable error.

(7) Comparison of the calculated values in runs 5 and 5′ illustrates this sensitivity. In the 5′ series of calculations, 10.07 mm. was used for the initial pressure instead of the 10.04 (±0.04) actually observed.

There is little doubt that the precision of the measurements could be further improved by additional refinements. However, the uncertainty introduced by neglect of the gas law deviations suggests that higher precision is of uncertain value. Certainly, the field is so new and the questions to be answered are so many that it appears more important now to concentrate on the more urgent problems and to leave further refinements to such a time as the need for even more accurate data becomes apparent.

Summary

Accurate dissociation data of addition compounds in gaseous systems are of considerable interest and value for theoretical organic chemistry. A simple technique for precise measurement of such dissociations has been developed and tested by a series of studies on the dissociation of trimethylamine–trimethylboron. The tests indicate that by this method the dissociation constants can be determined to 2% and the heat of dissociation to 0.1%.

Acid–Base Studies in Gaseous Systems. II. The Anomalous Base Strength of the Methylamines; A New Manifestation of Steric Strain[1,2]

BY HERBERT C. BROWN,[3] HERMAN BARTHOLOMAY, JR., AND MODDIE D. TAYLOR

Organic acids and bases have played a significant role in the development of modern physical theories.[4] The influences which structure and substituents exert on the relative strengths of acids and bases are an important part of the foundations upon which such present-day theories as those of the "inductive effect" and the "resonance effect" are constructed. Although much research has been devoted to this subject, a number of interesting phenomena have not yet received satisfactory explanations.

One such phenomenon is the well-known anomalous behavior of the methylamines. The introduction of a methyl group into the ammonia molecule produces an increase in base strength which is ascribed to the positive inductive effect (+I) of the methyl group. The introduction of a second methyl group causes a further increase which is ascribed to the same effect. Introduction of a third methyl group, however, markedly reduces the strength of the tertiary amine formed[5] (Table I).

TABLE I

BASE DISSOCIATION CONSTANTS FOR AMMONIA AND THE METHYLAMINES AT 25°

Amine	$K_b \times 10^5$
NH_3	1.79
$CH_3 \rightarrow NH_2$	42.5
$(CH_3)_2NH$	59.9
$(CH_3)_3N$	6.31

The behavior of the normal aliphatic acids and amines furnishes other puzzling problems. Acetic acid is considerably weaker than formic acid, a result which might be expected in view of the inductive (+I) effect postulated for the methyl group. Propionic acid is still weaker, a fact which is also in accord with the theory. Butyric acid, however, is stronger than propionic.[6]

(5) Everett and Wynne-Jones, *Proc. Roy. Soc.* (London), **177A**, 449 (1941). Earlier values for the dissociation constants of the methylamines are summarized in this paper.

(6) Dippy, *Chem. Rev.*, **25**, 151 (1939). Particular attention is called to the graph on page 189 of this review. The increase in the acid strength of butyric acid has been ascribed to hydrogen bond formation between the end methyl group and the carboxyl group. Since we have observed similar phenomena in compounds where such hydrogen bond formation is impossible, this explanation is no longer satisfactory. The subject will be discussed in subsequent papers of this series.

Digitized by Arya Samaj Foundation Chennai and eGangotri

The normal aliphatic amines exhibit a similar phenomenon. The data, although less precise than those for the carboxylic acids, clearly show that the base strength rises in the series ammonia, methylamine, ethylamine, but drops with propylamine.[7]

Before attempting to explain these facts, it is important to know whether the phenomena are due primarily to the substances themselves or to indirect solution effects. The nature of the hydrogen acids has made their study difficult except by working with solvents of relatively high dielectric constant. Unfortunately, these are just the solvents which are the most complex and the least understood. By adopting the viewpoint advanced by G. N. Lewis[8] that the proton is but one out of many acids, it has become possible to draw conclusions regarding the relative strength of acids and bases from the dissociative characteristics of selected groups of addition compounds. By a suitable choice of the reference compounds, it is possible to make these dissociation studies in non-polar solvents, or even in the gas phase. The complexities of the polar solvents may thus be avoided. Such studies of generalized acids and bases in the comparative simplicity of the gas phase are now under way. The results already obtained not only furnish strong support for the Lewis concept of acids and bases, but they also throw light on the interesting problems previously mentioned. In the present paper, an investigation dealing with the first of these problems—the anomalous behavior of the methylamines—is reported. In this study, trimethylboron serves as the reference acid.

$$R_3N{:}B(CH_3)_3 \rightleftharpoons R_3N{:} + B(CH_3)_3$$
$$R = CH_3 \text{ and/or } H$$

Purification of Compounds

In order to obtain constants of the desired accuracy (heat of dissociation good to 0.1 or 0.2 kcal.; the dissociation constants correct to 1–2%), it was necessary rigorously to purify the substances used in the investigation.[9] Since the experimental technique used is sensitive to impurities of the order of 0.1%, efforts were directed to preparing materials containing this quantity of impurity as the upper limit.

Trimethylboron was prepared by the action of boron trifluoride on methylmagnesium bromide in butyl ether. The crude trimethylboron was distilled (under nitrogen) directly out of the reaction flask; the yields were over 80%. The substance was introduced into the high vacuum apparatus and subjected to a prior distillation, from a U-tube at −112° to a U-tube at −130°. The ammonia addition compound, prepared from the distillate, was purified by distillation from a tube held at 0°. The fraction used was cut when the saturation pressure had become constant and agreed with the known value for the pure compound. This fraction was then distilled into a flask and treated with a deficiency of pure dry hydrogen chloride in order to liberate the trimethylboron.

$$NH_3{:}B(CH_3)_3 + HCl \longrightarrow NH_4Cl + B(CH_3)_3$$

The trimethylboron thus obtained was again distilled from a −112° bath and trapped by a −130° bath. The material exhibited a vapor pressure which was independent of the vapor volume; the pressure observed was 680 mm. at −22.9° (m. p. of carbon tetrachloride). The product combined with pure ammonia exactly in the molecular ratio 1:1 to form an addition compound with the correct saturation pressure. The pure trimethylboron was stored in large flasks as a gas. No change in its properties has been observed over a period of many months of storage.

Ammonia, obtained from a commercial tank of the anhydrous material, was treated with metallic sodium[10] until a permanent blue color was observed. A small middle fraction, sublimed at −80°, was collected in the vacuum apparatus. This ammonia was tensiometrically homogeneous; the vapor pressure was independent of the vapor volume; the value agreed with that of the ammonia vapor tension thermometer used.

Methylamine was generated from hydrochloride purified in the following manner. The hydrochloride (Eastman Kodak Co.) was washed several times with chloroform to remove traces of dimethylamine hydrochloride; then it was twice recrystallized from butanol. Finally, it was freed from possible traces of ammonia and trimethylamine by the process of Sharp and Solomon.[11] The free amine, obtained from the purified hydrochloride, was introduced into the vacuum line and placed over sodium. It was distilled from the sodium at −80°. The vapor pressure of the product was 422 mm. at −18.6° (measured with an ethyl ether vapor tension thermometer); this vapor pressure was independent of the vapor volume.

Dimethylamine was also generated from the hydrochloride (Eastman Kodak Co.) purified in the manner just described. The amine, after being treated with sodium, showed a vapor pressure of 561 mm. at 0°.

Trimethylamine was generated from an aqueous solution (Commercial Solvents Corp.); it was purified by treatment with freshly sublimed phosphorus pentoxide. This simple process, developed by Burg and Ingram,[12] removes ammonia and all primary and secondary amines. The pure trimethylamine thus obtained had a vapor pressure of 680.5 mm. at 0°.

In all of the purifications, the vapor pressure measurements were used only to check the absence of any gross impurity present in an amount greater than 1 mole per cent. The absence of impurities larger than 0.1 mole per cent. was assured by careful measurement of the saturation pressures of the addition compound at 0° and by observations on the constancy of the pressure while the addition compound was distilled.[9]

Results

Ammonia–trimethylboron,[13] $NH_3{:}B(CH_3)_3$.—The addition compound formed by ammona and trimethylboron was described first by Frankland[14] and later by Stock.[15] The melting point reported by these authors,[16] 56°, is much lower than the

(9) It was also necessary to devise improved methods for studying dissociations in the gas phase. These methods are described in the first paper of this series, THIS JOURNAL, **66**, 431 (1944).

(10) The sodium for drying the ammonia and the amines was prepared in the following manner to avoid possible contamination of the amines by hydrocarbon vapors. Molten sodium was kept under high vacuum until gases were no longer evolved. Hydrogen was then introduced and the sodium drawn up into 4-mm. glass tubes, which dipped beneath the surface of the metal. After the sodium had solidified, the tubes were removed. Short lengths of this tubing were cut off as the sodium was needed.

value, 73.2–73.7°, observed in the present investigation for the carefully purified product.

The saturation pressure[17] of the compound was studied over the temperature range from 0 to 59.7°. The data are listed in Table II and represented graphically in Fig. 1-A. The saturation pressure exhibits a behavior which appears to be general for addition compounds of the type under discussion. The values at low temperatures show a definite curvature in a log $P - 1/T$ graph; at higher temperatures they fall on a straight line.[18] The straight portion of the curve (20.0° and above) is represented satisfactorily by the equation

$$\text{Log } P = (-3095/T) + 11.229$$

The pressure above the solid would reach 760 mm. at 97.6° if the equation were valid to this temperature. However, since the compound melts at 73°, the "boiling point"[19] must lie somewhat higher than the above calculated value. Frankland[14] reports the boiling point as 110°.

TABLE II

SATURATION PRESSURES OF AMMONIA–TRIMETHYLBORON

Temp., °C.	0.0	4.2	10.5	15.0	20.0	28.0
Press., mm.	.95	1.33	2.12	3.16	4.70	8.81

Press., mm.	10.17	21.7	33.9	44.4	62.0	76.1

Stock and Zeidler report the compound to be highly dissociated (above 90%) at room temperature. In the present investigation, the dissociation of the substance over the temperature range from 54.8 to 130° was studied. The results are given in Table III and Fig. 1-B. The variation in the dissociation constants with temperature is represented by the equation

$$\text{Log } K_p = (-3007/T) + 8.723$$

The dissociation constant at 100° is 4.6 and the heat of dissociation is 13.75 ± 0.3 kcal. A comparatively large probable error (0.2% as compared with 0.1% for the derivatives of the other amines) is assumed because of the particularly difficult region (α = 0.90 to 0.99) in which the dissociation of the compound was studied. (The methods used for determining the accuracy of the dissociation data are described in the first paper of this series.)

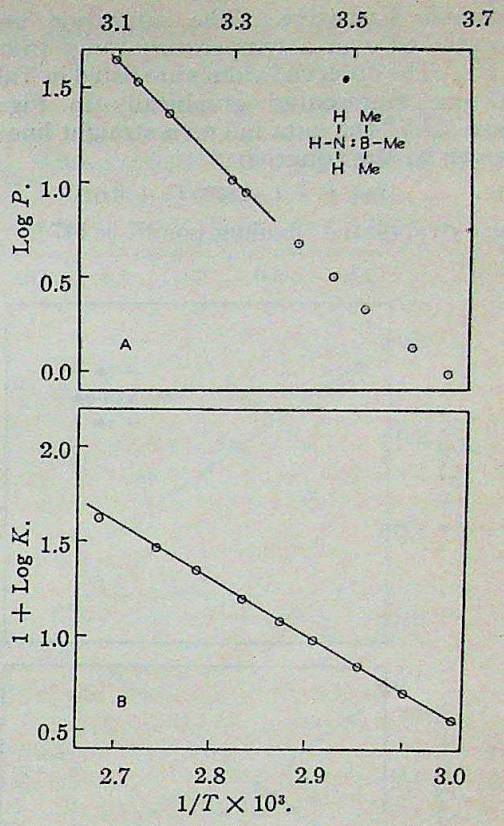

Fig. 1.—Ammonia–trimethylboron: A, saturation pressure data; B, dissociation data.

TABLE III

DISSOCIATION PRESSURES OF AMMONIA–TRIMETHYLBORON

Temp., °C.	Pressure, mm. Observed	Pressure, mm. Calculated[a]	Degree of dissociation, α	Dissociation constant, K (atm.)
54.8	57.62	30.20	0.908	0.356
60.1	59.22	30.68	.930	.501

ammonia derivative. The saturation pressure was studied over a temperature range from 0 to 93.1°. The observed values are listed in Table IV and are represented graphically in Fig. 2-A. Above 34.7° the data fall on a straight line which is given by the equation

$$\text{Log } P = (-2829/T) + 9.611$$

The extrapolated "boiling point" is 147°.

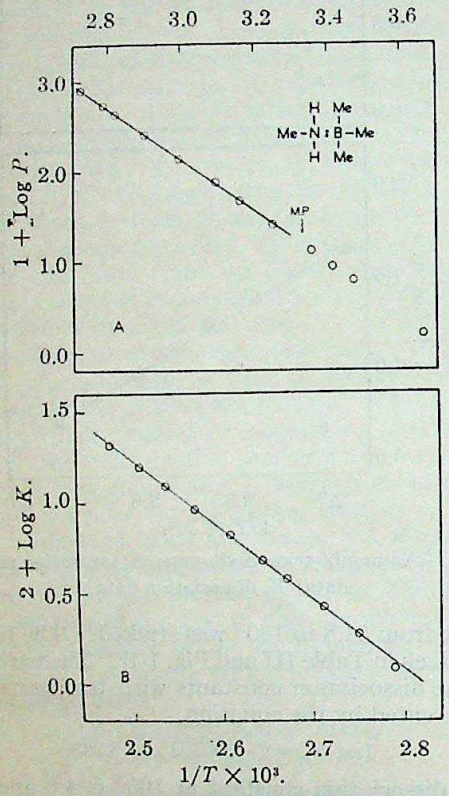

Fig. 2.—Methylamine–trimethylboron: A, saturation pressure data; B, dissociation data.

Under comparable conditions, the compound is considerably less dissociated than the ammonia derivative. The dissociation data observed over the temperature range from 85.4 to 132.9° are listed in Table V and represented graphically in Fig. 2-B. The dissociation constants can be represented by the equation

$$\text{Log } K_p = (-3856/T) + 8.880$$

The value of the dissociation constant at 100° is 0.0350 and the heat of dissociation of the compound is 17.64 ± 0.2 kcal.

Dimethylamine–trimethylboron, $(CH_3)_2NH:B(CH_3)_3$.—The addition compound formed by dimethylamine and trimethylboron also has not previously been described. It is a white solid which melts at 35.0–35.5° and resembles the methylamine derivative in volatility. The saturation pressure data (over the range from 0 to 74.6°) are given in Table VI and represented graphically in Fig. 3-A. The compound behaves like the corresponding methylamine derivative. Above 45.7° the saturation pressures can be represented by the equation

$$\text{Log } P = (-2902/T) + 9.860$$

The extrapolated "boiling point" is 143°.

TABLE VI

SATURATION PRESSURE OF DIMETHYLAMINE–TRIMETHYLBORON

0.0214 and the heat of dissociation of the complex is 19.26 ± 0.2 kcal.

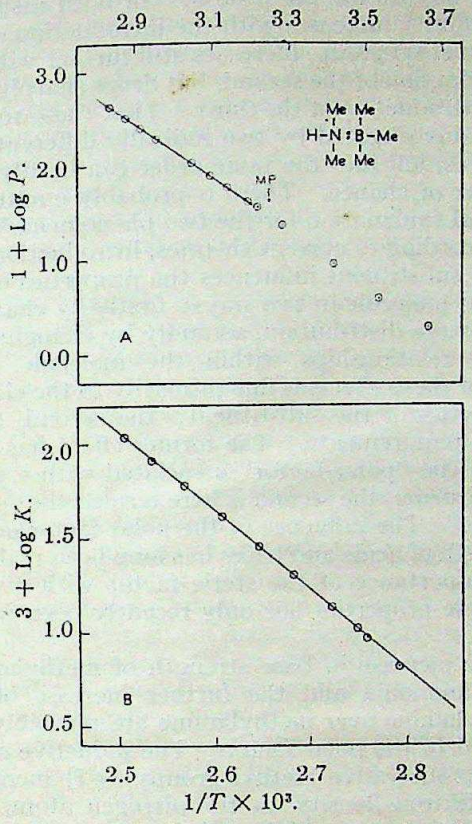

Fig. 3.—Dimethylamine–trimethylboron: A, saturation pressure data; B, dissociation data.

Trimethylamine–trimethylboron, $(CH_3)_3N:B(CH_3)_3$.—The complex, trimethylamine–trimethylboron, has been previously prepared and studied by Schlesinger and co-workers.[20] In view of the high accuracy demanded by the present study, the properties and the dissociation of the compound in the gas phase were reinvestigated. Trimethylamine–trimethylboron is a white crystalline solid which softens at 120° and melts at 128°. It is the second most volatile of the addition compounds under consideration, being exceeded in this respect only by the ammonia derivative.[21] Saturation pressure measurements are listed in Table VIII and illustrated in Fig. 4-A. Above 29.8° the saturation pressure data may be represented by the equation

$$\text{Log } P = -(3467/T) + 11.949$$

Below this temperature the graph shows the curvature to which attention has previously been called. The extrapolated "sublimation point" is 109.6°.

sented in Fig. 4-B.[22] The dissociation constants can be represented by the equation

$$\text{Log } K_p = -(3852/T) + 9.998$$

The value of the dissociation constant at 100° is 0.472 and the heat of dissociation is 17.62 ± 0.2 kcal.

Discussion

The dissociation data in Table X (*cf.* also Fig. 5) reveal that the relative affinities of ammonia and its methyl derivatives for trimethylboron are almost identical with the relative affinities o these amines for the proton. In both instances the affinity increases with the introduction of the first methyl group, increases still further with the introduction of the second, but drops sharply with the introduction of the third. That these amines, when investigated by two radically different procedures, fall into the same order can hardly be a matter of chance. There is probably one fundamental explanation for the two phenomena.[23]

TABLE X

SUMMARY OF DISSOCIATION DATA

Compound	K_{100}	ΔF_{100}	ΔH	ΔS
NH_3:B$(CH_3)_3$	4.6	−1134	13,750	39.9

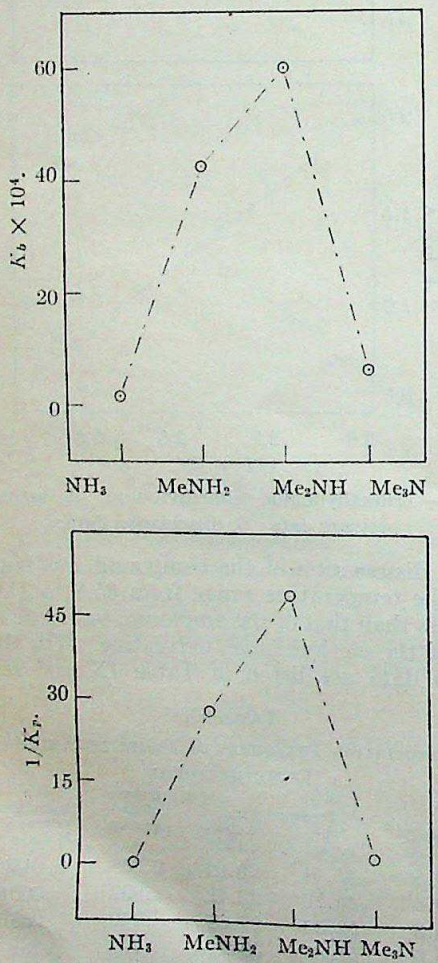

Fig. 5.—Base dissociation constants (K_p) at 25° of ammonia and the methylamines (top); dissociation constants (K_p) at 100° of the addition compounds of ammonia and the methylamines with trimethylboron (bottom).

According to current theories, introduction of a given substituent influences the properties of the parent molecule in two ways: firstly by changing the charge distribution, secondly by changing the steric relationships within the molecule. The first of these effects is due primarily to the electric properties of the substituent; the second, to its space requirements. The former effect has been called the "polar factor" associated with a given substituent; the second is here termed the "steric factor." The influence of the polar factor on the strength of acids and bases has long been realized; the importance of the steric factor with respect to these properties has only recently been recognized.

The increase in base strength of methylamine over ammonia and the further increase of dimethylamine over methylamine are plausibly ascribed to the polar factor. The inductive effect of two successive methyl groups (+I) increases the electron density on the nitrogen atom, and thus augments the ability of that atom to donate an electron pair to an acceptor, such as the proton or the boron atom in trimethylboron. There is, however, no apparent explanation in terms of the polar factor for the marked decrease in the donor properties of the nitrogen atom associated with the introduction of the third methyl group. It is plausible, therefore, to seek the reason for the phenomenon in the steric factor.

Previous investigations have shown that steric strain is important in determining the strength of acids and bases.[24] Thus pyridine is weaker than

(22) Other dissociation measurements of this compound are reported in the first paper of this series, where the dissociation of the complex was used to test the reliability of the experimental technique.

(23) A rough idea of the extent to which the base is weakened by the introduction of the third methyl group may be obtained as follows. The free energy of dissociation (at 100°) of methylamine–trimethylboron is approximately 3600 cal. greater than that of ammonia–trimethylboron. That is, the replacement of a hydrogen atom in ammonia by a methyl group increases by 3600 cal. the work required to separate the trimethylboron from the amine. Replacement of the second and third hydrogen atoms by methyl groups might be expected to increase the free energy of dissociation by approximately the same amounts. The free energy of dissociation (at 100°) of the dimethylamine compound would then be about 6000 cal., and that of the trimethylamine derivative about 9600 cal. The observed values, 2885 and 557 cal. respectively, indicate that some influence lowers the ΔF_{100} of the dimethylamine derivative by about 3500 cal. and that of the trimethylamine derivative by about 9000 cal.

It is interesting that the variation in the base strength of the amines is not due primarily to entropy effects. The interesting behavior of the ΔS term in the dissociation of these and related addition compounds will be discussed in a later paper.

trimethylamine when such acids as the proton (hydrogen chloride or hydrogen bromide), boron trifluoride, or borine are used to make the comparison, whereas the reverse is true when trimethylboron is so used. The weakness of trimethylamine when trimethylboron is the reference acid is ascribed to steric interference between the three methyl groups attached to the boron atom and the three methyl groups attached to the nitrogen atom.[25] The interference results in a force which tends to separate the two parts of the addition compound and thereby to increase its dissociation.

Another example of this type of strain is furnished by pyridine and α,α'-lutidine. The latter is a considerably stronger base than pyridine if the proton is used as the comparison acid. (The increase in base strength can readily be accounted for by the inductive effect of the methyl groups.) On the other hand, the comparatively large acid, boron trifluoride, reverses the order of these base strengths. Furthermore, α,α'-lutidine exhibits no basic properties whatsoever when the very bulky trimethylboron is the acid.[25]

These examples furnish clear cut illustrations of the type of steric strain under discussion—a face-to-face interference which markedly increases rissociation. For convenience, this type of steric dasain will be called "F-strain."

F-strain cannot be used as the basis of a satisfactory explanation of the behavior of the methyltmines. It is characteristic of F-strain that its magnitude depends on the steric requirements of both components. Thus, in the previously mentioned illustrations, the relative strengths of the amines differ, depending upon which acid, the proton, boron trifluoride, or trimethylboron, is used for the comparison. In the methylamines, however, the relative base strengths must be largely independent of the acid component since identical orders of base strengths are observed with both the proton and trimethylboron. The close similarity (Fig. 5) in the behavior of the dissociation constants, K_b, and the association constants, $1/K_p$, of the amines,[26] suggests that the correct explanation for this phenomenon must somehow be connected with the transformation of the trivalent nitrogen compound into an ammonium derivative. That is, the steric cause of the phenomenon under investigation must be in some way related to the fourth nitrogen bond; it must be of such a nature as to render relatively unimportant the steric factor of the group adding.

(25) See Fig. 2, p. 327, of reference 24.

(26) The magnitude of the base dissociation constant, K_b, is a measure of the affinity of the free amine for a proton. Actually, K_b/K_w should be compared, since that quantity is the equilibrium constant for the reaction

$$R_3N: + H^+ \rightleftarrows R_3N{:}H^+$$

However, no error is introduced in neglecting the constant factor, $1/K_w$, in making comparisons.

Similarly, the association constant, $1/K_p$, measures the affinity of the free amine for trimethylboron

$$R_3N: + B(CH_3)_3 \rightleftarrows R_3N{:}B(CH_3)_3$$

A simple explanation filling these requirements is available provided a not unreasonable assumption be made regarding the configuration of the free trimethylamine molecule.

There are theoretical reasons for believing that the three bonds of a trivalent nitrogen atom should be directed in space at angles of 90° to each other. In all cases which have been investigated, however, the angles are considerably greater, probably because they must be increased to accommodate the attached groups.[27] An electron diffraction investigation of trimethylamine led Brockway and Jenkins to the conclusion that the C–N–C angle in this molecule is $108 \pm 4°$.[28] In the explanation here proposed, it is assumed that the bond angle in trimethylamine is somewhat greater than the normal tetrahedral angle, probably close to the upper limit set by Brockway and Jenkins. In other words, the three rather bulky methyl groups spread the bonds of the nitrogen atom from their preferred configuration (90°) to a value greater than the tetrahedral angle.

In the trivalent nitrogen derivative, such spreading of the bond angles is relatively easy since the fourth position in the valence shell is not occupied. However, the addition of a fourth group to the vacant position, be it a proton or a trimethylboron molecule, forces the nitrogen atom toward a tetrahedral configuration and results in a reduction of the expanded angles. The methyl groups are, therefore, crowded toward each other, setting up a strain which reduces the stability of the addition compound.

The term "B-strain" is proposed for this effect. (The letter B is used to indicate that the interference which causes the strain is localized at the "back" of the molecule—trimethylamine in the case under discussion—away from the entering group; it is thus contrasted to F-strain which results from interference at the "front" of the molecule, at the interface between the two components of the addition compound.) B-strain should depend greatly upon the size of the groups attached to the nitrogen atom or any other small central atom, but should be relatively independent of the size of the adding group. The absence or relative unimportance of B-strain in ammonia and methylamine is accounted for by the fact that the small hydrogen atoms attached to the nitrogen atom permit the bond angle to approach the tetrahedral value without appreciable B-strain. On the other hand, the two methyl groups in dimethylamine and the three methyl groups in trimethylamine cannot adapt themselves so easily to the space available. The B-strain, in fact, is sufficient to reduce slightly the strength of dimethylamine and to reduce greatly that of trimethylamine.

The suggestion that B-strain is the primary cause of the anomalous behavior of the methyl-

amines does not mean that F-strain is absent. Indeed, the results previously reported[24] show that F-strain must be present. However, it probably increases regularly with the introduction of one, two or three methyl groups into the amine. The absolute magnitudes of the amine strengths are thus affected; their relative order, however, is not altered.

The proposed explanation leads to a number of interesting predictions; these are now being tested.

Acknowledgment.—The authors express their appreciation to Professors G. N. Lewis, R. S. Mulliken and Linus Pauling for their kindness in examining the manuscript and for their helpful suggestions.

Summary

1. The trimethylboron addition compounds with ammonia, methylamine, dimethylamine and trimethylamine have been prepared and characterized.

2. The dissociation of these compounds in the vapor phase ($R_3N{:}BMe_3 \rightleftarrows R_3N{:} + BMe_3$) has been studied; ΔH, ΔF and ΔS for the reactions have been measured.

3. The relative affinity of the methylamines for trimethylboron (measured by the dissociation constant of the complex) is identical with their affinity for the proton (measured by the dissociation constant of the base). In both instances, the base strength rises from ammonia to methylamine and to dimethylamine, but drops sharply from dimethylamine to trimethylamine.

4. To account for this observed order the strain resulting from the "steric factor" is divided into two kinds, "B-strain" and "F-strain." The anomalous behavior of the methylamines is ascribed to B-strain.

The Vapor Pressure of Beryllium at 1170–1340°K.

BY ROBERT SCHUMAN AND A. B. GARRETT

The vapor pressure of beryllium was determined by measuring the rate of vaporization in a vacuum. The theory and application of this method are adequately described by other investigators.[1,2,3,4] In the case of beryllium, the accommodation coefficient appears (qualitatively) to be unity within the limits of experimental error. This was true for iron,[2] copper,[2] nickel,[3] nickel oxide,[3] and for liquid and solid mercury.[5,6]

Experimental

The procedure was that of determining the loss of weight due to evaporation of a beryllium ring of known surface area; the ring was held at a constant known temperature by an induction furnace for a known length of time.

The beryllium was a very pure sample supplied by the Brush Beryllium Company with the analysis: 0.03% Fe, 0.008% Al, 0.004% Mg, 0.022% Si. The ring was made from the sample and had an effective area of evaporation of about 8.5 sq. cm.

The water-cooled cell was a modification of the one used by Marshall, Dornte and Norton,[2] but was made of Pyrex glass. The cell was constructed with two small-diameter water-cooled glass tubes sealed just inside the inner tube to prevent the formation of a continuous film of metal on the inside of the tube. The ring was supported by a tungsten tripod. The optical window at the top of the cell was protected from the metal vapors by a glass shutter.

The temperature was measured by a Leeds and Northrup No. 8622-C optical pyrometer with which the readings were easily reproducible to within 5°. The pyrometer was calibrated against the apparent black body temperature of melting silver, the silver being melted in a groove in an iron ring into which small holes had been drilled to serve as black bodies. The pyrometer was checked three times against the melting point of silver, the apparent melting points having a variation of 3°. The temperature of the beryllium ring used for determining the rate of evaporation was taken as the apparent emission temperature, and then corrected to black body temperatures by values of beryllium emissivities determined. The beryllium emissivities were obtained by comparing the apparent temperature readings of a polished beryllium surface and those of 1-mm. diameter, 4-mm. deep holes drilled in the specimen.

A pressure below 10^{-5} mm. of mercury was maintained throughout the run to prevent oxidation. In several runs in which the vacuum was poor, surface oxidation prevented or slowed up evaporation. A period of outgassing at dull red heat was also found valuable to eliminate adsorbed gases.

The weighings were made on a balance accurate to about ±0.05 mg.

Data.—The experimental results are recorded in Table I and Fig. 1 for the rate of vaporization. The temperatures given are the average temperature during the runs, and thus take into account small fluctuations in temperature during the run. The times are the effective times at the temperature indicated. The apparent emission temperatures for $\lambda = 6500$ Å. are given in terms of the black body temperatures by the equation

$$t_e = 0.904t_{bb} + 54.5 \quad (\pm 5°\ 800\text{–}1000°)$$

where t_e is the apparent polished surface temperature in °C. and t_{bb} is the corresponding black body temperature, °C. Runs 9 and 12 were of no value owing to surface oxidation.

Thermodynamic Considerations.—In order to check the validity of the vapor pressure results,

[a] ±0.2 mg.

the values of ΔH_0^0 were calculated from values of log P and T read off from the graph of log P *vs.* $1/T$ (Fig. 1). The thermodynamic relationship for ΔH_0^0 is

$$\frac{\Delta H_0^0}{T} = -R \ln p - \left(\frac{F^0 - H_0^0}{T}\right)_{\text{gas}} - \left(\frac{F^0 - H_0^0}{T}\right)_{\text{solid}}$$

The free energy function of the gas is dependent both on the vapor pressure results and on the spectroscopic energy levels of beryllium. Any error in it is due solely to the vapor pressure data. The function is

$$\left(\frac{F^0 - H_0^0}{T}\right)_{\text{gas}} = -3/2\ R \ln M - 5/2\ R \ln T + R \ln P - C - R \ln R - R \ln Q$$

For beryllium the ground state is $^1S_0$ and the next higher state is $^3P_0$ with a term value of 21981.4 cm.$^{-1}$. The second state contributes nothing to Q at the temperatures of the experiments, and the *a priori* probability of the ground state is 1, so, for this case, $Q = 1$. If P is measured in atmospheres, the value of $C + R \ln R$ is −7.267 (see ref. 7).

The free energy function of the solid is dependent only on specific heat data. The function is

$$\left(\frac{F^0 - H_0^0}{T}\right)_{\text{solid}} = \frac{1}{T}\int_0^T C_p\, dT - \int_0^T C_p\, d \ln T$$

The specific heats below 298°K. were those given by K. K. Kelley,[8] and the equation used for the higher range is[9]

$$C_p = 4.698 + 1.555 \times 10^{-3}T - 1.210 \times 10^{5}T^{-2} \quad (1\%,\ 273\text{–}1173°\text{K.})$$

(7) For a general discussion of the equation, see K. K. Kelley, *Bureau of Mines Bulletin*, **383**, 1 (1935).
(8) K. K. Kelley, *ibid.*, **434**, 84 (1941).
(9) K. K. Kelley, *ibid.*, **371**, 12 (1934).

In our calculations, this equation was used in a range somewhat above its upper limit of applicability.

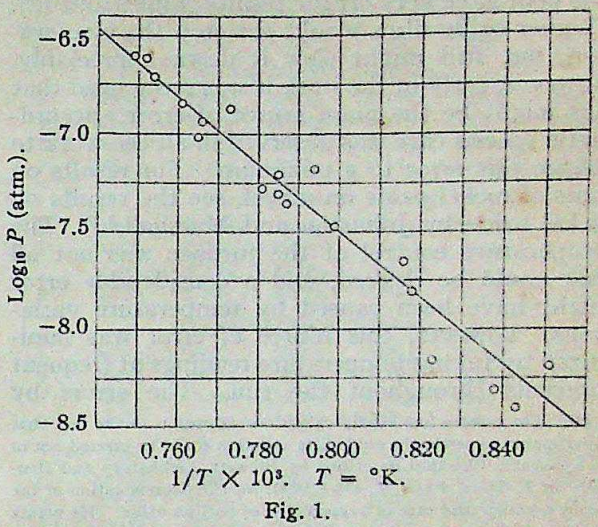

Fig. 1.

The calculated results of ΔH_0^0 are given in Table II. The trend in the ΔH_0^0 values, a variation of 5000 cal./mole over the temperature range studied would indicate that the curve is either (a) somewhat steeper than it should be, or (b), that the trend is due to inaccuracies in C_p, since the temperature is above the range of the C_p equation. We feel, however, that the curve drawn best represents the experimental data.

TABLE II

SUMMARY OF THERMODYNAMIC CALCULATIONS

T, °K.	log P (atm.)	$\frac{F^0 - H^0}{T}$ gas	$\frac{F^0 - H^0}{T}$ solid	ΔH_0^0, cal./mole
1550	−8.670	−73.966	−4.85	125,100
1200	−8.067	−71.421	−5.05	123,900
1250	−7.497	−69.016	−5.23	122,600
1300	−6.970	−66.798	−5.42	121,300
1350	−6.498	−64.826	−5.60	120,100

Other Considerations.—The log vapor pressure *vs.* reciprocal of temperature curve was drawn as a straight line; this plot is given in Fig. 1. The slope of the line in Fig. 1 corresponds to a heat of vaporization for beryllium of 78,800 ± 2000 cal./mole near 1250°K.

The trend in the ΔH_0^0 values might also indicate an accommodation coefficient different from unity; however, it is doubtful that it would differ enough from unity to cause as large a trend as observed. The fact that the beryllium did not deposit behind the small glass tubes in the cell would indicate a value near to unity.

The most likely sources of experimental error in this work are: first, the formation of an oxide film on the beryllium thick enough to greatly hinder the evaporation; second, inaccurately assumed temperatures due to fluctuations of temperature during the run; and also, to a lesser ex-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

tent, errors in the weighings and temperature readings. Of these, the first probably caused the largest errors, since runs in which the vacuum was poor gave very erratic results (runs 9 and 12). Thinner oxide films would not stop the evaporation, but still might slow it down appreciably. However, early in the work it was recognized that this might be the main source of error; accordingly, special care was observed in all the work to reduce this error to a minimum. For results on films of nickel oxide on nickel, see the results on nickel oxide by Johnston and Marshall.[3,10] The temperature control of the furnace was not all that could be desired, and a considerable error might have been caused by temperature variations; however, this source of error was minimized by taking temperature readings at frequent intervals throughout the run. The errors by other causes should be small in relation to these two.

Acknowledgment.—We wish to express our appreciation to the Brush Beryllium Company for the pure beryllium sample, and to Prof. H. G. Heil of the Mendenhall Laboratory of Physics, for the use of the high temperature equipment and for instructions in its use.

Summary

The vapor pressures of metallic beryllium in the range from 1170 to 1340°K. have been determined by the Langmuir method. The results are given in Table I, and a plot of log P *vs*, $1/T$ is given, Fig. 1. Values of ΔH_0^0 have been calculated and found to vary some with temperature, the mean value of ΔH_0^0 being (122,000 ± 2500) cal./mole. The heat of vaporization was also calculated, being 78,800 cal./mole at 1250°K. Possible sources of experimental error are considered, the slowing down of evaporation by thin oxide films probably being the most important. The accommodation coefficient appears to be unity.

COLUMBUS, OHIO RECEIVED NOVEMBER 12, 1943

(10) The referee has kindly called our attention to the fact that experiments to settle the oxide film question could be carried out in an apparatus like that described by Blewett, Liebhafsky and Hennelly in *J. Chem. Phys.*, **7**, 478 (1939), for the determination of the vapor pressure and rate of evaporation of barium oxide. He points out that if the rates of evaporation in such an apparatus are proportional to the area of the opening, then oxide films are not retarding the evaporation, provided that the vapor pressure equilibrium is maintained within.

Temperature Coefficients of Electrical Conductance of Solutions Containing Sodium Chloride, Potassium Chloride or Magnesium Sulfate or Mixtures Thereof

BY RAYMOND W. BREMNER

Introduction

Very little accurate information on the variation of electrical conductance with temperature is available in the literature. In this paper equations for very accurately calculating equivalent conductance as a function of centigrade temperature have been worked out. Temperature coefficients of equivalent conductance have been calculated with five-place accuracy. Temperature coefficients of specific conductance of certain standard potassium chloride solutions and of conductivity water have also been calculated. The variations of the coefficients due to temperature changes, concentration changes and mixing of electrolytes have been determined.

Calculations

Equivalent Conductance as a Function of Temperature.—Equation I was used for representing the equivalent conductances of twenty different solutions as a function of centigrade temperature.

$$\text{Eq. Cond.} = \Lambda = a + bt + ct^2 + dt^3 \qquad \text{(I)}$$

The preparation of solutions and the experimental data have been described previously.[1,2] The ratio of the number of millimoles of sodium chloride to the number of millimoles of magnesium sulfate in a given quantity of each of the four solutions that contain both of these salts is 16.4315. Similarly the ratio of the number of millimoles of sodium chloride to the number of millimoles of potassium chloride in a given quantity of each of the four solutions that contains both of these salts is 47.2916. The most dilute solution of each type is designated as Solution No. 1, while the most concentrated solution is designated as Solution No. 4. Solutions of intermediate concentrations are numbered 2 and 3, respectively.

The constants a, b, c and d of Equation I were evaluated from the experimental data for each solution by the method of least squares. By use of the resulting equations the equivalent conductance was calculated for each solution at 0, 5, 10, 15, 20 and 25°. The average deviation of the calculated from the experimentally determined value was only 0.006%. In no instance was the deviation greater than 0.02%, which is the approximate maximum error in the original data.

In Table I are listed the values of the constants of equation I for each solution. The constant (d), which is the coefficient of the term of highest degree, is in every instance negative. This indicates a point of inflection at a higher temperature

in each conductance *vs.* temperature curve, which is an essential requirement for an equation that satisfactorily represents electrical conductance as a function of temperature. The second degree equations $\Lambda = a + bt + ct^2$ and $\Lambda = \Lambda_0 (1 + at + bt^2)$ were found to be inadequate for making the calculations. The deviations of the calculated from the experimental values ranged up to 0.1% or more when they were used.

TABLE I

CONSTANTS FOR THE EQUATION $\Lambda = a + bt + ct^2 + dt^3$

4	$MgSO_4$	3.41678	34105_3	10905.1	64.458	− .6604
		Mixed Solutions of Sodium Chloride and Potassium Chloride			
1	NaCl	5.61836				
	+ KCl	0.1515_{22}	57582_0	17686.1	97.93_0	− .3787
2	NaCl	11.30020				
	+ KCl	0.3047_{56}	55165_3	16695.6	97.24_0	− .4700
3	NaCl	19.94439				
	+KCl	0.5378_{82}	52913_1	15896.9	85.328	− .2788
4	NaCl	27.26159				
	+ KCl	0.7352_{20}	51573_9	15320.1	85.140	− .3470
		Mixed Solutions of Sodium Chloride and Magnesium Sulfate			
1	NaCl	5.61836				
	+ $MgSO_4$	0.7041_{66}	54853_2	16883.9	97.266	− .3985
2	NaCl	11.30020				
	+ $MgSO_4$	1.41629	52080_2	15835.2	95.810	− .5179
3	NaCl	19.94439				
	+ $MgSO_4$	2.49969	49534_0	14940.6	84.325	− .3418
4	NaCl	27.26159				
	+ $MgSO_4$	3.41678	48002_4	14331.2	83.209	− .3909

For these reasons Equation I is recommended for use in calculating equivalent conductance as a function of centigrade temperature.

Temperature coefficients of equivalent conductance were calculated by use of Equation II and the constants are listed in Table I.

$$\text{Temp. coef. of eq. cond.} = \frac{d\Lambda}{\Lambda dt} = \frac{b + 2ct + 3dt^2}{\Lambda} \qquad \text{(II)}$$

They were calculated with five-place accuracy for each of the 20 different solutions at 0, 5, 10, 15, 20 and 25°, and are listed in Part 1 of Table II.

Specific Conductance as a Function of Temperature.—Equation III has been used previously to calculate the specific conductances of 0.01 demal and 0.1 demal potassium chloride solutions in the temperature range 0 to 25°[3]

$$\text{Sp. cond.} = L = a + bt + ct^2 + dt^3 \qquad \text{(III)}$$

PART 2—TEMPERATURE COEFFICIENTS OF SPECIFIC CONDUCTANCE

Coef. $\times 10^6 = (dL/Ldt) \times 10^6$

°C.	0	5	10	15	18	20	25
KCl 0.01D	2979_2	2703_6	2470_4	2270_1	2162_7	2095_7	1942_1
KCl 0.1D	29185	2653_9	2427_2	2230_4	2124_1	2057_5	1904_1
Conductivity water	43_{500}	36_{200}	31_{800}	29_{000}	28_{000}	27_{400}	26_{300}

When applied to the conductivity water used the constants obtained for specific conductance $\times 10^6$ are $a = 0.495$, $b = 0.0218$, $c = -0.000002$ and $d = 0.0000039$. Since the conductance of the water used was only a small correction factor, it was less accurately determined.

By use of Equation IV temperature coefficients of specific conductance were calculated; those of 0.01 demal and 0.1 demal standard potassium chloride solutions with five-place accuracy, and those of the conductivity water with three place accuracy. They are listed in Part 2 of Table II.

$$\text{Temp. coef. of sp. cond.} = \frac{dL}{Ldt} = \frac{b + 2ct + 3dt^2}{L} \qquad \text{(IV)}$$

Discussion of Results

Effects of Concentration.—As illustrated by Part 1 of Table II the temperature coefficients of equivalent conductance decrease with increasing concentration in every instance. This is probably because the coefficients for water are higher, as shown in Part 2 of Table II. The data on standard potassium chloride solutions substantiate this observation.

The effect of temperature on this decrease depends upon the particular salt or mixture of salts

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

involved. The decrease is most rapid at 0° and progressively becomes slower up to 25°, for all the solutions containing a high proportion of monovalent ions. Solutions containing only magnesium sulfate and water exhibit the reverse behavior. The decrease is slowest for the most dilute solutions (potassium chloride only) and progressively becomes more rapid to those of higher concentration (sodium chloride). These effects are best observed by plotting coefficients against concentrations.

Effects of Temperature.—The temperature coefficients of equivalent conductance considered decrease by about 1.5 to 2.0% of their values for each degree increase in temperature. The fact that they decrease is consistent with measurements showing coefficients to be negative at much higher temperatures. This decrease is most rapid for water and becomes less rapid the more concentrated the solution, except for solutions containing only magnesium sulfate and water. This difference and also the one mentioned in the preceding paragraph are likely due to the fact that magnesium sulfate is a different type of electrolyte in that it yields divalent ions.

Effects of Adding a Second Salt.—The addition of a salt that forms solutions with temperature coefficients higher or lower than those of sodium chloride solutions to the latter, produces solutions with coefficients of intermediate value. The magnitude of the intermediate value depends upon the concentration, and the temperature, even though the mole ratios are kept constant. The effect of adding a salt is either in opposition to or in addition to the effect of increasing the concentration, depending upon whether the coefficients of solutions of the added salt are higher or lower, respectively, than those of solutions containing only sodium chloride and water. For example, the addition of magnesium sulfate to sodium chloride solutions increases the temperature coefficients of the latter. Thus, two opposing factors are in operation, the effect of adding a salt with a larger temperature coefficient outweighing the effect of increasing the concentration.

When temperature coefficient is considered as a function of concentration, there is a pronounced maximum in the temperature coefficient at concentration no. 3 for magnesium sulfate solutions at 0°. Slight maxima occur also at the same concentration for this salt at 25° and for potassium chloride solutions at 0°. These maxima are reflected in the corresponding sodium chloride solutions to which the salts mentioned have been added. The maxima, particularly for the magnesium sulfate solutions at 0°, are larger than could be attributed to experimental errors, and as yet we can offer no explanation for them. It is a noteworthy fact that they occur mainly at 0°.

Summary

1. An equation is recommended for calculating the equivalent conductances of solutions as a function of centigrade temperature. The maximum deviation of the calculated from the experimental equivalent conductance was 0.02%, and the average deviation was only 0.006%.

2. By use of the differentiated form of the equation the temperature coefficients of equivalent conductance of twenty different solutions have been calculated with five-place accuracy at 0, 5, 10, 15, 20 and 25°. Also temperature coefficients of specific conductance have been calculated at 0, 5, 10, 15, 18, 20 and 25° for the conductivity water used and for 0.01 demal and 0.1 demal standard potassium chloride solutions.

3. Variations of temperature coefficients of electrical conductance of the salt solutions, due to concentration changes, temperature changes and the addition of a second salt have been determined.

Osmotic Pressures for Mixed Solvents[1]

BY FREDERICK T. WALL

During recent years osmotic pressure measurements have assumed increased importance as a means of determining molecular weights of high polymeric substances.[2a,b] Although the theory of osmotic pressures for simple systems has been well formulated, little attention has been devoted to the theoretical aspects of osmotic pressures for systems with mixed solvents. Since G. Gee[2] has carried out measurements under such conditions, it appears desirable to consider thermodynamically the significance of osmotic pressures for mixed solvents and to find out just what it is that one measures experimentally.

For an ordinary solution consisting of a solvent (A) and a solute (S), the osmotic pressure is a definite thermodynamic property of the solution. It is defined simply as the excess pressure which must be applied to the solution to increase the partial pressure of the solvent up to the vapor pressure of the pure solvent at the same tempera-

ture. If p_A^0 is the vapor pressure of pure A and p_A the partial pressure of A for the solution, then the osmotic pressure is given by[3]

$$P = \frac{RT}{\overline{V}_A} \ln \frac{p_A^0}{p_A} \qquad (1)$$

where $\overline{V}_A$ is the partial molar volume of A in the solution. Although one usually thinks of a semipermeable membrane in connection with osmotic pressure, it will be recognized that such a membrane need not exist to give equation (1) a definite meaning. Of course, if pure A is separated from a solution of S in A by a membrane impermeable to S, then P is just the excess pressure that must be applied to the solution to prevent solvent from passing through the membrane.

Consider now a solution of solute (S) in a mixture of solvents (A and B). One could define an osmotic pressure for each of the solvents by means of equations of type (1). That, however, would in general give two different osmotic pressures, neither of which would correspond to a measured pressure if one used a membrane permeable to both A and B but impermeable to S. Accordingly, it seems desirable to define a new osmotic pressure, bearing in mind the experiment which might be used for the measurement.

Suppose that a solution of S in A and B is separated from a mixture of A and B by a membrane impermeable to S only (Fig. 1). In the following discussion the term "solution" will be applied to the phase containing S and the term "solvent" to the other phase. Let x_i, p_i and $\overline{V}_i$ represent, respectively, the mole fraction, partial pressure and partial molar volume of the i-th component in the solution, and let the same symbols with primes (x_i', p_i', $\overline{V}_i'$) represent the corresponding quantities for the solvent. Also let p_i^0 be the vapor pressure of the pure ith component at the temperature of the experiment. For the sake of simplicity, it will first be supposed that Raoult's law holds. Since for high polymeric substances[4] and for many pairs of solvents, Raoult's law does not hold, the treatment will then be followed by a consideration of the effect of deviations from Raoult's law.

System with Raoult's Law Valid.—If Raoult's law holds, then

$$p_i = x_i p_i^0$$

and

$$p_i' = x_i' p_i^0 \qquad (2)$$

To prevent A from passing through the membrane, it is necessary to apply a pressure P_A on the solution, where

$$P_A = \frac{RT}{\overline{V}_A} \ln \frac{p_A'}{p_A} = \frac{RT}{\overline{V}_A} \ln \frac{x_A'}{x_A} \qquad (3)$$

(3) See, for example, MacDougall, "Physical Chemistry," rev. ed., The Macmillan Co., New York, N. Y., 1943, pp. 255–257.

(4) M. L. Huggins, *J. Phys. Chem.*, **46**, 151 (1942); P. J. Flory, *J. Chem. Phys.*, **10**, 15 (1942).

Likewise to prevent B from passing through the membrane, a pressure P_B must be applied, where

$$P_B = \frac{RT}{\overline{V}_B} \ln \frac{p_B'}{p_B} = \frac{RT}{\overline{V}_B} \ln \frac{x_B'}{x_B} \qquad (4)$$

In general P_A will not equal P_B; to make them equal, it is necessary that

$$\frac{1}{\overline{V}_A} \ln \frac{x_A'}{x_A} = \frac{1}{\overline{V}_B} \ln \frac{x_B'}{x_B} \qquad (5)$$

It is seen from equation (5) that if P_A equals P_B, the mole ratio of A to B on the two sides of the membrane will not be the same unless $\overline{V}_A = \overline{V}_B$.

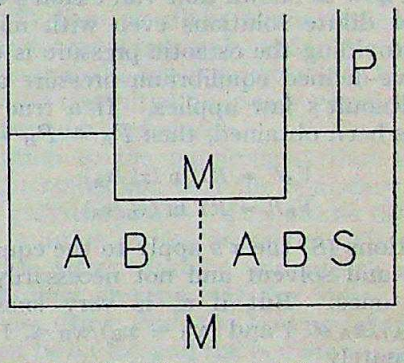

Fig. 1.—Solution (A,B,S,) separated from solvent (A,B) by membrane (M–M) which is impermeable to S.

Let us now investigate what will happen if the experiment illustrated in Fig. 1 is started with the same mole ratio of A to B on each side of the membrane. Then

$$\frac{x_B'}{x_B} = \frac{x_A'}{x_A} \qquad (6)$$

and

$$P_A \overline{V}_A = P_B \overline{V}_B \qquad (7)$$

Suppose $\overline{V}_A > \overline{V}_B$; then $P_A < P_B$. If a pressure P_A is applied to the solution, no A will pass through the membrane, but B will enter the solution, thus increasing the volume of the solution. On the other hand, if a pressure P_B is applied, no B will pass through the membrane, but some A will leave the solution, thereby decreasing its volume. Evidently there will be some intermediate pressure P (where $P_A < P < P_B$) such that the volume of the solution will remain stationary. This will occur when the ratio of the number of moles of A leaving the solution to the number of moles of B entering the solution is in the inverse ratio of their partial molar volumes. When this state is obtained, one might be inclined to call P the "osmotic pressure" of the solution. Actually (if one waits long enough), P will gradually change as diffusion takes place until equation (5) holds, and only then will true equilibrium be established. Accordingly this method of using mixed solvents will make osmotic pressure measurements time consuming, because diffusion must take place and equilibrium cannot be reached by the application of pressure alone. Moreover,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the final pressure will not be the osmotic pressure of the original solution but will be defined as that of the equilibrated solution.

To get the osmotic pressure of the original solution and to avoid diffusion, it would be necessary in principle to start with solvent and solution already satisfying equation (5). Under such circumstances an osmotic equilibrium can be established simply by the application of pressure. In practice this would be almost impossible to realize (especially if Raoult's law does not hold), since it presupposes more knowledge than is generally available.

It will now be shown that van't Hoff's equation holds for dilute solutions even with mixed solvents, providing the osmotic pressure is taken as the above-defined equilibrium pressure and providing Raoult's law applies. If a true equilibrium has been obtained, then $P_A = P_B = P$, and

$$\overline{V}_A P = RT \ln (x'_A/x_A)$$
$$\overline{V}_B P = RT \ln (x'_B/x_B) \qquad (8)$$

In equations (8) the x's apply to the equilibrated solution and solvent and not necessarily to the original ones. But if x_s is very small, then $(x'_A - x_A)/x_A \ll 1$ and $(x'_B - x_B)/x_B \ll 1$. Then approximately

$$\overline{V}_A P = RT \left(\frac{x'_A - x_A}{x_A}\right)$$

and

$$\overline{V}_B P = RT \left(\frac{x'_B - x_B}{x_B}\right) \qquad (9)$$

But from equations (9) it can be shown that

$$(x_A \overline{V}_A + x_B \overline{V}_B) P = x_S RT \qquad (10)$$

Let N_A, N_B and N_S be the total number of moles of A, B and S in a volume V of solution. Then

$$(N_A \overline{V}_A + N_B \overline{V}_B) P = N_S RT$$

or

$$(V - N_S \overline{V}_S) P = N_S RT \qquad (11)$$

Neglecting $N_S \overline{V}_S$ as compared to V, there is obtained van't Hoff's equation

$$PV = N_S RT \qquad (12)$$

If c equals the concentration of S in grams per unit volume, then

$$P/c = RT/M \qquad (13)$$

where M is the molecular weight of the solute.

System not Subject to Raoult's Law.—If Raoult's law does not apply, then the thermodynamic treatment of osmotic pressures for mixed solvents becomes more involved. The equations become complicated because cognizance must be taken of solvent non-idealities even when the system is infinitely dilute with respect to solute. Because of this persisting non-ideality, it is not obvious that van't Hoff's equation will apply at infinite dilution.

However, if one assumes that Henry's law applies to the solute, it can be shown that van't Hoff's equation should be valid at infinite dilution regardless of the nature of the solvents as long as their vapors obey the perfect gas laws. The proof of this proposition rests upon the use of the three-component counterpart of the Duhem–Margules equation, but the details of the calculation will not be supplied here.

Discussion

The first point to be noted in connection with the use of mixed solvents is that the composition of solvent will not be the same on each side of the membrane after osmotic equilibrium is established. Starting with the same solvent ratio on both sides of the membrane, the apparent osmotic pressure (corresponding to a stationary volume) will not in general be the same as the equilibrium pressure. If the difference is appreciable, then the use of a dynamic method of measurement may lead to erroneous results. However, if the mole fraction of solute is small, the apparent osmotic pressure will be practically the same as the final pressure and the solvent composition will be substantially the same on the two sides of the membrane.

If Raoult's law holds, extrapolation of the osmotic pressure equations to infinite dilution will give van't Hoff's equation. In this event, correct molecular weights for solutes can be obtained by the usual simple means. On the other hand, if Raoult's law does not hold for the mixed solvents, extrapolation to infinite dilution of solute will not yield van't Hoff's equation unless the solute obeys Henry's law, which assumption is reasonable. Accordingly, van't Hoff's equation can always be used in practice for extrapolation purposes.

Although the use of mixed solvents introduces some doubtful points, correct results can be obtained but the measurements may be time consuming because of the necessity for diffusion taking place. Gee[2] reports no complications in connection with the use of mixed solvents; in fact he reports certain advantages. It appears that the magnitudes of the new effects discussed in this paper are small for dilute solutions. What the effect will be on the slope of a curve in which P/c is plotted against c cannot be predicted simply.

The author is indebted to Dr. R. H. Ewart of the United States Rubber Company for helpful discussion and suggestions.

Summary

The problem of osmotic pressures for solutions with mixed solvents is considered thermodynamically. It is shown that in general the measured osmotic pressure has definite significance only if the solvent compositions are different on the two sides of the membrane and subject to certain relationships. However, it is shown that van't Hoff's equation can be expected to hold for in-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

finitely dilute solutions. For concentrated solutions certain complications can be expected in the experimental determination of osmotic pressures using mixed solvents, especially if a dynamic approach is employed.

The Concentration Distribution in Two-Salt Moving Boundaries

BY L. G. LONGSWORTH

Introduction.—The development of the schlieren scanning technique[1] for studying the electrophoresis of proteins has, somewhat unexpectedly, provided a tool with which to investigate in detail the moving boundaries that have been used for the measurement of the transference numbers of strong electrolytes. Such boundaries, it will be recalled, are formed between two solutions of binary salts having a common ion, the salt present in the region into which the boundary moves on passage of the electric current being called the "leading" electrolyte whereas that behind the boundary is termed the "indicator" electrolyte. Boundaries of this type will be called "two-salt" boundaries in order to distinguish them from other types of moving boundaries such as protein boundaries[2] and concentration boundaries.[3]

According to the theory developed by Weber[4] the mixing effect of inter-diffusion at a two-salt boundary is balanced by a separating effect due to ion migration[5] if the mobility, u_i, of the indicator ion constituent is less than the mobility, u_1, of the leading ion constituent and if the current is passed in the appropriate direction. Under these conditions the concentration distribution in the boundary for a given current density I is independent of the time and the boundary velocity is given by the relation

$$v = IT_1/FC_1 \qquad (1)$$

in which F is the faraday, T_1 the transference number of the leading ion constituent and C_1 is the concentration, in equivalents per milliliter, in the body of the leading solution. Whereas the concentrations of the salt solutions forming the boundary initially may be selected independently of each other, the concentration, C_i, of the column of indicator electrolyte that is formed by the advancing boundary is not independent of C_1 but is given by the relation

$$C_i = C_1T_i/T_1 \qquad (2)$$

in which T_i is the transference number of the indicator ion at the concentration C_i. If the boundary is formed initially between the leading solution and the indicator solution at a concentration C_i' which is different from that, C_i, required by equation (2), then, as will be demonstrated later in this paper, a concentration boundary between the indicator salt at the two concentrations C_i and C_i' remains near the initial boundary position as the two-salt boundary advances.

In addition to the requirement that $u_i < u_1$ there is the restriction that the boundary system be stable gravitationally. This means that if the indicator solution is less dense than the leading solution the latter must be underneath and the boundary must descend. If the indicator solution is more dense than the leading solution the latter must be on top and the boundary must rise. Moreover, since the densities of most salt solutions increase with increasing concentration, gravitational stability also requires that the initial indicator concentration, C_i', be equal to or greater than that, C_i, of the adjusted indicator solution for a rising boundary whereas for a descending boundary $C_i' \leq C_i$.

Under the conditions prevailing in previous work with two-salt boundaries the transition from one solution to the other occurs within less than a millimeter. Such a sharp boundary can be located accurately with the aid of relatively simple optical arrangements, advantage being taken of the difference of refractive index at the boundary, and this is sufficient for a determination of the boundary displacement and hence the transference number T_1. The optical devices previously employed have not, however, given information concerning the magnitude and distribution of the gradients in the boundary and the manner in which these vary with the current. This information can now be obtained with the aid of the schlieren scanning camera. It is the purpose of this paper to report measurements of the gradients in typical boundaries and to show that they are in agreement with Weber's theory.[4]

Experimental Results.—The patterns of Fig. 1, recorded during the electrolysis at 0.5°, of 0.1 N potassium iodate:0.1 N potassium chloride at a current density of 0.00655 amp./sq. cm., are typical of the results obtained in this research. The time interval between all of the patterns after the second was one hour. In order to avoid overlapping of the concentration boundary peak, each successive pattern has been displaced a fixed distance vertically. The line h_0 in each pattern

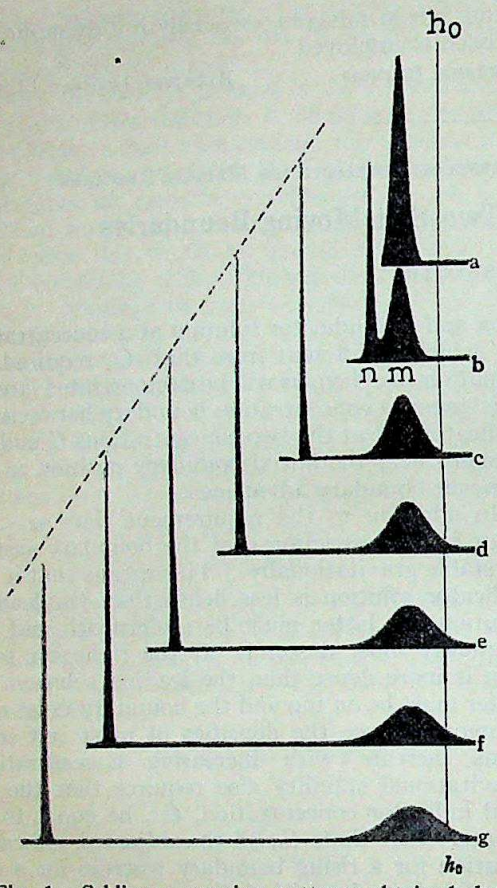

Fig. 1.—Schlieren scanning patterns obtained during the electrolysis of a boundary formed initially between 0.1 N KIO_3 and 0.1 N KCl.

is due to a graduation on the cell that serves as a reference mark from which all boundary displacements are measured. Except for the necessity of automatic regulation of the current[6] in work with two-salt boundaries, the apparatus and experimental procedures employed have been adequately described in recent papers by the author.[3,7]

Several features of the direct moving boundary method, previously inferred but unconfirmed experimentally, are at once apparent in Fig. 1. The first pattern, a, was obtained after the boundary had been formed and shifted from behind the opaque horizontal plates of the cell, but before the electric field was applied. On passage of the current this boundary separated, as shown in Fig. 1b, into the concentration boundary, m, between potassium iodate at the concentrations C_i and 0.1 N and the two-salt boundary, n, between potassium iodate at the concentration C_i and 0.1 N potassium chloride. On continued electrolysis, Figs. 1b–g, the concentration boundary spread progressively due to diffusion whereas the two-salt boundary acquired, by the time the pattern of Fig. 1c was recorded, a salt distribution that remained unchanged.

(6) Longsworth and MacInnes, This Journal, 60, 3070 (1938).

(7) Longsworth, *Chem. Rev.*, 30, 323 (1942).

With the patterns arranged as in Fig. 1, the constancy of the maximum gradient in the two-salt boundary is indicated by the fact that these maxima fall on a straight line. The slight decrease in the height of the peak as the boundary approaches the upper end of the channel, Fig. 1g, is probably due to a small convergence error inherent in the optical system[8] and not to a change in the salt distribution through the boundary. In one experiment in which the boundary displacement was balanced by addition of solution, thereby holding it at the same level and consequently maintaining the convergence error at a constant value, the salt distribution in the boundary did not vary during continuous electrolysis for two weeks.

As recently shown experimentally,[3] the displacement of the concentration boundary, m, of Fig. 1, is proportional to the difference of transference number between the two solutions of potassium iodate forming this boundary. The quantity of electricity passed in this experiment, although sufficient to cause the two-salt boundary, n, to move the length of the channel, was not large enough to permit a reliable determination of the concentration boundary displacement. The area of the peak corresponding to the boundary at m does, however, afford a measure of the concentration adjustment of the indicator electrolyte. Since the refractive index increment[9] for 0.1 N potassium iodate, using the mercury yellow line, is 0.00282 and the area of the concentration boundary corresponds to $\Delta n = 0.00102$, the adjusted concentration C_i is 0.0640 N. The displacement of the two-salt boundary in Fig. 1 gives a value of 0.504 for the anion transference number, T_i, of 0.1 N potassium chloride at 0.5°, in agreement with that, 0.505, obtained by extrapolation of the data of Allgood, Le Roy and Gordon.[10] Substitution of these figures in equation (2) gives 0.323 as the anion transference number, T_i, of 0.064 N potassium iodate. Since the precision of the refraction increments from measurements of pattern areas is about $\pm 1 \times 10^{-5}$, the error in T_i is probably not more than 1%. Although this error is greater than that characteristic of the direct de-

(8) Svensson, *Kolloid-Z.*, 90, 141 (1940).

(9) The refraction increments reported here have been determined at 0.5° with the aid of the schlieren scanning camera and a 60° hollow prism cell. The prism, filled with water, was placed in the thermostat in the focus of the camera, set for minimum deviation, and a scanning photograph was obtained. The prism was then rinsed and filled with a salt solution of known concentration and again photographed. The deflection D due to the salt solution is connected with the refractive index difference Δn and the prism angle α by the relation (R. W. Wood, "Physical Optics," The Macmillan Co., New York, N. Y., 1924) $\Delta n = \sin^{1}/_{2}(\alpha + D)/\sin {}^{1}/_{2}\alpha$. The reproducibility of this differential method, $\Delta n = 5 \times 10^{-6}$, compares favorably with that attainable with the Zeiss-Pulfrich refractometer. I have not been able to find data in the literature for comparison with my values at 0°. I have, therefore, also made measurements at 10°, 18 and 30° for several salts and these are in agreement with the best available data. Contrary to the general impression, the temperature coefficient of the refraction increment is not negligible for many salts at temperatures in the neighborhood of 0°.

termination of T_1 for the leading solution from the displacement of the two-salt boundary, the method just outlined will be useful when other methods are not available.

Another feature of the direct moving boundary method is illustrated in Fig. 2. In this figure the patterns of a 0.064 N potassium iodate: 0.1 N potassium chloride boundary, obtained during electrolysis at three different current densities, have been placed at the corresponding positions on the current axis. When mounted in this manner the maximum gradient of each pattern falls on a straight line passing through the origin, *i. e.*, this gradient is directly proportional to the current. With currents heavier than that corresponding to Fig. 2 c the light deflected by the steepest gradients in the boundary fails to enter the camera objective. Some idea of the sharpness of the boundaries used for routine transference number determinations may be obtained from the fact that the current densities employed range from five to ten times the maximum value used in the present research.

With lithium chloride as the indicator electrolyte for the potassium chloride, the boundary descends since the leading solution is heavier and must remain below. Moreover, the initial indicator salt concentration, C_i', should, therefore, be equal to, or less than, the adjusted concentration, C_i. Thus when a 0.05 N lithium chloride: 0.1 N potassium chloride boundary was studied in the same manner as the potassium iodate: potassium chloride boundary a stable concentration boundary was left behind near the initial position as the two-salt boundary descended. Since the refraction increment for 0.05 N lithium chloride is 0.00047_5 and the area of the concentration boundary corresponded to an increment of 0.00008_7, the adjusted concentration, C_i, may be computed to be 0.0592 N and T_i, by equation (1), is 0.294. When a 0.1 N lithium chloride solution was used to form the boundary, this solution, being heavier than the underlying 0.059 N solution produced by the migration of the two-salt boundary, mixed with the latter and the resulting schliere were clearly visible in the focus of the camera. This convective circulation partially penetrated the boundary, distorting it and causing it to move too rapidly. Similar disturbances were also apparent when the lithium chloride concentration was 0.065 N.

The Theory of Two-Salt Boundaries.—As has been shown conclusively in previous experimental work,[11] a two-salt boundary moves with a constant velocity under the influence of a constant current density. The present research demonstrates that under these conditions the concentration distribution through the boundary also does not change with the time. The concentrations are, therefore, functions of the time t and the coordinate h, *i. e.*, the vertical height in the channel, of the form

$$c = f(h - vt) \qquad (3)$$

in which v is the boundary velocity. This relation is the basis of Weber's theory for the concentration distribution in a two-salt boundary. The following is a brief statement of his theory.

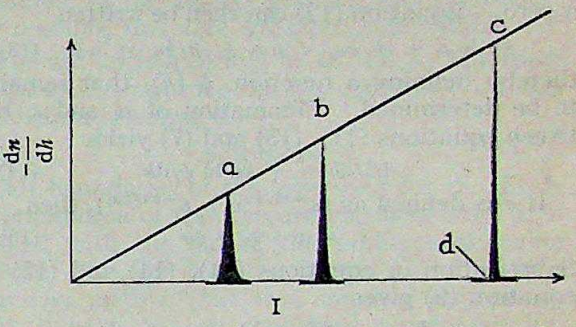

Fig. 2.—Patterns of a 0.064 N KIO_3: 0.1 N KCl boundary at three different current densities.

As has been shown in an earlier paper[11] the equation of continuity for an ion of the j-th kind is

$$\frac{\partial c_j}{\partial t} = \frac{\partial}{\partial h}\left[\frac{c_j u_j}{|z_j|}\left(\frac{\partial \mu_j}{\partial h} + z_j \frac{\partial E}{\partial h}\right)\right] \qquad (4)$$

and the expression for the current density is

$$I = -F\sum_{j=1}^{j=s}\frac{c_j u_j}{z_j}\left(\frac{\partial \mu_j}{\partial h} + z_j \frac{\partial E}{\partial h}\right) \qquad (5)$$

In these equations E and μ are the electrical and chemical potentials, respectively, both expressed in volts. The valence of an ion, account being taken of its sign, is denoted by z whereas $|z|$ indicates the magnitude only.

Since $\partial c/\partial t = -vf'(h - vt) = -v\partial c/\partial h$ from equation (3), equation (4) becomes, after integration

$$vc_j + \frac{c_j u_j}{|z_j|}\left(\frac{d\mu_j}{dh} + z_j \frac{dE}{dh}\right) = A_j \qquad (6)$$

in which A_j is a constant of integration. Since the present treatment will be restricted to a system in which the leading ion, l, and indicator ion, i, are monovalent cations, c denoting the common monovalent anion, equation (6) becomes

$$vc_l + c_l u_l(d\mu_l/dh + dE/dh) = A_l \qquad (7)$$
$$vc_l + c_l u_l(d\mu_l/dh + dE/dh) = A_l \qquad (8)$$
$$vc_c + c_c u_c(d\mu_c/dh - dE/dh) = A_c \qquad (9)$$

At $h = +\infty$, $c_i = 0$ and $A_i = 0$ while at $h = -\infty$, $c_l = 0$ and $A_l = 0$. Moreover, if equation (9) be subtracted from the sum of equations (7) and (8), it will be noted, on comparison with equation (5), that $A_c = I/F$ since electrical neutrality requires that $c_i + c_l - c_c = 0$.

Elimination of dE/dh between equations (7) and (8), followed by integration, assuming the mobilities to be constant, gives

$$\mu_i - \mu_l = (1/u_l - 1/u_i)vh + B' \qquad (10)$$

If, now, the approximation is made that

$$\mu = \mu_0 + k \ln c \qquad (11)$$

in which $k = RT/F$, R being the gas constant in

(11) MacInnes and Longsworth, *Chem. Rev.*, 11, 171 (1932).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

joules per degree and T the absolute temperature, equation (10) may be written

$$\ln(c_i/c_1) = (1/u_1 - 1/u_i)vh/k + B \qquad (12)$$

If the origin is taken at that level in the boundary for which $c_i = c_1$, the constant of integration, B, is zero. Equation (12) can then be written

$$\ln c_i + vh/ku_i = \ln c_1 + vh/ku_1 = \ln \psi \qquad (13)$$

thereby defining a function, ψ (h), that remains to be determined. Elimination of μ_i and c_i between equations (11), (13) and (7) yields

$$dE/dh = -kd \ln \psi/dh \qquad (14)$$

If σ is defined as $(e^{-vh/ku_i} + e^{-vh/ku_1})$, then

$$c_o = c_i + c_1 = \psi\sigma \qquad (15)$$

Substitution of equations (11), (14) and (15) in equation (9) gives

$$d\psi + \left(\frac{v}{2ku_c} + \frac{d \ln \sqrt{\sigma}}{dh}\right)\psi dh = \frac{I}{2kFu_o\sigma}\,dh$$

Since σ is a known function of h, this is an equation of the Bernouilli type[12] whose integrating factor is $\sqrt{\sigma}\, e^{vh/2ku_c}$ and whose solution is, therefore

$$\psi = \frac{I\, e^{-vh/2ku_o}}{2kFu_o\sqrt{\sigma}} \int_{-\infty}^{h} \frac{e^{vh/2ku_o}}{\sqrt{\sigma}}\,dh$$

the lower limit of integration being determined from the condition that ψ must vanish for $h = -\infty$. This is the result obtained by Weber. The same result is also obtained if i and 1 are monovalent anions.

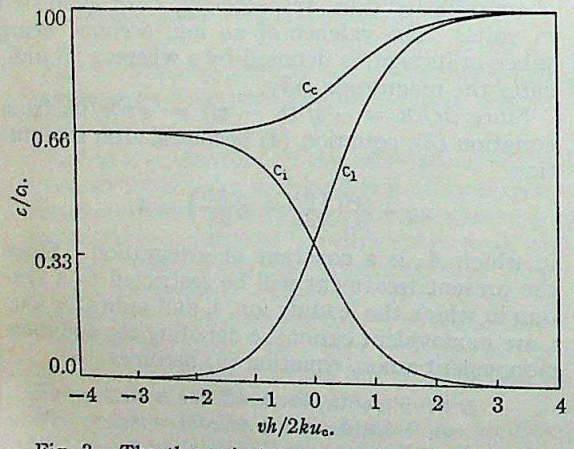

Fig. 3.—The theoretical concentration distributions of the indicator ion, i, the leading ion, 1, and the common ion, c, in a typical two-salt moving boundary.

Computations with the foregoing relations are greatly facilitated if the mobilities u_c and u_1 are simple multiples of u_i, which is very nearly the case for the boundaries studied in this research. Thus, by combining the transference numbers reported earlier in this paper with conductance data, one obtains, at 0° and for 0.1 N solutions, $Fu_K = 35.4 \simeq Fu_{Cl} = 35.9$ whereas $Fu_{Li} = 15.0 \simeq Fu_{IO_3} = 16.2 \simeq {}^1/_2\, Fu_{Cl}$. Consequently a close approximation is made by taking

$$2u_1 = u_1 = u_o = 35.6/F \qquad (16)$$

Equation (13) then becomes, on reference to equation (1)

$$c_1/C_1 = 1 - \sinh^{-1} y/y\sqrt{1 + y^2} \qquad (17)$$

and

$$c_i = c_1/y^2 \qquad (18)$$

in which $vh/2ku_c = \ln y$.

These functions are plotted in Fig. 3 and indicate the distribution of concentrations in a typical two-salt boundary.

Differentiation of equations (17) and (18) yields

$$\frac{2ku_c}{vC_1}\frac{dc_1}{dh} = \frac{1}{1 + y^2}\left(\frac{1 + 2y^2}{y\sqrt{1 + y^2}}\sinh^{-1} y - 1\right) \qquad (19)$$

$$\frac{2ku_o}{vC_1}\frac{dc_1}{dh} = \frac{1}{y^2}\left(\frac{2ku_o}{vC_1}\frac{dc_1}{dh} - 2\frac{c_1}{C_1}\right) \qquad (20)$$

The lower curve of Fig. 4 is a plot, in the reduced coördinates $vh/2ku_c$ and $(2ku_c/vC_1)dc/dh$, of equation (19) after multiplication of the left hand term by 10.8, the equivalent refractive increment for potassium chloride, while the upper curve corresponds to equation (20) after multiplication by 28.2, the increment for potassium iodate. The intermediate curve of Fig. 4 is the sum of the upper and lower curves and represents, therefore, the theoretical gradient curve, dn/dh, of the total refractive index. In so far as the theory is valid, this curve should correspond to those recorded experimentally. The scale of ordinates in Fig. 4 has been inverted to conform to the current practice in the publication of electrophoretic patterns.

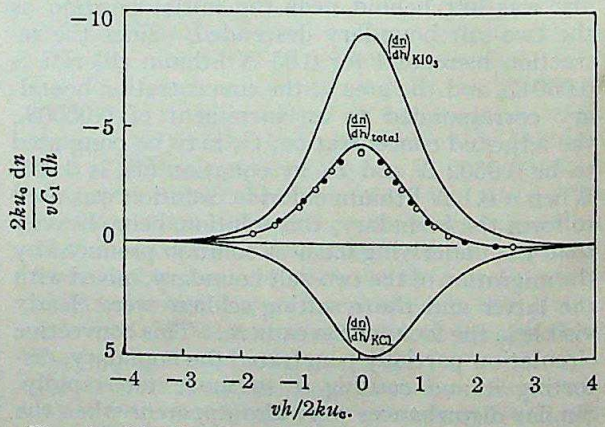

Fig. 4.—Distribution of the gradients dn/dh, of refractive index in a 0.064 N KIO_3:0.1 N KCl boundary.

With the aid of a two-coördinate comparator points were taken from the first two patterns illustrated in Fig. 2 and plotted as the circles and dots, respectively, in Fig. 4.[13] The agreement between

(12) E. B. Wilson, "Advanced Calculus," Ginn and Co., Boston, 1911, p. 210.

(13) Points taken from the pattern of Fig. 2c, corresponding to the highest current density, have not been plotted in Fig. 4 since this sharp boundary appears to be subject to a slight curvature error[3]. A comparison between theory and experiment similar to that of Fig. 4 was also made for the descending lithium chloride: potassium chloride boundary and substantial agreement was found, the somewhat greater deviations being due to divergence of the lithium ion mobility from the relation assumed in equation (16).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

the theory and experiment shown in this figure is surprisingly close, particularly in view of the simplifying assumptions that were found necessary. This agreement would appear to confirm completely the postulated mechanism, *i. e.*, that the boundary is the result of the interaction of diffusion and of ionic migration, and gives us still further confidence in the moving boundary method.

Since the maximum in the total gradient curve does not occur at $h = 0$, it is essential to locate this maximum accurately in order to have a reference point on the abscissa scale from which to plot the experimental data. For this purpose the expression for d^2n/dh^2 was obtained, set equal to zero, and the roots determined from a plot of the function. The position of the maximum depends, of course, on the relative values of the equivalent refraction increments and occurs at $\ln y = 0.419$ for the lithium chloride: potassium chloride boundary and at $\ln y = 0.037$ for the potassium iodate: potassium chloride boundary. In the latter case the theory also predicts a slight minimum in the gradient curve at $\ln y = 2.8$. It is of considerable interest that close inspection of the patterns reveals this minimum (see d of Fig. 2, for example) and that both its position and magnitude are in agreement with the theory. Owing to the relatively great density of potassium iodate solutions the minimum in the refractive index gradient curve is not accompanied by a corresponding minimum in the density gradient and the boundary remains, therefore, gravitationally stable.

The author is indebted to Dr. D. A. MacInnes of these Laboratories for his continued interest and helpful discussion.

Summary

Salt boundaries of the type used for the direct determination of transference numbers have been studied with the aid of the schlieren scanning camera. Several features of the direct moving boundary method that were assumed in previous work have now been confirmed experimentally. Under the influence of a constant current the concentration distribution through a moving boundary does not change with the time and is given accurately by Weber's theory. Moreover, the adjusted concentration of the indicator solution, and hence its transference number, may be determined from the electrophoretic patterns.

The System Ammonium Nitrate–Sodium Nitrate

BY EDWARD O. HOLMES, JR., AND DAVID REVINSON

In connection with the volunteer research program conducted by the Committee on Eutectics of the National Research Council, the senior author found that he was unable to confirm the accepted data on the system ammonium nitrate–sodium nitrate that he used to standardize his technique. The discrepancies in the determination of the points on the solubility curves were so large as to suggest that the work of Early and Lowry[1] on this system might be in error.

As a result, this investigation was begun to redetermine all parts of the system and to study the various factors that might lead to error such as (1) the method of purification of materials, (2) the length of drying of the purified materials and (3) the technique of determining points on the curve.

Purification of Materials.—The pure ammonium nitrate was supplied by the Committee on Eutectics.[2] It was of highest purity and the dry material was found by analysis to contain 100.01% ammonium nitrate. It was ground frequently and kept in a desiccator over Anhydrone for the entire period of the research. This material was used in all determinations.

The sodium nitrate (Merck Reagent) was further purified by two methods: (A) thrice recrystallized from water, ground frequently and kept over Anhydrone; (B) precipitated by concentrated nitric acid, washed with water, twice recrystallized, ground and kept over Anhydrone.

Thermometers.—Two thermometers used were of the twenty-four inch 0.1° type. Both were calibrated against the melting points of pure organic compounds and one by the Bureau of Standards, in addition.

The Melting Point Measurements

(a) Standard Microtechnique.—This technique consisted in weighing out a sample of a tenth of a gram into a three-inch test-tube, fusing the mixture and stirring until clear, cooling and removing the solid melt, grinding it to a powder, introducing a portion of the ground material into a 2-mm. capillary tube and then determining the point at which the last crystals disappeared on very slow heating.

It was found that the Thiele–Dennis melting point apparatus did not give satisfactory results, so a melting point apparatus had to be devised that would permit better heat control and give more uniform results. This was accomplished by building a special gas control valve for the conventional apparatus which consists of a beaker full of oil over a microburner, and surrounding the bulb of the thermometer by a glass basket into which the capillary melting point tube was placed. A description of this apparatus can be found in the *Journal of Chemical Education*.[3]

This method worked quite satisfactorily for the left-hand side of the system, the solubility curve of ammonium nitrate, but difficulty was experienced on the right-hand side, the solubility curve of sodium nitrate. The trouble was caused by a rapid settling out of solid sodium nitrate

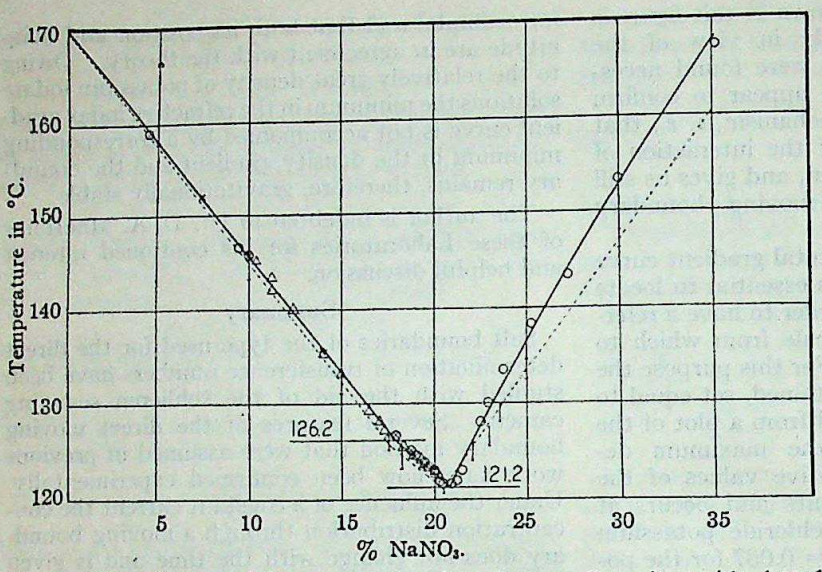

Fig. 1.—Phase diagram of the system ammonium nitrate–sodium nitrate (the dotted lines are Early and Lowry's curves).

crystals on cooling the original melt so that unless the melt was ground and mixed for a long time, a uniform sample could not be obtained. This process was undesirable as ammonium nitrate is very hygroscopic and every effort was made to keep the sample as dry as possible. On account of the steepness of solubility curves, it was absolutely necessary to use samples of accurately known composition, as a 0.1% error in composition makes a 0.3° error in the melting point of the mixture.

No such difficulty was encountered on the ammonium nitrate solubility curves as the crystals were of about the same density as the liquid melt and tended to float or rise slowly, and made a thick mesh long before the eutectic point was reached.

(b) **Improved Microtechnique.**—Our improved microtechnique consisted in eliminating a lack of uniformity of the sample by weighing tenth-gram samples of ammonium nitrate and sodium nitrate directly into a flared 12 mm. tube that had been drawn down into a thin-walled capillary and using the sample as a whole in the melting point determination.

As the rate of heating naturally makes a great difference in the temperature at which the last crystal disappears, observations were usually made at several rates of heating and the melting point at zero rate was obtained by graphical extrapolation.

Vigorous stirring of the oil-bath was necessary regardless of the rate of heating. Once in a while, we succeeded in stopping the oil-bath at the exact temperature at which the last crystal disappeared, which represents a zero-rate of heating. Temperatures so obtained corresponded with those from the zero-rate extrapolation method, as would be expected.

Both samples of sodium nitrate (A) and (B) were used here but no difference was found in the results. Points determined by this technique are considered to be the most reliable and those in which we have the most confidence.

(c) **Macrotechnique.**—The macrotechnique consisted in using a 20-g. sample (to reduce weighing error) in a test-tube, usually six-inch, then heating the sample over a microburner with the same apparatus as in the microdetermination except that the thermometer was placed directly in the melt, and the glass basket omitted. The melt was stirred by a glass stirrer shaped like a ring, which could be moved up and down around the thermometer. With a heating rate of about 0.3–5° per minute, the temperature at which the last crystal disappeared was noted.

The reason for taking such large samples was that Early and Lowry[1] used samples of this size and we wanted to see whether or not the size of the sample had any effect on the temperature at which the last crystal disappeared.

(d) **Cooling Curves.**—In order to compare points obtained by an entirely different method, we ran cooling curves on mixtures weighing 20 g. representing compositions in the various sections of the phase diagram, three on the ammonium nitrate solubility curve, one close to the eutectic and two on the sodium nitrate solubility curve.

The method consisted in weighing the 20-g. samples directly into a test-tube, usually six-inch, fitted with a stirrer. The sample was melted in an oil-bath and then the test-tube with its molten contents was placed in a larger test-tube having glass wool in the bottom and a cork ring to keep the smaller inner tube containing the melt properly centered. The larger tube was placed in an oil-bath over a microburner and the oil stirred with a large ring stirrer during all determinations.

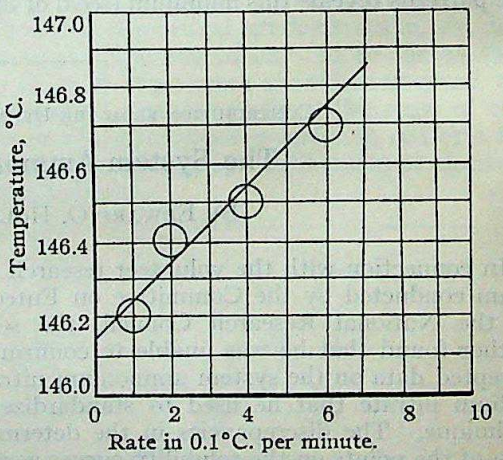

Fig. 2.—Temperatures at which last crystals dissolved, extrapolated to zero rate.

The temperature of the oil-bath was raised until it was several degrees above that at which the crystals were expected to appear on cooling and the melt was perfectly clear. Now the burner valve was set in such a position that the oil-bath would cool slowly to about 115°. The melt and the oil-bath were constantly stirred and the temperature of both read at regular intervals. The temperature at which the first crystals appeared was carefully

TABLE I

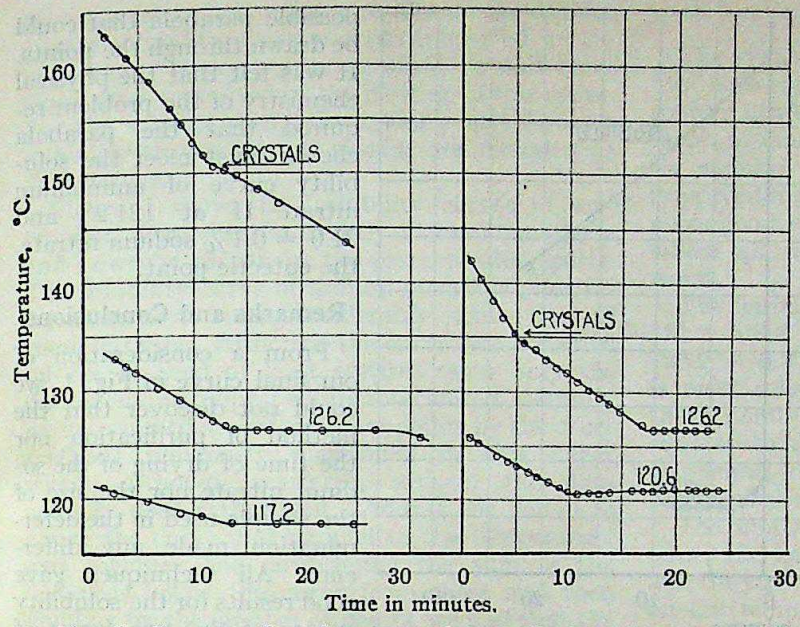

Fig. 3A.—Cooling curve for mixture containing 7.5% $NaNO_3$.

Fig. 3B.—Cooling curve for mixture containing 14.0% $NaNO_3$.

noted in each run. These temperatures appear in Fig. 1 as points marked (X) on the ammonium nitrate solubility curves. Several runs were made on each mixture. In at least one run, each of the mixtures was allowed to cool to the eutectic point. A characteristic cooling curve for each mixture is plotted in Fig. 3 and the results are tabulated in Table I.

When these values, which are averaged values derived from our cooling curves, are considered in relation to the values obtained from our improved microtechnique, it is seen that the temperature of the appearance of crystals and the breaks in the cooling curves correspond closely on the ammonium nitrate side of the diagram. However, on the sodium nitrate side the temperature at which the first crystals appeared on cooling falls above the curve but the break in the cooling curve falls much below in the case of the 25.00% mixture and does not appear at all in the case of the 30.00% mixture. The arrows in Fig. 3 indicate the temperature at which the crystals appeared.

We found the transition temperature for the change of ammonium nitrate I into ammonium nitrate II to be 126.2 ± 0.2° which is a degree higher than the value obtained by Early and Lowry.[1]

We also found that the temperature of the eutectic halt varied with the composition of the melt as Early and Lowry[1] had previously noticed, those values nearer to the eutectic point being constant and in good agreement, while those further away, in either direction, were lower as Table I shows. It seemed reasonable to these authors and also to us to take the average of these constant values near the eutectic point as the true value of the eutectic point, namely, 121.2 ± 0.2°. This value is 0.4° higher than that of Early and Lowry.[1]

Discussion of Results

Both theory and practice indicate that the values of the eutectic temperature from the cooling curve method (Fig. 3) are more reliable than those obtained by any melting point method. It was impossible, no matter how hard we tried nor what technique was used to cause mixtures to melt sharply at or close to the eutectic point: stirring is impossible and heat conduction is the poorest just when the largest amount of heat must be transferred. The melting point methods, whether micro or macro, are at their worst at the eutectic point but improve rapidly at higher temperatures where good stirring is possible and less heat must be transferred through the glass walls of the capillary.

Construction of the Phase Diagram (Fig. 1).—Much careful consideration was given to the construction of the phase diagram. The eutectic temperature and the transition temperature were assumed to be correct, as we obtained repeated check values (±0.2°) for these. We assumed the solubility curve for ammonium nitrate II to be a straight line and its equation was found[4] by the method of least squares, using all points as the consistency of the data is good over

Fig. 3F.—Cooling curve for mixture containing 30.0% $NaNO_3$.

this range. By substituting the eutectic temperature (121.2°) in this equation we found the eutectic composition to be 21.0 ± 0.1%. Similarly, we found the composition at which this line comes to an end at the transition temperature to be 18.0 ± 0.1%.

The equation for the solubility curve of ammonium nitrate II plotted in the region above 120° is

$$\%\ NH_4NO_3 = -0.586(T°C. - 120) + 21.6563$$

For the solubility curve of ammonium nitrate I, we drew a straight line from its melting point to the end of the solubility curve for ammonium nitrate II, as there appeared to be no curvature.

The solubility curve for sodium nitrate presented a problem. Considerable deviation was noticed in the data obtained by the various methods. Moreover, the data suggested that it might consist of two parts but in absence of any other substantiating information we assumed it to be a smooth parabolic curve.

Using the points obtained from our improved microtechnique only, which we considered most reliable because our sample had dried the longest time and our technique had been perfected, we[4] applied the method of least squares to our data and obtained the best parabola that would intersect the solubility curve of ammonium nitrate II at 121.2°. The equation for this parabola plotted in the area above 120° is

$$\%\ NaNO_3 = 20.645 + 0.2556(T°C. - 120) + 0.0009737(T°C. - 120)^2$$

While this is not the best one for the points chosen, the sums of the squares of the deviations are very little greater than those of the best possible parabola that could be drawn through the points. It was felt that the physical chemistry of the problem required that the parabola chosen must meet the solubility curve of ammonium nitrate II at 121.2° and 21.0 ± 0.1% sodium nitrate, the eutectic point.

Remarks and Conclusions

From a consideration of our final curve in Fig. 1, we could not discover that the method of purification nor the time of drying of the sodium nitrate nor the size of the sample used in the determination made any difference. All techniques gave good results for the solubility curves of the two forms of ammonium nitrate. On the other hand the only one that

gave consistent and reliable results on the sodium nitrate solubility curve was our improved microtechnique. Hence points obtained by this technique only were used in the plotting of this curve. For the sake of comparison, Early and Lowry's solubility curves for this system are included as dotted lines.

Figure 1 shows the solubility curves of ammonium nitrate to be slightly higher than Early and Lowry's[1] curves for the corresponding parts. The solubility curve of sodium nitrate is most interesting as it runs considerably above that of these authors. Although the curve was obtained by the method of least squares using only the data from our improved microtechnique, actually we determined seventeen other points by the other methods previously mentioned in this paper which, although scattered, support the data actually used rather well. Adding the distances above the curve and parallel to the temperature axis together and subtracting the sum of the distances below the curve from these and then dividing by the number of points, we find that the average deviation per point is 0.05° under the curve.

Summary

The system ammonium nitrate–sodium nitrate has been redetermined over the range 0–35% sodium nitrate. The solubility curves for the two forms of ammonium nitrate are linear while that for sodium nitrate is distinctly parabolic. An improved microtechnique has been developed that gives good results except near the eutectic point where all melting point methods are at their worst.

The eutectic temperature was found to be 121.2 ± 0.2° and the transition temperature to be 126.2 ± 0.2° by the cooling curve method which is most reliable for these temperatures. Using these points and applying the method of least squares to the curves, the eutectic composition was found to be 21.0 ± 0.1% sodium nitrate and the transition composition to be 18.0 ± 0.1%.

The method of purification of the sodium nitrate, the length of time of drying the materials and the size of the sample appear to have no effect on the temperature of disappearance of the last crystal on heating the melt.

The Heat of Acetylation of α- and β-D-Glucose from the Heats of Combustion of the Pentaacetates[1]

BY THEODORE H. CLARKE AND G. STEGEMAN

In the investigation of the thermal properties of sugars which is being carried out in this Laboratory, some interest developed in the determination of the heats of combustion of α- and β-D-glucose pentaacetate, wherein the isomeric structural differences involve a much heavier radical than is present in the case of α- and β-D-glucose.

In this paper are presented the results of the combustion measurements, the specific heats of the compounds at 25°, and an approximate value of the density (used to correct the weight to the vacuum basis). From these and other data the heats of formation and the heats of acetylation were calculated.

A general description of the calorimetric equipment used in these determinations has been reported.[2] The energy equivalent of the calorimeter was determined by the use of benzoic acid obtained from the National Bureau of Standards. Sample No. 39e having a certified heat of combustion of 26428.4 international joules[3] or 6317.60 conventional cal. per gram mass *in vacuo*, was employed under the following conditions which are recommended.

The reaction is referred to 25°; the oxygen pressure should be 30 atmospheres; the weight of the sample should be 3 g. per liter of bomb volume; the bomb is to contain 3 g. of water per liter of bomb volume.

These conditions were adhered to with sufficient exactness so that no additional corrections were necessary.

The results of six determinations produced a value: C_{Sys} = 2772.95 ± 0.2 cal./°C. (precision error, ± 0.009%). The value was redetermined upon the completion of the measurements and no change was detected. The bomb has a volume of 0.516 liter and contained 1.5 ml. of water and oxygen at an initial pressure of 30 atmospheres. The initial temperature of the calorimeter was adjusted to 22.6 to 22.7° and the average temperature rise was 3.15°. The temperature rise in degrees was determined from the resistance *vs.* time readings as outlined by Dickinson.[4] Calculations of the heats of combustion were made following the method outlined by Dickinson which gives the heat of combustion at the final temperature reached in the combustion process. The necessary specific heats were employed to correct the values to 25°.

Heat Evolved by the Sample = $(C_{Sys.} + C_{Sample})\Delta t - q_{Fe} - q_{HNO_3} - q_{Igniter}$
(For α-isomer, sample 1a) = 8753.37 + 1.86 − 17.60 − 0.58 − 89.14

The defined calorie = 4.1833 int. j.[5] is the unit of energy employed. Deviations are recorded in terms of the precision error.[6] The optical rotations were determined at 20° using the proper dichromate filter to give D line illumination. A two-decimeter tube was employed. Melting points, obtained by the use of an Anschütz thermometer, were determined in the usual manner.[7]

Treatment of Samples.—Two samples each of α- and β-D-glucose pentaacetate were obtained from Eastman Kodak Co. and were given the following treatment:

The original samples were dissolved in and recrystallized from four to six times from absolute alcohol. It was the purpose of the treatment to produce a material whose heat of combustion would show no change following a recrystallization. For example, product 1a (Table I) was recrystallized six times. The sample was then divided and half of it was given an additional crystallization from absolute alcohol. This product is designated as 1b. The two products were then dried *in vacuo* over calcium chloride and drierite, respectively, at room temperature until a constant weight was obtained. The time interval was about twenty-four hours between weighings. An additional drying for twenty-four hours at 40° and in the case of a second sample at 60° and 0.01 mm. resulted in no further loss in weight.

The values for the optical rotations and melting points were reported by Hudson and Dale.[8] For the α-isomer the value of the optical rotation is listed as 96.7° for a 5.302% solution in benzene and a melting point of 112–113°. For the β-isomer the values listed are 2.2° for a 5.061% solution in benzene and a melting point of 132°. The products prepared in this Laboratory gave rotation values of 96.7° and 2.1°, and melting points of 112.7° and 132.0° for the α and β isomers, respectively.

Data.—The combustion data for the prepared products were obtained in the following manner. The first two determinations indicated as 1a were made on the sample which had received the smaller number of recrystallizations. The third and in one case a fourth determination indicated as 1b were made on the sample which had received an additional crystallization. The combustion data and the number of recrystallizations of each product are listed in Table I.

The derived results and certain other data are presented in Table II. The derived values are $-\Delta U_B$, the isothermal heat of combustion in kcal. per mole under the bomb conditions; $-\Delta U_R$, the heat of combustion in kcal. per mole with the reactants and products at a pressure of one atmosphere; $-\Delta H_R$, the isobaric heat of combustion at one atmosphere; and $-\Delta H^0_{f298.16}$, the heat of formation in kcal. per mole at one atmosphere and constant pressure. It was assumed that the product burned was completely oxidized to carbon dioxide and water. The heats of formation of the pentaacetates were calculated from the heats of combustion employing the values, −68,318.1[9] and −94,029.8[10] cal. per mole

for the heats of formation of liquid water and gaseous carbon dioxide.

Discussion of Results

Karrer and Fioroni[11] reported a value for the heat of combustion of glucose pentaacetate. On the basis of the 1942 value for the heat of combustion of benzoic acid and in units of the defined calorie, Karrer and Fioroni's value is 1722.4 kcal. per mole for $-\Delta U_B$. It is not clearly stated that these authors were dealing with α-D-glucose pentaacetate, but this is assumed to be the case. No value has been reported previously for β-D-glucose pentaacetate.

The following equation indicates that the acetylation of glucose with acetic acid is an endothermic reaction for both isomers.

D-glucose (s) + 5 acetic acid (l) = D-glucose pentaacetate (s) + $5H_2O$ (l)

α-isomer, ΔH = 6.32 kcal./mole
β-isomer, ΔH = 8.92 kcal./mole

The use of acetic anhydride, however, produces the acetylation with a considerable evolution of energy.

D-Glucose (s) + 5/2 acetic anhydride (l) = D-glucose pentaacetate (s) + $5/2H_2O$ (l)

α-isomer, ΔH = −30.88 kcal./mole
β-isomer, ΔH = −28.29 kcal./mole

The rather large exothermic value for ΔH in the latter reaction suggests that the use of the acetic anhydride will produce a favorable yield of the pentaacetates since the ΔF value will probably have the same order of magnitude. This is in harmony with experience.

In making the indicated calculations the following thermal values were employed. The values employed have been recalculated by the authors in terms of the defined calorie and based on the 1942 value for the heat of combustion of benzoic acid. This places all values secured by and utilized by the authors on a comparable basis. The heat of combustion of α-D-glucose is given as $-\Delta H_R$ = 669.81 kcal./mole.[12] Employing the values for carbon dioxide and water previously mentioned, the heat of formation was calculated to be −304.28 kcal./mole. The authors used the value obtained by Huffman and Fox for the heat of combustion of β-D-glucose of $-\Delta H_R$ = 671.33 kcal. per mole. Huffman and Fox state that this value is not of the highest precision, but it is probably very near to the true value. While its agreement with a value calculated from solution data is good, Huffman and Fox point out that the same type of irregularities may have complicated both measurements. The calculated heat of formation from the data of Huffman and Fox for β-D-glucose is −302.76 kcal. per mole. The heat of formation of acetic acid was calculated to be −116.20 kcal./mole, from the heat of combustion reported by Schjanberg.[13] The heat of formation of acetic anhydride was calculated to be −149.20 kcal./mole from the heat of combustion by Thomsen.[14]

While the conversion of β- to α-D-glucose is accompanied by a heat evolution of about 1.5 kcal./mole,[12] the conversion of β- to α-D-glucose pentaacetate is accompanied by a heat evolution of about 4.0 kcal./mole. How much of this heat effect is to be attributed to the β- to α-shift about the saccharide carbon cannot be estimated at present on the basis of information now available

Summary

Values for the heats of combustion at 25° and 1 atm. pressure are given for α- and β-D-glucose pentaacetate. The value for the specific heat at 25° is also reported. From these and other data, the heats of formation and heats of acetylation were computed.

The Mode of Action of Sulfonamides

BY IRVING M. KLOTZ

Since the discovery that *p*-aminobenzoic acid inhibits the action of sulfonamides,[1] attempts have been made to correlate the activity of these drugs with their structure. Some investigators[2] soon observed that the sulfonamide potency seemed to be directly related to the amount of the ionic form of the drug. The work of Cowles[3] indicated that sulfonamide activity increased as the acid *pK* of the drug decreased toward 7, but that further increase in acid strength resulted in diminished activity. A more comprehensive study by Bell and Roblin[4] has shown that bacteriostatic activity is a parabolic type of function of acid strength of the sulfonamide, with maximum potency being obtained, in a solution of *p*H 7, with drugs whose *pK*'s are approximately 6.7.

Inasmuch as current opinion attributes sulfonamide activity to the blocking of an enzyme system,[1] it was considered advisable to examine

the available data from the point of view of the general concepts of acidity and the law of mass action. A brief qualitative description of the approach has been given previously.[5] A detailed account of the treatment and results is presented in this paper.

Bacteriostatic Effect of Sulfonamides

Consider a buffer solution with a fixed hydrogen ion concentration, (H^+), a fixed total concentration, T, of the enzyme or protein, P, and a given total concentration, S, of the sulfonamide, HD. Since the buffer equilibrium and the ionization product of water are fixed and known we need consider only the following equilibria in the solution.

$$H^+ + D^- = HD \quad (1)$$
$$H^+ + P = PH^+ \quad (2)$$
$$P + OH^- = POH^- \quad (3)$$
$$P + D^- = PD^- \quad (4)$$

(For basic sulfonamides HD would be replaced by HD^+, D^- by D and PD^- by PD.) For each of these equilibria we may set up the corresponding mass law expression.

$$(H^+)(D^-)/(HD) = K_{HD} \quad (5)$$
$$(P)(H^+)/(PH^+) = K_{PH^+} \quad (6)$$
$$(P)(OH^-)/(POH^-) = K_{POH^-} \quad (7)$$
$$(P)(D^-)/(PD^-) = K_{PD^-} \quad (8)$$

Since the total concentration of sulfonamide must equal the sum of the concentrations of the various forms in which the drug is present in solution, we can write the equation

$$S = (D^-) + (HD) + (PD^-) \quad (9)$$

Similarly for the protein

$$T = (P) + (PH^+) + (POH^-) + (PD^-) \quad (10)$$

It is now possible to derive an expression for S in terms of variables having experimental significance. For convenience in algebraic manipulation, the following definitions have been made.

$$\frac{(D^-)}{(HD)} = \frac{K_{HD}}{(H^+)} = \lambda \quad (11)$$

$$1 + \frac{(H^+)}{K_{PH^+}} + \frac{(OH^-)}{K_{POH^-}} = \sigma \quad (12)$$

Using (6) and (7) to eliminate (PH^+) and (POH^-) from (10) and re-grouping terms one obtains the expression

$$T = \sigma(P) + (PD^-) \quad (13)$$

Similarly, making use of (11) and (8) one can eliminate (D^-) and (HD) in (9) and then use (13) to replace (P) in the resultant expression and obtain

$$S = \left[\left(1 + \frac{1}{\lambda}\right)\frac{\sigma K_{PD^-}}{T - (PD^-)} + 1\right](PD^-) \quad (14)$$

It seems reasonable to assume that bacteriostasis occurs when a given amount of the sulfonamide–enzyme complex, PD^-, has been formed. If S is the quantity of sulfonamide just sufficient to produce bacteriostasis, (PD^-) in (14) must be a constant. To find the drug of maximum potency at a given pH one must minimize S with respect to K_{HD} while (PD^-) and the pH are held constant.

$$\frac{\partial S}{\partial K_{HD}} = \frac{1}{(H^+)}\frac{\partial S}{\partial \lambda} = \frac{(PD^-)\,\sigma K_{PD^-}}{(H^+)[T - (PD^-)]}\left\{\left(1 + \frac{1}{\lambda}\right)\left(\frac{1}{K_{PD^-}}\right)\left(\frac{\partial K_{PD^-}}{\partial \lambda}\right) - \frac{1}{\lambda^2}\right\} = 0 \quad (15)$$

Inspection shows quickly that the factor within the brackets must be the vanishing one. Rearrangement of terms within the brackets and use of (11) to replace λ, leads to the following form of the minimizing condition

$$\frac{d \ln K_{PD^-}}{d \ln K_{HD}} = \frac{(H^+)}{K^0_{HD} + (H^+)} \quad (16)$$

where K^0_{HD} is the acid ionization constant of the drug which is active at a minimum S. Using the symbol f to represent the left-hand side of (16) and then converting the latter equation into its logarithmic form, one obtains

$$pK^0_{HD} = p\mathrm{H} - \log\left(\frac{1 - f}{f}\right) \quad (17)$$

Were f known for the bacterium–sulfonamide complex, one could calculate K^0_{HD}, and for *E. coli*, for example, the value so obtained could be compared with that observed by Bell and Roblin.[4] In the absence of the pertinent data, one can still test (17) by using the known value of pK^0_{HD}, calculating f for the *E. coli*-sulfonamide complex, and comparing the value so obtained with that which may be derived from the work of Davis and Wood[6] for the plasma protein–sulfonamide complex.

Bell and Roblin[4] found that a plot of bacteriostatic effectiveness versus pK for about a hundred sulfonamides in a solution at pH 7 showed a maximum at a pK of about 6.7. Substituting the appropriate values into (17) we find $f = 0.3$.

Davis and Wood,[6] using a dialysis technique, have determined the amounts of sulfonamide bound to plasma protein for a series of seven drugs. They have expressed their results "as the percentage of the value of the unbound drug which is bound per gram of protein."[6] If we designate this percentage by 100α, and in view of the approximate nature of the following calculation consider P directly proportional to T (see equation (13)), then

$$(\text{Bound drug}) = \alpha\sigma(P)\,(\text{Unbound drug}) \quad (18)$$

where the parentheses represent concentrations. Since the unbound drug may consist of HD and D^-, (18) becomes

$$(PD^-) = \alpha\sigma(P)[(HD) + (D^-)] \quad (19)$$

Making use of (5) one obtains

$$(PD^-) = \alpha\sigma(P)\left[(D^-)\frac{(H^+)}{K_{HD}} + (D^-)\right] \quad (20)$$

Since the pH of the solutions used by Davis and Wood was 7.4, one may insert the numerical value of (H^+) and transform (20) into

(5) Klotz, *Science*, **98**, 62 (1943).

$$\frac{(PD^-)}{(P)(D^-)} = \alpha\sigma\left[\frac{4.0 \times 10^{-8}}{K_{HD}} + 1\right] \qquad (21)$$

The left-hand side of (21) is the inverse of K_{PD^-}, the dissociation constant of the serum protein–sulfonamide complex (P being expressed in grams, the other concentrations in moles). Hence, one may write

$$\sigma K_{PD^-} = \frac{1}{\alpha\left[\frac{4.0 \times 10^{-8}}{K_{HD}} + 1\right]} \qquad (22)$$

Using values of α given by Davis and Wood[6] and those of K_{HD} in the tables of Bell and Roblin[4] we have calculated σK_{PD^-} for six of the seven drugs for which data are available. (The results for sulfaguanidine have been omitted, because of the conflicting data in the literature on its acid ionization constant. If the acidity is actually too small to be measured in water then the ionization constant of the acid form of sulfaguanidine, HD^+, should be used in the following graph.) Figure 1 shows that a straight line is a sufficiently good approximation to the relationship between log (σK_{PD^-}) and log K_{HD}, for the available data are not very precise. The slope of the line is f and is equal to 0.5. Thus if there is any similarity in behavior of the proteins in *E. coli* to those in blood plasma, the value of 0.3 obtained for the former case is apparently a very reasonable one.

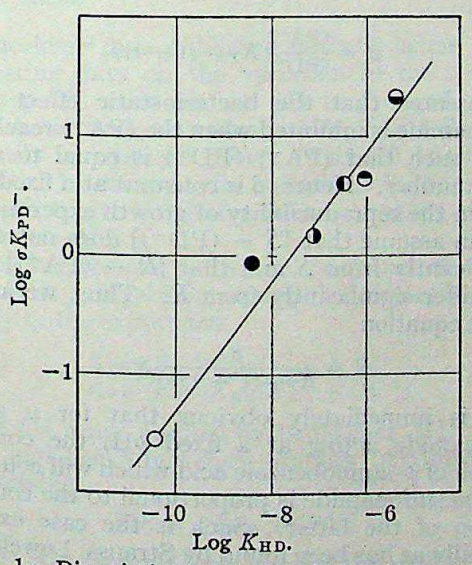

Fig. 1.—Dissociation constants of the plasma protein–sulfonamide complexes: ◒, sulfacetamide; ◓, sulfapyrazine; ◐, sulfadiazine; ◑, sulfathiazole; ●, sulfapyridine; ○, sulfanilamide.

Equation (17) also predicts that as the pH of the medium is increased, the pK of the sulfonamide of maximum potency should also increase. This is in agreement with the results reported by Cowles[3] for *E. coli*. His data, summarized in Fig. 2, show a definite displacement of the potency curves toward higher pK's as the pH is increased. Similar results have been obtained by Brueckner[7] for *Staph. aureus*, *B. subtilis* and *Ps. pyocyanea*.

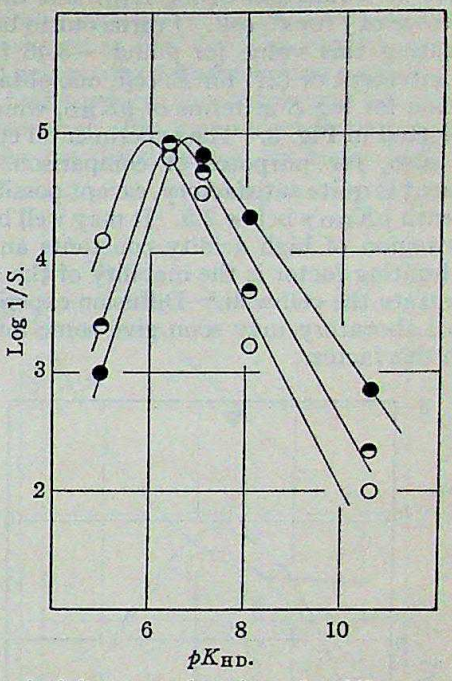

Fig. 2.—Activity as a function of acidity at various pH's for *E. coli*: ○, pH 6.0; ◓, pH 6.8; ●, pH 7.6.

These results indicate that a reasonable first approximation to the relationship between K_{PD^-} and K_{HD} would be

$$K_{PD^-} = kK_{HD}{}^{f} \qquad (23)$$

the integrated form of

$$\frac{d \ln K_{PD^-}}{d \ln K_{HD}} = f \qquad (24)$$

f and k being constants. This equation may be substituted into (14) to give an explicit expression for S, which in turn may be converted into logarithmic form

$$\log [S - (PD^-)] = \log k' + \log\left(1 + \frac{H^+}{K_{HD}}\right) + f \log K_{HD} \qquad (25)$$

k' is a constant for a fixed pH and is given by the equation

$$k' = \frac{\sigma k(PD^-)}{T - (PD^-)} \qquad (26)$$

In general, the amount of bound drug, (PD^-), will be small compared to the total amount of sulfonamide. Hence, we may use log S instead of log $[S - (PD^-)]$ in equation (25), and obtain the following expression after a simple rearrangement

$$\log S - \log\left(1 + \frac{H^+}{K_{HD}}\right) = \log k' + f \log K_{HD} \qquad (27)$$

This relationship affords an alternative and more reliable method of evaluating f from the entire range of data, as well as an opportunity for evaluating k'.

Using the data of Bell and Roblin,[4] one can plot the sum of the terms on the left-hand side of equation (27) as a function of log K_{HD} and thus obtain a value of f for *E. coli*. f turns out to be 0.37. Substituting this value for f and -3.46 for log k', the intercept of (27) for *E. coli*, one obtains an expression for log S in terms of pK_{HD}, which has been plotted in Fig. 3. The experimental curve is shown also, for purposes of comparison. The agreement is quite satisfactory, except possibly for drugs with pK_{HD}'s below 3.5. It may well be that in this region of high acidity constants an additional limiting factor is the inability of the anions to penetrate the cell wall.[3] Diffusion experiments in this Laboratory may soon give some information on this factor.

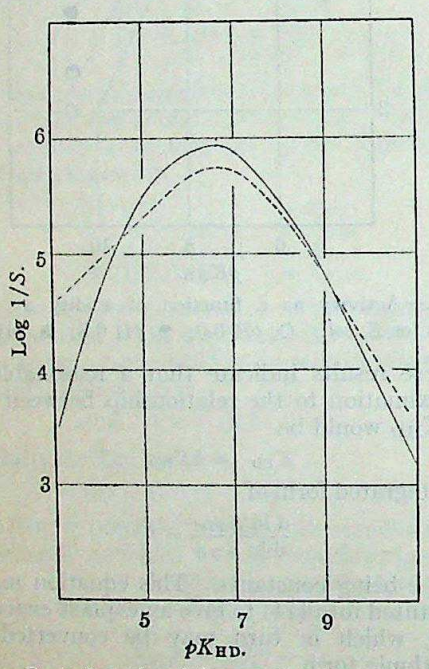

Fig. 3.—Bacteriostatic acivity as a function of acidity, for *E. coli*: - - -, calculated; ——, experimental.

Inhibition of Bacteriostasis by *p*-Aminobenzoic Acid

The inhibitory action of *p*-aminobenzoic acid on sulfonamide activity is also amenable to the mass law treatment. Consider a buffer solution containing a total concentration, T, of enzyme and a concentration, R, of *p*-aminobenzoic acid, HA. To this solution the sulfonamide is added until one reaches a concentration, S, beyond which bacteriostasis will set in. For the solution described one must consider two more equilibria in addition to those of equations (1) to (4).

$$H^+ + A^- = HA \quad (28)$$
$$P + A^- = PA^- \quad (29)$$

In addition to equations (5), (6), (7), (8) and (9) which the system must satisfy we can set up the following mass law expressions

$$(H^+)(A^-)/(HA) = K_{HA} \quad (30)$$
$$(P)(A^-)/(PA^-) = K_{PA^-} \quad (31)$$

and the following stoichiometric relationships

$$R = (A^-) + (HA) + (PA^-) \quad (32)$$
$$T = (P) + (PH^+) + (POH^-) + (PD^-) + (PA^-) \quad (33)$$

With these new equations one can derive a suitable expression for R. Rearrangement of (9) gives the equation

$$(D^-) = \frac{S - (PD^-)}{1 + 1/\lambda} \quad (34)$$

A similar expression, obviously, can be written for (A^-)

$$(A^-) = \frac{R - (PA^-)}{1 + 1/\rho} \quad (35)$$

where

$$\rho = \frac{K_{HA}}{(H^+)} = \frac{(A^-)}{(HA)} \quad (36)$$

The quotient of (34) by (35) becomes

$$\frac{(D^-)}{(A^-)} = \frac{S - (PD^-)}{R - (PA^-)} \frac{1 + 1/\rho}{1 + 1/\lambda} \quad (37)$$

Making use of (8) and (31) to obtain another expression for the ratio $(D^-)/(A^-)$

$$\frac{(D^-)}{(A^-)} = \frac{(PD^-)K_{PD^-}}{(PA^-)K_{PA^-}} \quad (38)$$

we can obtain the following equation

$$[R - (PA^-)] = \frac{\beta}{K_{PD^-}(1 + 1/\lambda)} [S - (PD^-)] \quad (39)$$

where

$$\beta = \frac{(PA^-)}{(PD^-)} K_{PA^-}(1 + 1/\rho) \quad (40)$$

We assume that the bacteriostatic effect of a sulfonamide is inhibited when the (PA^-) reaches a value such that $(PA^-)/(PD^-)$ is equal to some fixed number. Hence, β is constant at a fixed pH. Within the reproducibility of growth experiments, we can assume that $[S - (PD^-)]$ does not differ significantly from S and that $[R - (PA^-)]$ does not differ significantly from R. Thus, we arrive at the equation

$$R = \frac{\beta}{K_{PD^-}(1 + 1/\lambda)} S \quad (41)$$

It is immediately obvious that for a given sulfonamide acting at a fixed pH, the concentration of *p*-aminobenzoic acid which will counteract the sulfonamide is proportional to the concentration of the latter. Such is the case experimentally as has been found by Strauss, Lowell and Finland,[8] by Wood,[9] and by Brueckner.[7]

Furthermore, the following equation can be derived readily from (41) and (23)

$$\log \frac{R}{S} = \log \frac{\beta}{k} - 0.37 \log K_{HD} - \log \left(1 + \frac{H^+}{K_{HD}}\right) \quad (42)$$

The data of Rose and Fox[10] have been used to test this relationship. Only one constant, log β/k, has been evaluated from their data, and the calcu-

lated values of log R/S have been compared, in Fig. 4, with the logarithm of the observed ratios. The experimental points do not deviate from the theoretical line to a degree greater than the reproducibility of the results.

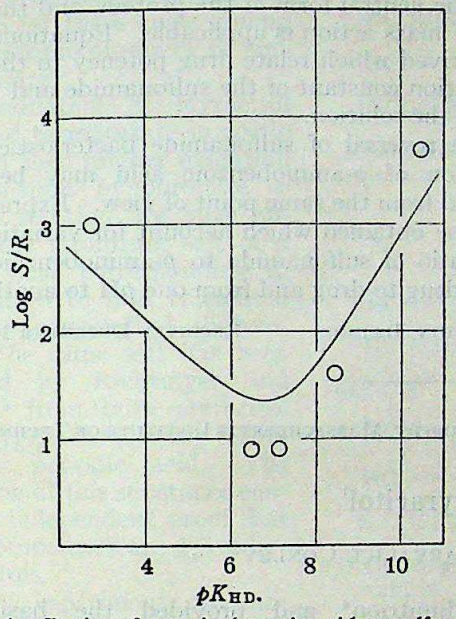

Fig. 4.—Ratios of *p*-aminobenzoic acid to sulfonamide. The solid line is the calculated curve, the circles the experimental points.

Brueckner[7] has published recently some very interesting data on the variation in the sulfonamide–p.a.b. ratio as the *p*H is changed. His work shows that for sulfanilamide, S/R falls continuously as the *p*H range from 6.5 to 8.9 is covered. In contrast, for sulfathiazole, S/R falls from *p*H 6.0 to 7.0 but remains constant thereafter until *p*H 8.9.

Such behavior is a direct consequence of equation (41). Algebraic manipulation leads one readily to the expression

$$\frac{S}{R} = \frac{K_{PD^-}(PD^-)K_{HA}[K_{HD} + (H^+)]}{K_{PA^-}(PA^-)K_{HD}[K_{HA} + (H^+)]} \qquad (43)$$

In the *p*H range studied by Brueckner, $(H^+) << K_{HA}$, and hence one may simplify (43) into the relationship

$$S/R = \epsilon[K_{HD} + (H^+)] \qquad (44)$$

where ϵ is a constant for a given sulfonamide. The reason for the very different behavior of sulfanilamide and sulfathiazole now becomes obvious. In the former case ($pK = 10.43$), $K_{HD} << (H^+)$ over the entire *p*H range, and hence S/R should be directly proportional to the (H^+) concentration. For sulfathiazole ($pK = 7.12$), however, (H^+) is larger than K_{HD} only for *p*H's quite a distance below 7, and at *p*H's appreciably above 7, (H^+) becomes negligible with respect to K_{HD}. Hence, S/R falls uniformly down to a *p*H of about 7, but beyond that becomes constant, because the right-hand side of (44) becomes essentially constant.

That the experimental data agree satisfactorily with the quantitative predictions of equation (44) is shown in Fig. 5. The results have been plotted in logarithmic fashion to expand the region of low hydrogen-ion concentration, but it should be noted that this form of representation also magnifies the discrepancies for small S/R ratios.

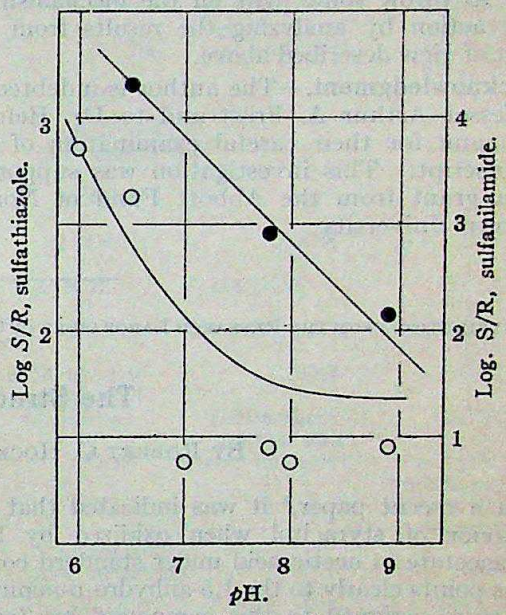

Fig. 5.—Ratios of *p*-aminobenzoic acid to sulfonamide as a function of *p*H for *Staph. aureus:* ●, sulfanilamide; ○, sulfathiazole; ——, calculated values.

Conclusion

These calculations show that on the basis of the simple assumption that sulfonamide inhibition of bacterial growth is due to a reversible combination between the basic molecule or anion and an enzyme one can account quantitatively for the various aspects of bacteriostasis and for the resumption of growth by the addition of *p*-aminobenzoic acid. Other more detailed hypotheses[3,4] are unnecessary, and do not give as comprehensive a picture as that derived from the law of mass action.

It should be pointed out, however, that the equations which have been derived may express only a necessary condition for activity but not a sufficient one. It is quite likely that some compounds combine with the enzyme and, nevertheless, are not chemotherapeutically active. Thus, Davis and Wood[6] have found that metanilamide and various inactive substituted sulfonamides, as well as active sulfonamides, combine with blood plasma proteins. Perhaps some structural factor is included in the conditions for activity, but the nature of this additional factor will probably be uncertain until the enzyme system or systems involved are identified clearly.

The equations derived here are based on very

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

general fundamental principles which may be applicable to many other chemotherapeutic or biological actions. Anionic antiseptics in general, if their action is reversible, may fit equations analogous to those derived above. The equations describing the action of cationic reagents can also be derived very readily. When comprehensive quantitative data on drug activities in these various cases are available, it may be possible to throw some light on the mechanism of their action by analyzing the results from the point of view described above.

Acknowledgment.—The author is indebted to Professor Arthur A. Frost and to Dr. Helmut Gutmann for their careful examination of the manuscript. This investigation was supported by a grant from the Abbott Fund of Northwestern University.

Summary

The inhibition of bacterial growth by sulfonamides may be accounted for quantitatively by assuming that the action is due to a reversible combination between the basic form of the drug and the neutral form of the protein, and that the law of mass action is applicable. Equations may be derived which relate drug potency to the acid ionization constant of the sulfonamide and to the *p*H of the solution.

The reversal of sulfonamide bacteriostasis by addition of *p*-aminobenzoic acid may be considered from the same point of view. Expressions may be obtained which account for variations in the ratio of sulfonamide to *p*-aminobenzoic acid from drug to drug and from one *p*H to another.

The Structure of Styracitol[1]

BY ROBERT C. HOCKETT AND MARYALICE CONLEY[2]

In a recent paper,[3] it was indicated that the behavior of styracitol when oxidized by lead tetraacetate in acetic acid under standard conditions points clearly to the 1,5-anhydro-D-mannitol structure assigned to this compound by Zervas and Papadimitriou.[4] It was stated further that because the configuration of styracitol has been the subject of so much controversy[5] and because this oxidation method is relatively new, we would seek other evidence concerning the configuration of this substance. The rate-of-oxidation measurement would appear to offer an extremely simple and rapid method of solving such structural problems as this, provided that it can be depended upon invariably to give the right answer. Hence the establishment of the styracitol structure beyond question was essential to any extension of the oxidation procedure to other problems.

In 1931, Asahina and Takimoto[5] reported the complete methylation of this anhydro-alcohol and claimed the isolation of *d*-dimethoxysuccinic acid from the products of oxidation of tetramethyl styracitol by nitric acid. The formation of this acid is entirely incompatible with the 1,5-anhydromannitol structure assigned by Zervas and Papadimitriou[4] and provided the basis for Asahina's claim that styracitol is 1,5-anhydro-D-sorbitol. Zervas' synthesis of the compound[5] appears to establish the position of the ring and to limit the structural possibilities to the two alternatives mentioned.

We have undertaken to repeat the work of Asahina and Takimoto in order to discover the cause of this disagreement. Styracitol has been prepared synthetically by the method of Zervas.[5] Methylation by the procedure of West and Holden[6] yielded a tetramethyl ether of the expected composition and whose properties agreed well with those reported by the Japanese workers and by Freudenberg and Sheehan.[5] On oxidation of this ether with nitric acid, we obtained two substances that were definitely identified by means of well-known derivatives. These were oxalic acid and *l*-(−)-dimethoxysuccinic acid. None of the *d*-(+)-dimethoxysuccinic acid was found and the mother liquor left after separation of the two acids described above was somewhat levorotatory. Therefore, the experimental observations of Asahina and Takimoto were erroneous.

It should be noted that while the formation of the *d*-dimethoxysuccinic acid would be definitive, the levo isomer could be produced from either structure proposed for styracitol. Hence, the present work must be regarded as only removing a puzzling discrepancy and not in itself a structure proof. The isolation of *meso*-dimethoxysuccinic acid, D-arabotrimethoxyglutaric acid or of D-xylotrimethoxyglutaric acid would be necessary to complete the proof. Since, however, Richtmyer

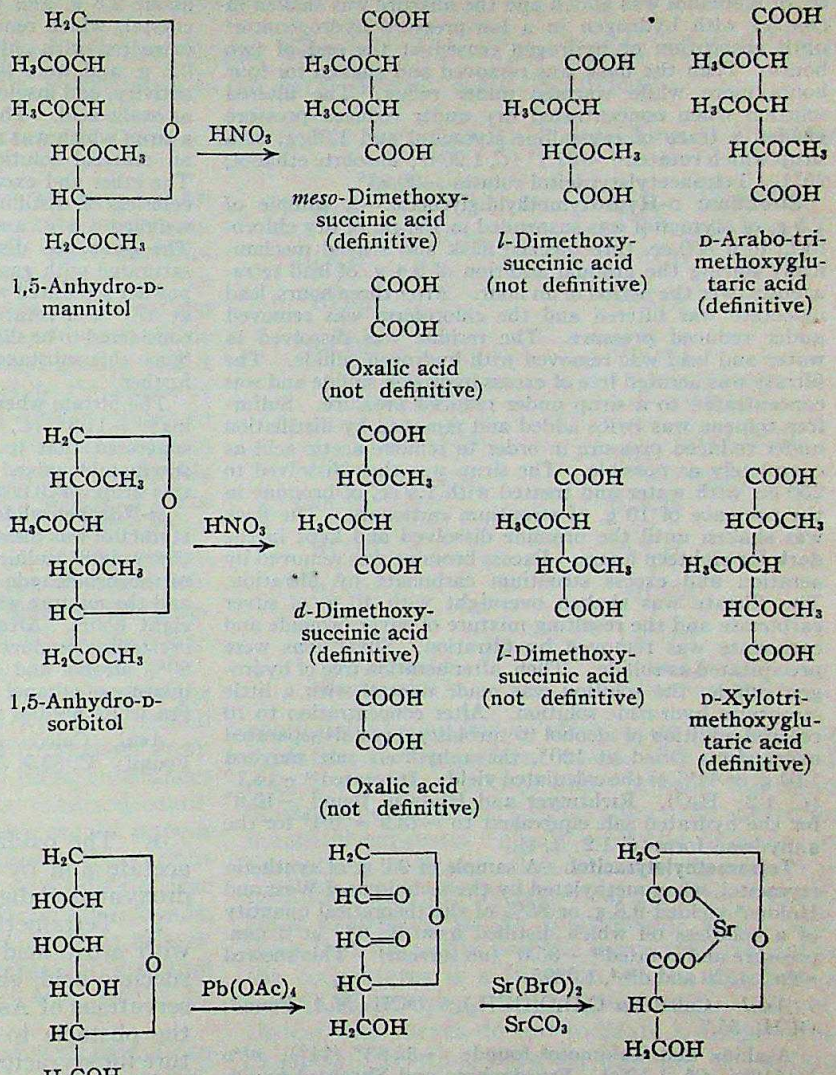
and Hudson have further confirmed the conclusions of Zervas and Papadimitriou first by demonstrating that polygalitol and styracitol are epimers and then by synthesis of polygalitol,[7] a search for these acids among the oxidation products is now unnecessary.

By oxidation of styracitol with lead tetraacetate in acetic acid and then further oxidation by strontium hypobromite in aqueous solution, we have obtained the strontium salt of a dibasic acid corresponding in composition to that calculated for D-hydroxymethyl diglycolate. The same salt has been obtained by Richtmyer and Hudson[8] from both styracitol and polygalitol following oxidation by periodic acid. The formation of this substance constitutes independent proof that these compounds are 1,5-anhydrohexitols.

In one experiment, we substituted Adams platinum oxide catalyst[9] in an alcoholic medium for palladium in acetic acid for the hydrogenation of tetraacetylhydroxyglucal to tetraacetyl-1,5-anhydrohexitol. The hydrogen absorption occurred normally but the main product was not tetraacetylstyracitol. Instead, a sirup of opposite sign of rotation[10] +37.1 (*C*, 1.2037; alcohol; 25°) was obtained. Richtmyer and Hudson[8] have reported a rotation of +38.9° (in $CHCl_3$) for tetraacetylpolygalitol. This experiment not only supports the claim that these two anhydro alcohols are epimers[11] but suggests the possibility of controlling the course of hydrogenation. This possibility will be explored further.

We report also the properties of a mono-*m*-nitrobenzylidenestyracitol prepared by Dr. Mortimer H. Nickerson, formerly of this Laboratory.[12]

POSSIBLE OXIDATION PRODUCTS OF TETRAMETHYLSTYRACITOL



Experimental

Tetraacetylstyracitol.—Tetraacetylhydroxyglucal was prepared by the method of Maurer and Mahn[13] and palladium black by the method of Willstätter and Waldschmidt-Leitz.[14] A sample of 13.2 g. (0.08 mole) of the former and 2.0 g. of the latter was placed with 100 cc. of pure acetic acid in a modified Adams hydrogenation apparatus[9] and shaken in contact with hydrogen at 23 lb. pressure. The pressure fell about 4.5 lb. (900 cc. of hydrogen absorbed) within a few hours (calcd. 895 cc.). After eight hours at room temperature, the catalyst was filtered and the solution was diluted with an equal volume of water. Three extractions with 75-cc. portions of chloroform were made and the combined extracts were washed free of acetic acid with 3% aqueous sodium bicarbonate, dried with sodium sulfate and concentrated under reduced pressure to a sirup.

Styracitol.—The sirupy tetraacetylstyracitol was dissolved in 40 cc. of dried methanol in which a tiny piece of sodium had been dissolved and the mixture was heated under reflux at 70° bath temperature for one hour. On cooling, 3.2 g. of styracitol separated, and 0.5 g. more was recovered after concentrating; yield, 57%. The product melted 154–155° and rotated[10] −50.9° (*C*, 0.4900; H_2O). Asahina gives m. p. 155° and rotation −49.9° (H_2O; 17°) as the constants for styracitol from *Styrax obassia*.

Hydrogenation of Tetraacetylhydroxyglucal with Platinum Catalyst.—Adams platinum oxide[9] (0.3 g.) was reduced with hydrogen in the presence of 10 cc. of dry

methanol. Then 2 g. of acetylated hydroxyglucal in 40 cc. of methanol was added and the mixture was shaken in contact with hydrogen in a low-pressure hydrogenator[9] until absorption of hydrogen ceased at the end of two hours. Then the flask was removed and shaken for four hours more while warmed under reflux. The filtered solution when concentrated dry under reduced pressure yielded a trace of crystalline styracitol and 1.05 g. of a sirup which rotated[10] +37.1° (*C*, 1.2037; absolute ethanol; 25°). Tetraacetylstyracitol rotates −20.86°.

Strontium D-Hydroxymethyldiglycolate.—A sample of 1.5 g. of styracitol was suspended in 150 cc. of dry chloroform in a 500-cc. three-necked flask and stirred mechanically during the gradual addition of 9.4 g. of lead tetraacetate over the period of an hour. After three hours, lead diacetate was filtered and the chloroform was removed under reduced pressure. The residue was dissolved in water and lead was removed with hydrogen sulfide. The filtrate was aerated free of excess hydrogen sulfide and was concentrated to a sirup under reduced pressure. Sulfur-free toluene was twice added and removed by distillation under reduced pressure in order to remove acetic acid as completely as possible. The sirup was then dissolved to 250 cc. with water and treated with 1.5 cc. of bromine in the presence of 10 g. of strontium carbonate. The flask was shaken until the bromine dissolved and kept in the dark for eighteen hours. Excess bromine was removed by aeration and excess strontium carbonate by filtration. The filtrate was shaken overnight with 10 g. of silver carbonate and the resulting mixture of silver bromide and carbonate was removed by filtration. Silver ions were precipitated as sulfide. Then, after aeration free of hydrogen sulfide, the solution was made neutral with a little strontium hydroxide solution. After concentration to 10 cc. and addition of alcohol to turbidity, crystals separated overnight. Dried at 120°, the anhydrous salt weighed 1.04 g. or 44% of the calculated yield. It rotated[10] −14.1° (*C*, 1.2; H_2O). Richtmyer and Hudson[7] found −10.8° for the hydrated salt equivalent to −13.9 ± 0.4° for the anhydrous form (*C*, 1.2; 1, 4).

Tetramethylstyracitol.—A sample of 9.0 g. of synthetic styracitol, when methylated by the technique of West and Holden[6] yielded 9.8 g. or 85% of the theoretical quantity of a colorless oil which distilled from 88–93° at 2 mm. pressure and rotated[10] −35.0° (no solvent). This showed $n^{23}D$ 1.4520 and $d^{26.5}_4$ 1.0895.

Anal. Calcd. for $C_6H_8O(OCH_3)_4$: OCH_3, 56.4. Found: OCH_3, 55.7.

Asahina and Takimoto[5] found: −35.63° (14°); $n^{14}D$ 1.45162; d^{18}_4 1.1092. Freudenberg and Sheehan[5] found: −36.5°(23°); n^{25} 1.4520; d 1.0849.

Oxidation of Tetramethylstyracitol by Nitric Acid.—A mixture of 5 g. of tetramethylstyracitol and 33 cc. of concentrated nitric acid (d. 1.42) was digested on the steam-bath for five hours. Then the mixture was diluted with water and concentrated under reduced pressure to a sirup. Water was added and reëvaporated six times to remove most of the nitric acid. The residue weighed about 2.5 g. and was a mixture of sirup and large flat crystals which remained undissolved when the sirup was extracted with chloroform. The crystals weighed about 0.5 g. and were identified by melting point, optical inactivity, and insolubility of the calcium salt in acetic acid, as oxalic acid. The chloroform extract was evaporated to a sirup which was redissolved in dry ether and mixed with an ethereal solution of diazomethane[15] in large excess. The ether and excess reagent were evaporated to leave a colorless oil distilling from 70–85° at 0.5 mm. The liquid weighed 1.6 g. and rotated[10] −8.4° (*C*, 2.3; CH_3OH). The ester was dissolved in dry methanol (10 cc.) and saturated with gaseous ammonia. Almost at once a fine powder separated which was filtered and dried. It melted at 270° and rotated −78.2° (*C*, 0.0192; H_2O). It was considered to be slightly impure *l*-dimethoxysuccinamide.[16] Since this substance is not definitive, it was not purified further.

The filtrate when evaporated dry yielded a sirup rotating[10] −11.3° (*C*, 1.7288; CH_3OH). The low rotation suggested that it contained a little more *l*-dimethoxysuccinamide mixed with inactive material. The weight of this sirup was 0.6634 g.

***m*-Nitrobenzylidenestyracitol.**—A sample of 0.4 g. of styracitol was dissolved in 1 cc. of water and 1 cc. of 50% (by weight) sulfuric acid was added. Then 1 g. of *m*-nitrobenzaldehyde in 3.5 cc. of butyl acetate was added and the mixture was shaken mechanically for about forty-eight hours. After two more days in a refrigerator, a crystalline product was filtered, washed with 50% alcohol, 80% alcohol and dry ether. Recrystallized from a 1:3 mixture of ethanol and ethyl acetate, the substance formed fine white needles melting 175–175.5°.

Anal. Calcd. for $C_{13}H_{16}O_7N$: C, 52.6; H, 5.05. Found: C, 52.9, 52.5; H, 5.60, 5.72.

Summary

1. The oxidation of styracitol by lead tetraacetate and by strontium hypobromite to D-hydroxymethyl diglycolate is described.

2. Tetramethylstyracitol has been oxidized with nitric acid to oxalic acid and *l*-dimethoxysuccinic acid, showing that the experimental observations of Asahina are incorrect and removing the obstacle to acceptance of the Zervas structure for styracitol.

3. A *m*-nitrobenzylidene derivative of styracitol is described.

Lead Tetraacetate Oxidations in the Sugar Group. V.[1] The Rates of Oxidation of Open-Chain Polyalcohols in Dry Acetic Acid Solution[2]

BY ROBERT C. HOCKETT, MARGARET T. DIENES, HEWITT G. FLETCHER, JR.,[3] AND HUGH E. RAMSDEN

In a series of recent papers,[1,4] we have shown the behavior toward lead tetraacetate, of a number of vicinal triols in which the three carbinol groups form part of a six-membered ring. In such structures, the configurations of the carbon atoms are responsible for definite and predictable space relations among the hydroxyl groups and it has been found possible to correlate the shape of the oxidation curves obtained under standard conditions, with these space relations and certain other structural features. It appears possible from these correlations, to predict which of three types of oxidation curve will be found for a given glycopyranoside or, conversely, to deduce certain structural features from the type of curve observed. Moreover, the same considerations apply to anhydrides of polyalcohols[4] as to glycopyranosides of like ring type.

It now becomes of interest to determine the types of oxidation curve which will be obtained from open-chain polyalcohols with various numbers of hydroxyl groups, when these substances are oxidized under the same standardized conditions.[5] In such compounds there would appear to be no fixed space relations among the various hydroxyl groups because of the possibility of free rotation around the carbon-to-carbon single bonds. A definite relation between the amount of oxidant consumed and the number of carbinol groups present in an unbroken row, might be expected.

In the present paper, we report such oxidations of glycol, glycerol, erythritol, arabitol, mannitol, sorbitol and dulcitol. Another group of open-chain compounds is provided by the diacetamide derivatives of the sugars which are obtained in the course of the Wohl degradation.[6] Four of these were on hand from previous studies: "D-threose diacetamide,"[7] "D-erythrose diacetamide,"[8] "D-arabinose diacetamide"[9] and "D-lyxose diacetamide."[9]

The results are shown in two figures. First, it may be noted that the configuration of an open-chain polyalcohol has no effect upon the course of oxidation in the present cases. Mannitol, dulcitol and sorbitol do not differ beyond the limits of experimental error, so that the curve shown for mannitol expresses equally well the behavior of the other hexitols. Second, the curves when examined in a purely empirical manner, seem to show a striking family relationship which indicates that the position of the curve with respect to the coördinates is a function of the number of free COH groups in an *unbroken* series. Nevertheless, the curves do not indicate a simple stoichiometric relation between amount of oxidant used and the number of such alcohol groups. We have many evidences that the reactions are complex and do not accept for the oxidation of polyalcohols by lead tetraacetate in dry acetic acid, the simple mechanism proposed by Malaprade[10] for the oxidation of such polyols by periodic acid in water. One of the several disturbing elements is the oxidation of by-product formic acid by lead tetraacetate. The rate of this reaction, measured under comparable conditions, is recorded for comparison. Only glycol which produces no formic acid ceases to consume oxidant at the "theoretical" level of one mole.

Nevertheless, if standard conditions are used, it is probable that open-chain polyalcohols containing the same number of C–OH groups in a series, will give similar curves so long as substituents of extreme difference in polarity are absent. A case in point is the striking similarity between the oxidation curves of glycerol and the two "tetrose diacetamides" on the one hand and

those of erythritol and the two "pentose diacetamides" on the other.

Standard conditions, of course, must be chosen arbitrarily and such a choice has been recorded in the fourth paper of this series.[1] It may also be helpful to attempt an expression in words of the position where the curve of any polyol should be found if it is determined under the standard conditions: At a time between five and ten hours under these conditions, each polyol will reach a consumption of $n - 1$ moles of lead tetraacetate if it contains n free COH groups in an unbroken series. However, no stoichiometric significance is to be attached to this statement and progressive deviations are to be expected as we ascend the series since the excess of oxidant cannot be made infinite in practice. Nevertheless, the curves recorded in Fig. 1 may provide a valuable frame of reference in solving the structures of polyalcohol derivatives when used judiciously. In a previous paper[11] several glycols of widely differing structures were shown to be similar enough in behavior so that no difficulty would be experienced in identifying them as compounds containing one adjacent pair of C–OH groups.

We are indebted to the Atlas Powder Company for samples of pure mannitol and sorbitol.

Experimental

Procedure.—These experiments were carried out under the exact conditions described by Hockett, Dienes and Ramsden.[1]

Materials

Mannitol and Sorbitol.—Highly pure samples were supplied by the Atlas Powder Company of Wilmington, Delaware.

Dulcitol.—Eastman Kodak Company material was used.

Arabitol.—This substance was prepared by deacetylation of the pure pentaacetate.[12]

Erythritol.—A sample from the Eastman Kodak Company was found to be highly pure.

Glycerol.—A sample of C. P. grade was fractionated in an efficient column under reduced pressure. Because of the hygroscopic nature of this substance, an analysis was made for water. A few drops were placed in a 25.0-cc. volumetric flask which was immediately stoppered and weighed. The glycerol was then dissolved and made up to the mark with dry acetic acid which had been analyzed for water by the method of Almy, Griffin and Wilcox.[13] An aliquot of the acetic acid solution was analyzed for water and the dry weight of the glycerol calculated. The water content of the glycerol was found to be only 1.32%. Then a volume sufficient to give the desired sample weight of glycerol (0.0230 g.) was measured from a dry buret into a 100.0-cc. volumetric flask. The oxidation was carried out as usual.

Glycol.—Eastman C. P. ethylene glycol was fractionated under reduced pressure.

Formic Acid.—Mallinckrodt Analytical Reagent grade of specific gravity 1.20, containing about 13% water, was allowed to stand in contact with anhydrous oxalic acid for several days and was then decanted and distilled under reduced pressure. The distillate was kept for several days in contact with boric anhydride and then distilled from boric anhydride.[14]

Summary

1. The oxidation of open-chain polyalcohols by lead tetraacetate in dry acetic acid under standard conditions, has been measured.

2. An empirical relation between the position of the oxidation curve and the number of carbinol groups present in a continuous chain is stated.

3. The lack of effect of configuration on the oxidation behavior of open-chain polyalcohols is noted.

4. The action of lead tetraacetate upon dry formic acid under the standard conditions is described.

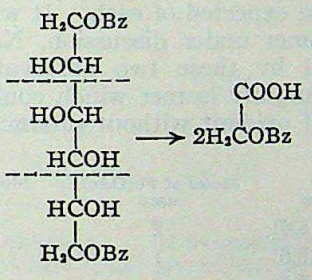
Lead Tetraacetate Oxidations in the Sugar Group. VI.[1] The Structures of Certain Di- and Tribenzoates of D-Sorbitol and D-Mannitol

BY ROBERT C. HOCKETT AND HEWITT G. FLETCHER, JR.[2]

In 1898, Einhorn and Hollandt[3] described a dibenzoyl mannitol prepared by the action of a limited amount of benzoyl chloride upon mannitol in pyridine solution. Some years later, Ohle and collaborators[4] assigned these benzoyl groups to the four and five positions since oxidation with neutral potassium permanganate yielded a product which they identified as dibenzoyl mesotartaric acid. Brigl and Grüner[5] showed that this identification was erroneous and that the oxidation product is benzoylglycolic acid. Not only was the product compared directly with synthetic benzoylglycolic acid and dibenzoyl mesotartaric acid, but crystalline glycolic acid was isolated after debenzoylation. Since, moreover, the dibenzoylmannitol sample appeared to be a pure chemical individual and since the yield of benzoylglycolic acid was more than 50% of the theoretical, the benzoyl groups were assigned to the one *and* six positions.



This structure implies that the primary hydroxyl groups are acylated much more rapidly than the more numerous secondary ones, an observation which is entirely in accord with many others to the same effect which have been made in recent years.[6]

In 1932, Alexander Müller[7] isolated a dibenzoyl-D-sorbitol by acylating D-sorbitol under similar conditions. It has been assumed without direct proof that this is also a 1,6-dibenzoate, because of the now general view that the primary alcohol groups will react first. A confirmation of this assumption is to be desired.

In a previous publication,[1] we have shown the behavior of open-chain polyalchohols when they are oxidized by lead tetraacetate under certain standard conditions. Similar oxidation of partially esterified polyalcohols should provide information concerning their structures very rapidly, easily and with samples on a micro scale. The observation of whether or not formaldehyde is produced and the number of moles of this aldehyde, is also carried out very easily and with very small samples.[8]

Fifteen isomeric D-sorbitol diesters are possible if the two substituent groups are identical. The table below shows how many moles of oxidant should be consumed by each in five to ten hours under standard conditions. It also shows the number of moles of formaldehyde to be expected from each.

No.	Isomer	Moles of $Pb(OAc)_4$ used	Moles of HCHO produced
1	1,2	3	1
2	1,3	2	1
3	1,4	2	1
4	1,5	2	0
5	1,6	3	0
6	2,3	2	1
7	2,4	1	1
8	2,5	1	0
9	2,6	2	0
10	3,4	2	2
11	3,5	1	1
12	3,6	2	1
13	4,5	2	1
14	4,6	2	1
15	5,6	3	1

These two experimental observations alone, will positively identify isomers no. 5, 8 and 10 since they give unique combinations of oxidant consumption and formaldehyde production. Three other combinations occur twice each so that in these six cases, the two experiments will limit the possible structures to two (4 and 9, 7 and 11, 1 and 15). Choice between the two alternatives will require further observations upon the oxidation products and this may not always be possible on a micro scale. Finally, the remaining combination occurs six times so that distinction of the corresponding isomers (2, 3, 6, 12, 13, 14) will be relatively difficult.

We succeeded in preparing a dibenzoyl-D-sorbitol with the properties reported by Müller. On oxidation it gave no trace of formaldehyde. Under standard conditions, it consumed just

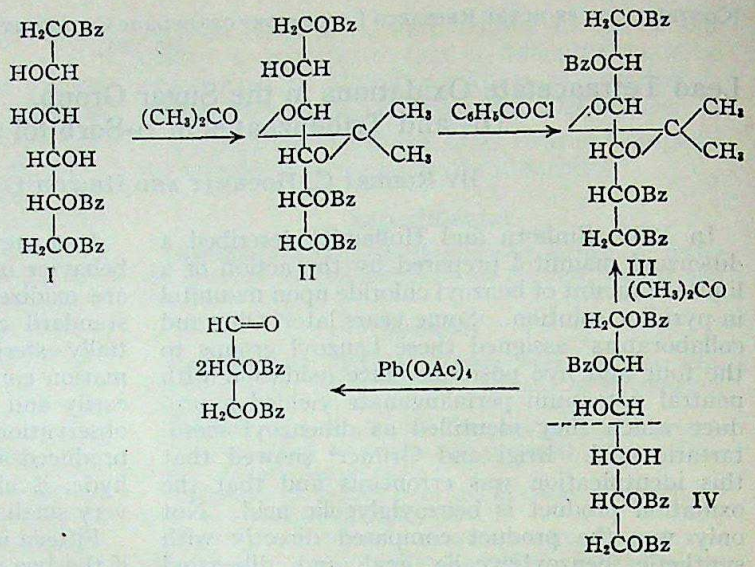
under three moles of oxidant in the critical time (Fig. 1). Therefore, $n - 1 = 3$ and $n = 4$ carbinol groups in an unbroken series. This behavior is very much like that of erythritol whose oxidation curve is plotted in Fig. 1 for comparison. Thus the 1,6 structure is confirmed.

As a by-product in the preparation of 1,6-dibenzoyl mannitol, Ohle and collaborators[4] obtained a tribenzoyl mannitol which melted at 162° and rotated[9] −18.0° in acetone (*C*, 1.721) or −44.0° in pyridine (*C*, 1.862). This compound was considered by Brigl and Gruner to be 1,2,6-tribenzoylmannitol[10] (which is identical with the 1,5,6 isomer). Their evidence is as follows: This tribenzoyl mannitol (I) combines with acetone to give a sirupy monoacetone derivative (II) whose one remaining hydroxyl group may be benzoylated to give the known 1,2;5,6-tetrabenzoyl-3,4-isopropylidene-D-mannitol (III). The structure of the last has been proved by the observation that it can be made by combining acetone with 1,2;5,6-tetrabenzoyl-D-mannitol (IV) whose structure in turn was proved by its nearly quantitative oxidation by lead tetraacetate to dibenzoyl-D-glyceric aldehyde.[11] These deductions are valid only if there is no shift of benzoyl groups.



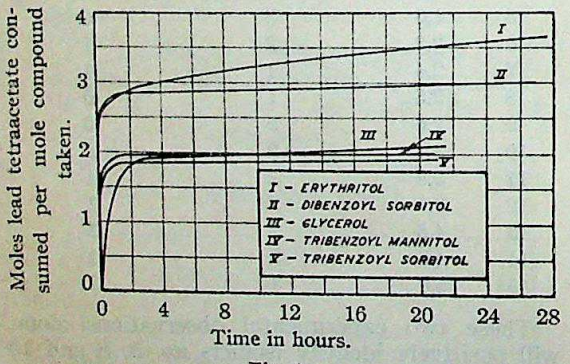


Fig. 1.

It should be noted that this evidence is not quite sufficient to *prove* the structure of the tribenzoyl-mannitol since a 2,5,6-tribenzoate could give the same reactions. The 1,2,6 structure is the more probable of the two possibilities since it is reasonable to suppose that the tribenzoate is formed by further acylation of the predominating 1,6-dibenzoyl-mannitol. However, an oxidation by lead tetraacetate under standard conditions can settle this point definitely since a 1,5,6 ester should behave like glycerol while a 2,5,6 ester would behave more like ethylene glycol. The oxidation curve plotted on Fig. 1 shows unequivocally that the 1,5,6 (1,2,6) formulation is correct.

The following table, showing all the possible trisubstituted mannitols in which the three substituting groups are alike, indicates the lead tetraacetate consumption and the formaldehyde production to be expected of each. It will be noted that the isomer under discussion, No. 4, could be identified by these two observations alone since it is the only isomer which could consume two moles of oxidant without producing formaldehyde.

No.	Isomer	Moles of $Pb(OAc)_4$ used	Moles of HCHO produced
1	1,2,3 (4,5,6)	2	1
2	1,2,4 (3,5,6)	1	1
3	1,2,5 (2,5,6)	1	0
+4	1,2,6 (1,5,6)	2	0
5	1,3,4 (3,4,6)	1	1
6	1,3,5 (2,4,6)	0	0
7	1,3,6 (1,4,6)	1	0
8	1,4,5 (2,3,6)	1	0
9	2,4,5 (2,3,5)	0	0
10	2,3,4 (3,4,5)	1	1

In the course of our repreparation of 1,6 dibenzoyl-D-sorbitol we obtained as a by-product, a small quantity of a tribenzoyl-D-sorbitol which apparently has not been described before. The possible number of trisubstituted D-sorbitols is twice as great as for trisubstituted mannitols since the sorbitol molecule is less symmetrical. These isomers are listed with their expected behavior.

No.	Isomer	Moles of $Pb(OAc)_4$ used	Moles of HCHO produced
1	1,2,3	2	1
2	1,2,4	1	1
3	1,2,5	1	0
+4	1,2,6	2	0
5	1,3,4	1	1

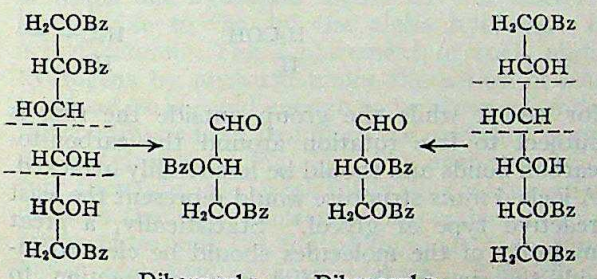
No formaldehyde was obtained when tribenzoyl-D-sorbitol was oxidized and the consumption of oxidant was two moles at the critical time (Fig. 1). The structure therefore is limited to 4 or 10.

To distinguish between these two possibilities it is only necessary to determine whether this tribenzoate yields dibenzoyl-D-glyceric aldehyde or dibenzoyl-L-glyceric aldehyde on oxidation with lead tetraacetate.



1,2,6-Ester | Dibenzoyl-L-glyceraldehyde | Dibenzoyl-D-glyceraldehyde | 1,5,6-Ester

The D-form of this reference compound is well-known from the work of Brigl and Grüner[10] and has a rotation[9] of $-35.6°$ in benzene. It follows that the L-form would rotate $+35.6°$. Since an oxidation by lead tetraacetate would be expected to destroy all other asymmetric centers and to yield the triose derivative almost quantitatively, it should suffice to oxidize a weighed sample of tribenzoyl hexitol with lead tetraacetate in a definite volume of benzene solution and to observe the final rotation attained. This plan was first tried out upon 1,2,6-tribenzoylmannitol which should yield dibenzoyl-D-glyceraldehyde mole for mole. The reading obtained was $-0.21°$ in a 2-dm. tube as compared with $-0.22°$ calculated. A similar oxidation was then performed upon an equal weight of tribenzoylsorbitol and a final rotation of $+0.22°$ was recorded. This must be due to the L-form of dibenzoylglyceraldehyde and establishes the structure of the original compound as 1,2,6-tribenzoyl-D-sorbitol.

We wish to express our indebtedness to the Atlas Powder Company of Wilmington, Delaware, for samples of pure mannitol and sorbitol.

Experimental

1,6-Dibenzoyl-D-mannitol.—Prepared as described by Brigl and Grüner,[5] our product was obtained in 29.1% yield and melted 182.3–183.3° (cor.).

1,2,6-Tribenzoyl-D-mannitol.—The alcoholic mother liquors from preparation of the 1,6-dibenzoate deposited crystals on standing in the refrigerator. Recrystallized from alcohol, these formed large needles melting sharply at 166.5–167.0° (cor.) and rotating[6] $-43.7°$ (*C*, 1.0096; pyridine). A melting point of 163° and rotation of $-44°$ have been recorded.[4]

1,6-Dibenzoyl-D-sorbitol.—Thirty grams of pure sorbitol was dissolved in 600 cc. of pyridine at 80° and, after cooling to 10°, the rapidly stirred solution was treated with 36 cc. of benzoyl chloride added dropwise over the period of one and one-half hours. After two hours of standing at 20°, about two-thirds of the pyridine was removed under reduced pressure at 50° and the remaining solution was poured in a thin stream into 500 cc. of water with rapid stirring. Overnight in an ice-chest, the precipitated sirup became largely crystalline. Concentration of wash waters *in vacuo* yielded a few grams more material. The combined precipitates were dissolved in 120 cc. of boiling 95% alcohol which, on cooling, deposited 18.6 g. of crude 1,6-dibenzoylsorbitol. Recrystallization from 70 cc. of boiling alcohol gave 16.8 g. of white crystals melting at 142.2–143.2° (cor.); yield, 26.2%. They rotated $+1.11°$ (*C*, 0.9006; pyridine). Müller[7] reported a melting point of 141° and a rotation in pyridine of $+1.85°$.

1,2,6-Tribenzoyl-D-sorbitol.—The combined mother liquors from the dibenzoate were treated with water to the turbid point. On standing first at room temperature and then in the ice-chest, there separated 8.8 g. of microcrystalline material which was much more soluble in alcohol than the dibenzoate. This product consisted of two or more difficultly-separable compounds (possibly the 1,5,6 isomer was present). By fractionation from hot toluene and then from chloroform, 2.8 g. of 1,6-dibenzoate was removed. The residue was recrystallized from alcohol several times by addition of water and attained a maximum melting point at 147.7–148.3° (cor.). The final yield was 0.125 g. The compound rotated $-11.1°$ (*C*, 1.080; $CHCl_3$; 24.8°).

Anal. Calcd. for $C_{27}H_{26}O_9$: C, 65.58; H, 5.30. Found: C, 65.3, 65.5; H, 5.87, 5.67.

Rates of Oxidation of 1,6-Dibenzoylsorbitol, 1,2,6-Tribenzoylsorbitol and 1,2,6-Tribenzoylmannitol.—Exactly the conditions described by Hockett, Dienes and Ramsden[12] were used except that the molar concentration of samples was exactly twice the now-established standard of 0.0025 *M*. This difference in concentration has only a very small effect upon the oxidation rates of polyalcohols.

Oxidation of 1,2,6-Tribenzoyl-mannitol to Dibenzoyl-D-glyceric-aldehyde.—A sample of 0.0261 g. was suspended in 4.3415 g. of sulfur-free benzene saturated with water. With shaking 0.0521 g. (a 2.23 molar ratio) of crystalline lead tetraacetate was added. The mixture was shaken a minute and then left for twenty-four hours at room temperature. At 20°, the clear supernatant liquid then rotated $-0.21°$ in a 2-dm. tube. A rotation of $-0.22°$ would be expected if conversion to the glyceraldehyde ester was quantitative.

Oxidation of 1,2,6-Tribenzoyl-sorbitol to Dibenzoyl-L-glyceric-aldehyde.—A similar experiment was made using 0.0250 g. of tribenzoylsorbitol, 4.3434 g. of damp benzene and 0.0510 g. (2.28 molar ratio) of lead tetraacetate. At the end of thirty-six hours the supernatant liquid rotated $+0.22°$ in a 2-dm. tube. Calculation, assuming quantitative oxidation to dibenzoyl-L-glyceraldehyde of specific rotation $+35.6°$, predicts $+0.22°$.

Summary

1. The compounds previously described as

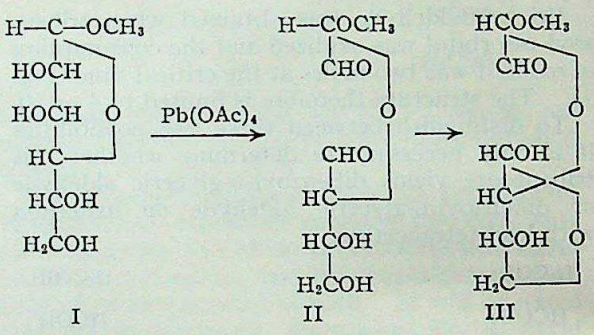
Lead Tetraacetate Oxidations in the Sugar Group. VII.[1] The Oxidation Rates of Ethyl β-D-Galactofuranoside, Methyl α-D-Mannofuranoside and 3,6-Anhydro-D-sorbitol[2]

BY ROBERT C. HOCKETT, MORTIMER H. NICKERSON AND WILLIAM H. REEDER, III

In previous publications,[1] we have described the behavior of two types of compounds toward lead tetraacetate in dry acetic acid under standard conditions: (1) polyalcohols with a six-membered glycoside or ether ring and (2) open-chain polyalcohols. We have also demonstrated the use of lead tetraacetate oxidations in establishing the structures of new compounds of these classes.[3] Interest now centers upon the behavior of glycofuranosides and anhydroalcohols with a five-membered ether ring.

Criegee[4] has already reported some work upon oxidation of furanosides and of aldonic acid gamma lactones by this agent. In particular, he has pointed out the impossibility of obtaining formaldehyde by the cleavage of hexo-pyranosides whereas certain furanosides will produce this easily identified aldehyde. He has also performed certain kinetic experiments and has assigned second-order rate constants to some of the reactions. However, since many lead tetraacetate oxidations have two or more distinct successive stages, we have found it instructive to record the oxidation rates in graphical form and have preferred to use a large excess of the oxidizing agent in order to render some of the reactions pseudo-unimolecular.

Hence, we have repeated the oxidation of methyl α-D-mannofuranoside under the conditions that have been established as standard in this Laboratory.[5] An inspection of the structural formula (I) permits prediction of the type of curve to be expected, on the basis of generalizations previously stated.[5] Thus, of the two glycol structures which can be attacked, the one inside the ring is held rigidly in a *cis* position favorable



I II III

for attack while the group outside the ring is subject to free rotation around the carbon-to-carbon bonds and should be less readily attacked. A locked *trans* structure would represent the least reactive type of glycol.[6] Statistically, a great majority of the molecules should be cleaved inside the ring in the initial stage of reaction, to give the dialdehyde marked II. The latter, being a *gamma* hydroxy-aldehyde, would be expected to rearrange to a cyclic hemiacetal, establishing an equilibrium in which the proportion of open-chain isomer would be exceedingly small but finite.[4,7] The cyclic hemiacetal itself should be unoxidized but the small proportion of free aldehyde present would account for a slow further oxidation.

The over-all prediction, therefore, is (1) the consumption of one molar equivalent of lead tetraacetate very rapidly, followed by a sharp break in the curve and a very much slower subsequent oxidation; (2) formation of only a trace of formaldehyde.[4] The figure shows that the first prediction is very strikingly realized.

The predicted behavior of ethyl β-D-galactofuranoside is quite different. Examination of the structure shows two positions initially available for attack. Since the one inside the ring is locked in the unfavorable *trans* position, it appears that, statistically, most of the molecules would first be attacked outside the ring. This con-

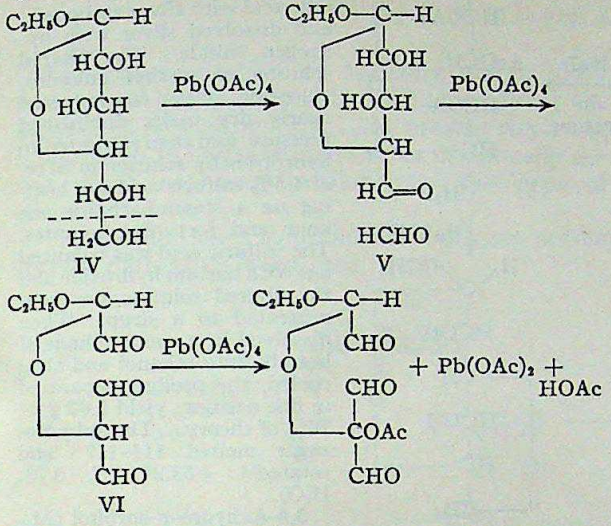
ception leads to prediction of a nearly equi-molar production of formaldehyde along with an aldehyde V. The latter, having an unbroken ring, is



sterically impeded in forming a cyclic hemiacetal. Therefore, further oxidation may proceed at the 2,3 position to give a hypothetical trialdehyde VI in which one hydrogen should have an activity comparable to that of the alpha hydrogens in acetylacetone. The replacement of such alpha hydrogens by acetoxyl under the action of lead tetraacetate is rapid enough to be observed under the conditions used (compare the oxidation curve for acetyl acetone Fig. 1). The over-all prediction, therefore, is (1) a relatively slow consumption of more than two molecular proportions of lead tetraacetate and (2) the production of an equimolar quantity of formaldehyde. The figure shows confirmation of the first prediction and formaldehyde was found qualitatively.

A consideration of the possible aldohexofuranosides suggests that they may all fall into one or the other of two groups with respect to their oxidation behavior. All those with a *cis* structure inside the ring may be expected to act like methyl α-D-mannofuranoside while all containing a *trans* structure may very well give curves of the type observed for the ethyl β-D-galactofuranoside. Further experimentation will be required to substantiate this hypothesis. Criegee's observation that methyl β-D-glucofuranoside produces formaldehyde is in accord with it.

The case of a ketohexofuranoside or of an aldopentofuranoside differs in that there is no glycol pair outside the ring. Therefore, formaldehyde should never be found and the two types (*cis* and *trans*) will both consume only one molar proportion of oxidant, differing markedly in rate. The fructose furanosides show this behavior.[7]

In 1912, Fischer and Zach[8] described a crystalline 3,6-anhydro-D-sorbitol. This substance differs from a furanoside only in that the alkoxyl

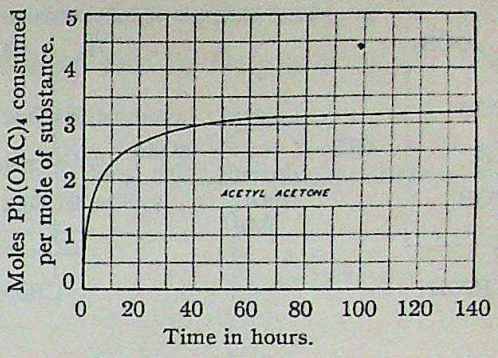

Fig. 1.

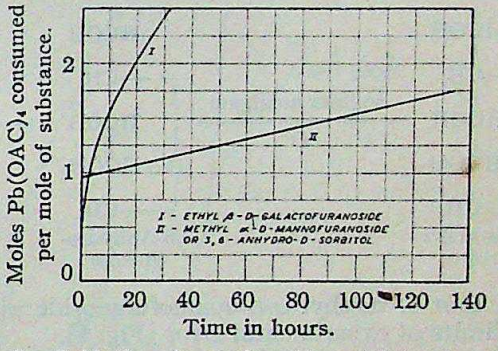

Fig. 2.—Oxidations in acetic acid containing less than 0.05% water: concentration of sample, 0.0025 molar; molar ratio of oxidant, 15.2/1.

group has been replaced by hydrogen. It might be expected to show an oxidation curve of the first type and to resemble the mannofuranoside closely. A close resemblance between the behavior of these two compounds would encourage us to apply the oxidation procedure in solving some of the many structural problems remaining in the little-known group of the anhydrides of polyalcohols.

Fischer and Zach introduced the anhydro ring by treating methyl 6-desoxy-6-bromo-2,3,4-triacetyl-α-D-glucopyranoside with barium hydroxide. We preferred to use the corresponding iodo compound prepared as described by Compton,[9] following Fischer's procedure in hydrolyzing the anhydroglucoside to the anhydro-glucose and in reducing the last with sodium amalgam to the anhydro-sorbitol.

The method of preparation eliminates any possibility of a Walden inversion at carbon atom number three during ether formation. Since there is no oxygen attached to the sixth carbon, the ether ring oxygen must be provided from the group upon carbon number three. Hence no bond of the third carbon atom has been broken and no inversion can have occurred. The structure of 3,6-anhydro-D-sorbitol, for the reasons enumerated, can be considered as established without question.

Oxidation of this sorbitan by lead tetraacetate under standard conditions, gave a curve identical

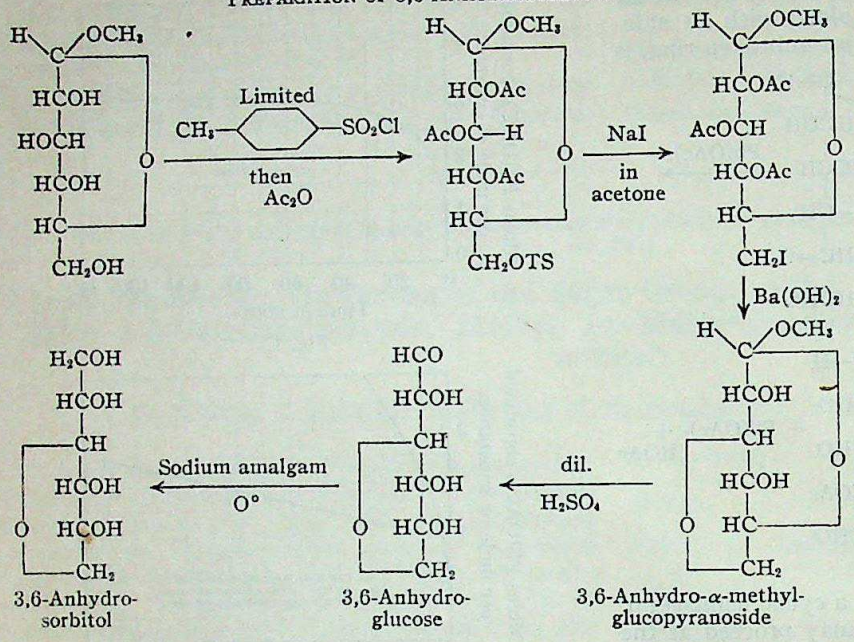
PREPARATION OF 3,6-ANHYDROSORBITOL



with that of methyl α-D-mannofuranoside within the limits of experimental error (Fig. 1).

We are very greatly indebted to Professor Eugene Pacsu of Princeton University for samples of the two furanosides, to Dr. Morris Zief of this Laboratory for repeating rate-of-oxidation measurements under more strictly anhydrous conditions and to Mr. Edward B. Weinberger, formerly of this Laboratory, for measuring the rate of oxidation of acetylacetone.

Experimental

Ethyl β-D-Galactofuranoside.[10]—This sample melted at 85–86° and rotated[11] −102° (*C*, 0.500; H_2O).

Methyl α-D-Mannofuranoside.[12]—This sample melted at 118–119° and rotated[11] +108°.

Methyl 2,3,4-Triacetyl-6-*p*-toluenesulfonyl-α-D-glucopyranoside (M.H.N.).—The sirupy compound was prepared exactly as described by Compton[9] from a 10-g. sample of methyl α-D-glucopyranoside.

Methyl 2,3,4-Triacetyl-6-desoxy-6-iodo-α-D-glucopyranoside (M.H.N.).—The entire sample of sirupy tosyl ester was treated with sodium iodide as described by Compton.[9] Our product weighed 9 g., representing 40.5% of the theoretical yield from the methyl glucoside used. It melted 143–145° and rotated[11] +113.3° (*C*, 0.94; $CHCl_3$).

3,6-Anhydro-D-glucose (M.H.N.).—The purification of methyl 3,6-anhydro-α-D-glucopyranoside was omitted in the present work.[8] A sample of 20 g. of nearly pure methyl 6-desoxy-6-iodo-triacetyl-α-D-glucopyranoside was dissolved at the boiling point in 300 cc. of 50% (by vol.) ethanol. One hundred grams of barium hydroxide octahydrate, finely ground, was added and the mixture was heated under reflux for two hours. After cooling, filtration through carbon and evaporation to a sirup, the latter was extracted repeatedly with a 50:50 mixture of ethanol and ethyl acetate. The combined extracts were evaporated and the remaining sirup was dissolved in water. Barium ions were balanced out accurately with dilute sulfuric acid, hydriodic acid with silver carbonate, and dissolved silver with hydrogen sulfide. The filtered solution of methyl anhydroglucoside was concentrated nearly dry under diminished pressure, and then subjected to hydrolysis by solution in 50 cc. of 4.5% sulfuric acid and heating on a steam-bath for one hour and forty-five minutes. The sulfuric acid was balanced out with barium hydroxide and the filtered solution was concentrated to a sirup. When dissolved in a small volume of hot absolute ethanol and then cooled, the product separated in fine needles; yield 5.67 g. or 76% of theory. The anhydrosugar melted 114–117° and rotated[11] +53.2° (*C*, 0.73; H_2O).

3,6-Anhydro-D-sorbitol (M.H.N.).—Five grams of anhydro glucose dissolved in 50 cc. of water was subjected to a rapid stream of carbon dioxide gas while 140 g. of sodium amalgam was added in successive 10-g. portions. The gas both served to keep the solution stirred and maintained the medium at the very slight alkalinity of a sodium bicarbonate solution. No cooling was used. By the time the last portion of amalgam was exhausted, only a faint reducing power toward Fehling solution remained. Mercury was separated and sodium bicarbonate was converted to sulfate by titration with dilute sulfuric acid (methyl orange). After filtration through carbon the solution was evaporated nearly dry under reduced pressure. The salts were extracted repeatedly with hot absolute ethanol and the combined, filtered extracts were concentrated to a sirup. This was redissolved in a minimum volume (30 cc.) of hot ethanol and ethyl acetate was added to incipient turbidity. Tabular crystals soon separated; yield, 3.85 g. Recrystallized from hot ethyl acetate, these melted at 108–109°.

Rate of Oxidation Measurements.—The samples were oxidized in solutions of the concentration adopted as standard by Hockett, Dienes and Ramsden,[5] that is, 0.0025 molar with respect to sample and with a 15.2/1 molar ratio of oxidant to substance.

Detection of Formaldehyde.—The sample is dissolved in a small volume of water in a distilling flask and an excess of lead tetraacetate in acetic acid is added. After a few minutes, the water and acetic acid are distilled under reduced pressure into a receiver cooled in an ice and salt mixture. The distillate is then tested for formaldehyde by adding a saturated solution of 2,4-dinitrophenylhydrazine in 2 *N* hydrochloric acid. If formaldehyde is present there occurs an almost instantaneous precipitation of the hydrazone, melting at 166°. This method is adaptable for either qualitative or quantitative determination.

Summary

1. The rates of oxidation of methyl α-D-mannofuranoside, ethyl β-D-galactofuranoside and 3,6-anhydro-D-sorbitol have been measured.

2. Correlations between structure and oxidation behavior have been pointed out.

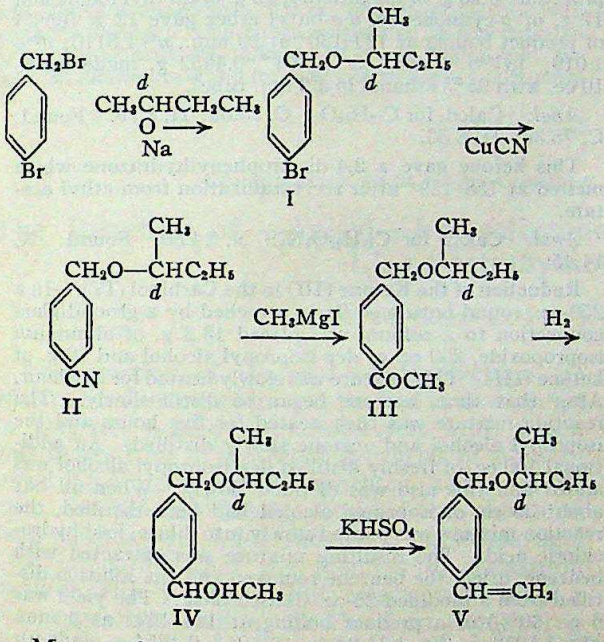
An Optically Active Styrene Derivative and its Polymer[1]

BY C. S. MARVEL AND C. G. OVERBERGER

The polymerization of optically active vinyl monomers[2] has been found useful in studying the kinetics of polymerization. The present work was undertaken to increase the number of optically active vinyl monomers available for this type of research.

The method used to obtain the optically active styrene derivative is outlined



Many of these reactions were first carried through with the methyl benzyl ether series so that there would be the least possible waste of the optically active *s*-butyl alcohol in the final synthesis. Since some of these derivatives are new, they are recorded in the experimental part of this paper.

The optically active styrene derivative (V) obtained in this synthesis had a specific rotation of +12.07° when prepared from *d*-*s*-butyl alcohol with a rotation of +11.5°. The change in specific rotation during polymerization was not great; the polymer had a specific rotation of +10.15° based on the monomer unit. In kinetic work this means an observed rotation change of 0.92° to 0.77° over a period of twenty-seven hours. The readings made at two to three hours intervals varied only by 0.03 to 0.04°. Since the polarimeter cannot be read with greater accuracy than ±0.01°, due to convection currents, the progress of this polymerization cannot be very accurately followed by polarimetric methods. However, taken as a whole the experiment plotted in the curve indicates that the polymerization follows first order kinetics.

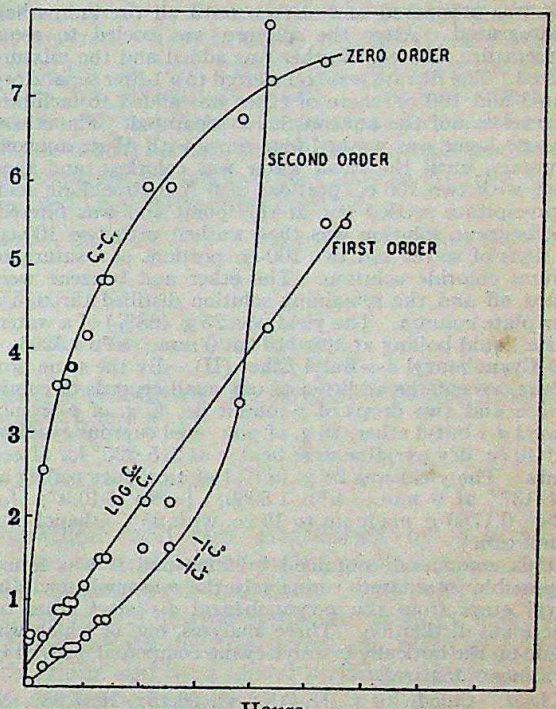


Fig. 1.

Experimental Part

p-Bromobenzyl *d*-*s*-Butyl Ether (I).—The method of Sah and Lei[3] for making benzyl ethers was modified for this reaction.

In a 500-cc., three-necked, round-bottomed flask equipped with condenser, stirrer and dropping funnel were placed 35 g. of *d*-*s*-butyl alcohol ($[\alpha]^{25}D$ +11.5°), 200 cc. of dry benzene and 10.9 g. of sodium (small shavings). The reaction mixture was allowed to reflux on the steam-bath with stirring for fifteen hours until all the sodium had dissolved. To this was added with stirring 118 g. of *p*-bromobenzyl bromide dissolved in 200 cc. of dry benzene. The addition took about fifteen minutes. The reaction mixture was then stirred for five hours while refluxing on a steam cone. The sodium bromide which precipitated was filtered and washed with two 75-cc. portions of benzene. The benzene layer was extracted with two 100-cc. portions of water to remove sodium bromide, the layers were separated and the benzene solution was dried over sodium sulfate. The solvent was removed and the resulting solution distilled through a column. The ether boiled at 109–110° at 8 mm. The yield was 70 g. (49.1%) $n^{20}D$ 1.5331; d^{24}_{24} 1.255; $[\alpha]^{25}D$ +10.2° (α, 0.39°, 0.1921 g. made up to 10 cc. with 95% ethanol in a 2-dm. tube).

Anal. Calcd. for $C_{11}H_{15}OBr$: C, 54.33; H, 6.22. Found: C, 53.80; H, 5.90.

p-Cyanobenzyl Methyl Ether.—This ether has been prepared by von Braun and Zobel[4] by a different and more involved set of reactions.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

In a dry, 200-cc., round-bottomed flask fitted with a ground-glass condenser and protected from moisture with a calcium chloride tube was placed 50 g. of *p*-bromobenzyl methyl ether, 22.3 g. of dry powdered cuprous cyanide and 35 cc. of pyridine dried over potassium hydroxide. This mixture was heated in a Wood's metal bath at 215–225° for fifteen hours. The reaction mixture was poured while still hot (100°) into 150 cc. of aqueous ammonia (sp. gr. 0.90) and 150 cc. of water. One hundred and forty cubic centimeters of benzene was added and the flask was stoppered and shaken until all the lumps had disintegrated. After the mixture was cooled to room temperature, 100 cc. of ether was added and the mixture filtered. The filtrate was transferred to a 1-liter separatory funnel and 100 cc. more of ether was added to facilitate separation and the aqueous layer separated. The ether–benzene layer was washed four times with dilute aqueous ammonia, until the wash water was colorless, and then twice with two 100 cc. portions of 6 *N* hydrochloric acid. A precipitate settled out at this point and was filtered. The benzene solution was then washed with two 100-cc. portions of water and two 100-cc. portions of a saturated sodium chloride solution. The ether and benzene were boiled off and the remaining solution distilled through a four plate column. The yield was 25 g. (68%) of a water-white liquid boiling at 108–110° at 9 mm.; $n^{20}D$ 1.5265.

p-Cyanobenzyl *d-s*-Butyl Ether (II).—By the same procedure, except the addition of ten small crystals of cupric sulfate and two drops of *p*-tolunitrile, 40 g. of *p*-bromobenzyl *d-s*-butyl ether, 16 g. of powdered cuprous cyanide, and 40 cc. dry pyridine were heated at 215–225° for fifteen hours. The yield was 28 g. (90%) of a product boiling at 134–137° at 9 mm.; $n^{20}D$ 1.5080; $[\alpha]^{23}D$ +10.9°; (α, 0.39°, 0.1780 g. made up to 10 cc. with 95% ethanol in a 2-dm. tube).

This compound contained bromine and it was found impossible to separate completely the *p*-bromobenzyl *d-s*-butyl ether from the *p*-cyanobenzyl *d-s*-butyl ether by fractional distillation. Three analyses, one of which was made on the optically inactive cyano compound, proved to be almost identical.

Anal. Calcd. for $C_{12}H_{15}ON$: C, 76.15; H, 7.98; N, 7.40. Found: Sample 1, C, 74.63; H, 7.94; Sample 2, C, 74.32; H, 7.49; Sample 3, C, 74.33; H, 7.93; N, 6.85.

Sample (3) was made with *dl-s*-butyl alcohol. By calculation, the amount of *p*-bromobenzyl *d-s*-butyl ether in the mixture is 8.3%. No further attempt to separate the compound was made as this intermediate is relatively unimportant and the next compounds in the series proved to have the correct analyses.

Hydrolysis of *p*-Cyanobenzyl *dl-s*-Butyl Ether.—In order to have evidence of the quality of the cyano compound, it was converted to the acid by hydrolysis. In a 200-cc. round-bottomed flask equipped with condenser was placed 15 g. of potassium hydroxide dissolved in 50 cc. of 95% ethyl alcohol. To this was added 5 g. of *p*-cyanobenzyl *d-s*-butyl ether. This was then refluxed by means of an oil-bath for thirty hours. The solution was filtered and the sodium salt dissolved in 20 cc. of water. The solution was then acidified with dilute hydrochloric acid and the precipitate filtered. Upon purification by treatment with Norite and recrystallization from a water–95% alcohol mixture a small amount of a white solid was obtained melting at 77–78°.

Anal. Calcd. for $C_{12}H_{16}O_3$: C, 69.20; H, 7.74. Found: C, 69.09; H, 7.69.

p-Acetobenzyl Methyl Ether.—In a 200-cc., three-necked, round-bottomed flask equipped with a stirrer, condenser, and dropping funnel was placed 8.56 g. of magnesium covered with 30 cc. of dry ether. To this with stirring was added over a period of one-half hour, 50 g. of methyl iodide dissolved in 120 cc. of ether (to give 3 moles excess of methylmagnesium iodide). The mixture was allowed to stir for fifteen minutes after all the iodide had been added. To this Grignard reagent was added with stirring 26 g. of *p*-cyanobenzyl methyl ether in 100 cc. of ether. This addition took ten minutes. The mixture was then heated under a reflux condenser for two hours. The complex was decomposed in iced, dilute hydrochloric acid. Benzene was added (about 200 cc.) and the organic layer separated. Fifty cubic centimeters of a 2% hydrochloric acid solution was added to the benzene layer and the solution refluxed for one hour. The water layer was then separated, the benzene layer dried, benzene removed and the resulting solution distilled through a four-plate column. The yield was 15 g. (52%) of a water-white liquid boiling at 104–105° at 9 mm., $n^{20}D$ 1.5280.

The ketone was converted to the 2,4-dinitrophenylhydrazone by the standard method[5] and this derivative was recrystallized from ethyl acetate, m. p. 170–171°.

Anal. Calcd. for $C_{16}H_{16}O_5N_4$: C, 55.80; H, 4.68. Found: C, 55.56; H, 4.67.

p-Acetobenzyl *d-s*-Butyl Ether (III).—Using the same procedure 9.26 g. of magnesium, 52 g. of methyl iodide and 17 g. of *p*-cyanobenzyl *d-s*-butyl ether gave 12 g. (65%) of product boiling at 129–130° at 10 mm., n^{20} 1.5110; d^{24}_{24} 1.019; $[\alpha]^{20}D$ +10.8° (α +0.91°, 0.4952 g. made up to 10 cc. with 95% ethanol in a 2 dm. tube).

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.69; H, 8.79. Found: C, 75.36; H, 8.56.

This ketone gave a 2,4-dinitrophenylhydrazone which melted at 158–159° after recrystallization from ethyl acetate.

Anal. Calcd. for $C_{19}H_{22}O_5N_4$: N, 14.50. Found: N, 14.45.

Reduction of the Ketone (III) to the Carbinol (IV).—In a 250-cc., round-bottomed flask, attached by a ground-glass connection to a column was placed 13.2 g. of aluminum isopropoxide, 200 cc. of dry isopropyl alcohol and 10 g. of ketone (III). This mixture was slowly heated for one hour. After that time, acetone began to distill slowly. The reaction mixture was then heated for five hours and the isopropyl alcohol and acetone slowly distilled. An additional 100 cc. of freshly distilled dry isopropyl alcohol was added and this also was distilled slowly. When all but about 30 cc. of isopropyl alcohol had been distilled, the reaction mixture was poured slowly into dilute, iced hydrochloric acid. The resulting mixture was extracted with benzene, dried, the benzene removed and the solution distilled from a modified 25-cc. Claisen flask. The yield was 6 g. (60%) of a product boiling at 144–149° at 9 mm. $n^{20}D$ 1.5056, $[\alpha]^{23}D$ +11.2° (α, +0.91°, 0.4054 g. made up to 10 cc. with 95% ethanol in a 2-dm. tube).

Anal. Calcd. for $C_{13}H_{20}O_2$: C, 74.95; H, 9.67. Found: C, 75.76; H, 9.62.

p-Vinylbenzyl *d-s*-Butyl Ether (V).—A mixture of 1.2 g. of fused, finely powdered potassium hydrogen sulfate and 0.2 g. of hydroquinone was fused in a 50-cc. modified Claisen flask fitted with a receiver and heated with a metal bath (200–220°). A stream of nitrogen, purified to remove oxygen and water, was introduced beneath the surface by means of a capillary tube through the same rubber stopper that contained a dropping funnel. The flask was evacuated to a pressure of 60–100 mm. Seven grams of the alcohol was dropped slowly (fifteen minutes) onto the molten potassium hydrogen sulfate at the temperature and pressure specified. About 4 g. of impure product was carried over into the receiver. The distillate was dissolved in 40 cc. of ordinary ether, washed with 20 cc. of a 5% sodium hydroxide solution, then with 20 cc. of a saturated calcium chloride solution and dried over calcium chloride. The solvent was removed and residue distilled in a 10-cc. modified Claisen flask. The yield was 3 g. (47%) of a product boiling at 111–113° at 8 mm., $n^{20}D$ 1.5179; $[\alpha]^{25}D$ 12.8; (α, +0.57, 0.4459 g. made up to 10 cc. with dry dioxane).

Anal. Calcd. for $C_{13}H_{18}O$: C, 82.05; H, 9.53. Found: C, 82.10; H, 9.25.

Polymerization of *p*-Vinylbenzyl *d*-*s*-Butyl Ether.—A mixture of 0.7600 g. of the styrene derivative and 0.1748 g. of benzoyl peroxide was made up to 10 cc. in dry dioxane and placed in a 1-dm. water-jacketed polarimeter tube and held at 55°. The rotation of this solution when first measured was +0.917°. After heating at 55° for twenty-four hours the rotation had dropped to +0.722°. Readings were made at various intervals during this time and the results of the experiment are plotted in Curve I. It will be noted that the best curve is obtained when first order kinetics are assumed. The errors in reading any one rotation are probably about 10%. The polymer which precipitated from the solution at the end of the run by adding methyl alcohol was a soft mass which could not be obtained in a satisfactory state for further study. Evaporation of the solvent gave a brittle mass. In order to obtain a sample for analysis, a dioxane solution of this polymer was slowly dropped into 100 cc. of methyl alcohol with vigorous stirring. One cubic centimeter of concentrated hydrochloric acid was added, 10 cc. of water and the solution allowed to stand for over twelve hours. A gummy powder or a gum settled which hardened on standing. This was finely ground and dried for two weeks in a vacuum desiccator.

Anal. Calcd. for $(C_{12}H_{16}O)_n$: C, 82.05; H, 9.53. Calcd. for $C_6H_5CO_2[(C_{12}H_{16}O)_8(O)_{11}]_n$: C, 73.27; H, 8.25. Found: C, 73.47; H, 8.44.

Summary

p-Vinylbenzyl *d*-*s*-butyl ether, an optically active styrene derivative, has been prepared and polymerized. The rotation change during polymerization is not great and accurate kinetic studies are difficult to make. The indication is that the polymerization follows first order kinetics.

Some methyl ethers related to the intermediates were synthesized by new methods or for the first time and they were characterized.

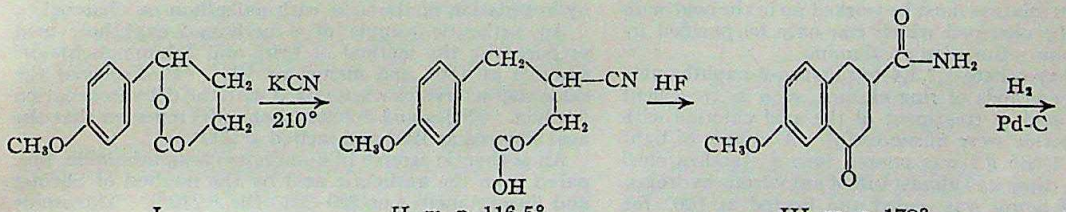
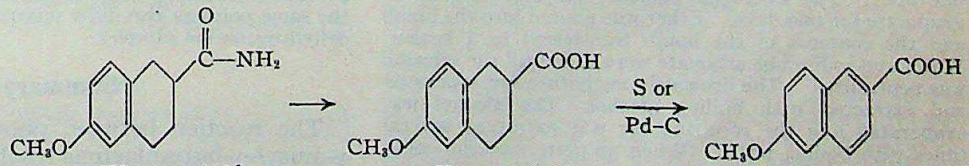
The Reaction of γ-Anisyl-γ-butyrolactone with Potassium Cyanide: 6-Methoxy-1,2,3,4-tetrahydro-2-naphthoic Acid

BY CHARLES C. PRICE AND WILLIAM KAPLAN

The reaction of γ-anisyl-γ-butyrolactone (I) with potassium cyanide[1] was studied in an attempt to prepare γ-anisyl-γ-cyanobutyric acid, which was desired for a projected synthesis of 6-methoxy-1,2,3,4-tetrahydro-1-naphthoic acid. However, the product finally obtained was shown to be 6-methoxy-1,2,3,4-tetrahydro-2-naphthoic acid (V), indicating that the reaction of potassium cyanide with γ-anisyl-γ-butyrolactone involves a rearrangement leading to the formation of γ-anisyl-β-cyanobutyric acid (II).



I II, m. p. 116.5° III, m. p. 178°



IV, m. p. 141° V, m. p. 151° VI, m. p. 196°

A similar rearrangement was observed by Blaise,[2] who found that the reaction of potassium cyanide with γ-methyl-γ-valerolactone yielded γ-methyl-β-cyanovaleric acid instead of the expected γ-cyano acid.

The structure of 6-methoxy-1,2,3,4-tetrahydro-2-naphthoic acid was established by dehydrogenation with sulfur or palladium on charcoal to yield 6-methoxy-2-naphthoic acid (VI). The identity of the dehydrogenation product was established by its melting point, the melting point of its amide and by a mixed melting point of each with authentic samples.[3]

Experimental

β-Anisoylpropionic Acid.—Following the directions of Fieser and Hershberg,[4] a 95% yield of β-anisoylpropionic acid, m. p. 144°, was obtained from the reaction between anisole (302 g.) and succinic anhydride (294 g.) in the presence of aluminum chloride (777 g.) when the precaution was taken of finely powdering the succinic anhydride crystals.

γ-Anisyl-γ-butyrolactone.—The keto-acid (140 g.) was added to 1 liter of absolute ethyl alcohol and the solution refluxed for several days, water being removed by calcium

carbide in a Soxhlet extractor. Upon completion of esterification the excess alcohol was removed by distillation and 500 cc. of isopropyl alcohol and 85 g. of vacuum-distilled aluminum isopropylate were added. Distillate boiling at 60° was very slowly removed through a fractionating column until ten drops failed to give a precipitate with a dilute hydrochloric acid solution of 2,4-dinitrophenylhydrazine. The isopropyl alcohol was then removed by distillation and excess 20% sulfuric acid added. The organic layer and the ether washings of the aqueous layer were combined and extracted with sodium hydroxide solution. The material remaining in the ether was refluxed for several hours with sodium hydroxide solution after removal of the ether by distillation. This sodium hydroxide solution was then washed with ether and added to the previous sodium hydroxide solution. The combined solutions were acidified and kept on the steam cone for an hour. The organic layer was taken up in ether and washed with dilute sodium bicarbonate solution. The ether solution was concentrated and placed in the icebox for several days. The lactone crystallized; filtration yielded 96 g. (79%) of γ-anisyl-γ-butyrolactone.

γ-Anisyl-β-cyanobutyric Acid (II).—The lactone (101 g.) and dried potassium cyanide (100 g.) in small crystals were put in a flask which had been dried in a Bunsen flame. A mechanical stirrer was attached. Dry nitrogen was passed slowly into the flask, which was kept at 210° for three and a half hours. The cold mass was dissolved in water and washed with ether. The water solution was acidified under the hood, cooled and extracted with ether. The ether was extracted with sodium bicarbonate solution and the dissolved ether was removed from the bicarbonate solution at room temperature by bubbling air through the solution. When the bicarbonate solution was acidified, a brown oil separated which solidified in a few hours. The solid mass was washed several times with cold benzene until the washings were colorless. A yield of 35 g. of tan solid was obtained which was used directly in the next step. Pure crystals for analysis and neutral equivalent were obtained by extraction of the light tan solid with a mixture of 50% benzene and 50% heptane in which the compound was moderately soluble at elevated temperatures. The pure γ-anisyl-β-cyanobutyric acid (II) melted at 116.5° (cor.).

Anal. Calcd. for $C_{12}H_{13}O_3N$: C, 65.74; H, 5.98; N, 6.38; neut. eq., 219. Found: C, 65.90; H, 5.98; N, 6.23; neut. eq., 221.

The reaction mixture must be worked up in the cold or an oily tar will be obtained which can only be purified by chromatographic adsorption on alumina.

6-Methoxy-4-keto-1,2,3,4-tetrahydro-2-naphthamide (III).—Usual methods of ring closure, such as treatment with sulfuric acid or treatment of the acid chloride with aluminum chloride were unsuccessful. A sample of light tan cyano-acid (35 g.) was poured into a stainless steel bomb (250-cc. capacity) almost full of anhydrous hydrogen fluoride. The bomb was sealed and heated at 100° for one hour. The hydrogen fluoride was then allowed to evaporate for two days. Ether was poured into the bomb and the contents of the bomb transferred to a beaker. Water and sodium bicarbonate were added till the solution was neutralized. The brownish precipitate was separated and extracted with boiling alcohol. The alcohol was evaporated and the resulting tar was extracted several times with boiling water. When no more material could be extracted from the tar, concentrated sulfuric acid was added to it. After a week the acid was diluted with water and the tar was boiled with 20% sodium hydroxide. The small white residue thus obtained was added to the material previously extracted from the tar and the whole was washed with dilute sodium hydroxide and recrystallized from water. A yield of 10 g. of **6-methoxy-4-keto-1,2,3,4-tetrahydro-2-naphthamide (III), m. p. 178° (cor.),** was obtained.

Anal. Calcd. for $C_{12}H_{13}O_2N$: C, 65.74; H, 5.98; N, 6.38. Found: C, 65.59; H, 5.97; N, 6.59.

The oxime was prepared following the directions of Shriner and Fuson,[5] m. p. 217–219° (cor.).

Anal. Calcd. for $C_{12}H_{14}O_4N_2$: C, 61.95; H, 6.02; N, 11.92. Found: C, 62.16; H, 6.25; N, 12.06.

6-Methoxy-1,2,3,4-tetrahydro-2-naphthamide (IV).—The amide (400 mg.) and 0.4 g. of 10% palladium on charcoal were put in a citrate bottle and 40 cc. of absolute alcohol added. The bottle was put in a shaker under 41 lb. pressure of hydrogen for two hours. The catalyst was then removed by filtration and the alcohol evaporated. The residue was washed with ether and recrystallized from boiling water. A yield of 250 mg. (68%) of **6-methoxy-1,2,3,4-tetrahydro-2-naphthamide, m. p. 141°** (cor.), was obtained.

Anal. Calcd. for $C_{12}H_{15}O_2N$: C, 70.22; H, 7.37; N, 6.83. Found: C, 70.40; H, 7.57; N, 6.66.

6-Methoxy-1,2,3,4-tetrahydro-2-naphthoic Acid (V).—A sample of 0.866 g. of the amide in 12 cc. of hydrochloric acid, 12 cc. of water and 8 cc. of glacial acetic acid was refluxed for three hours. The precipitate was removed by filtration and dissolved in sodium bicarbonate solution. The solution was acidified after treatment with Norite. The original mother liquor was evaporated to a small volume and the precipitate worked up with the main fraction. A yield of 0.730 g. (85%) of **6-methoxy-1,2,3,4-tetrahydro-2-naphthoic acid, m. p. 151°** (cor.), was obtained.

Anal. Calcd. for $C_{12}H_{14}O_2$: C, 69.88; H, 6.84. Found: C, 69.65; H, 6.87.

Attempts at demethylation with alcoholic potassium hydroxide and with glacial acetic acid–constant boiling hydrobromic acid mixtures were unsuccessful.

Dehydrogenation to 6-Methoxy-2-naphthoic Acid.—The amide (0.389 g.) and sulfur (0.140 g.) were heated at 210–245° for twenty minutes. The reaction mixture was sublimed at 5 mm. and sulfur removed from the sublimate with concentrated sodium sulfide solution. The residue was digested with alcohol and recrystallized from benzene. The product melted at 225° and gave a positive test for sulfur upon elementary analysis. This substance was probably the thio-amide. The amide was hydrolyzed with an alcoholic potassium hydroxide solution and an acid was obtained which melted at 194–196°. Dehydrogenation of the 6-methoxy-1,2,3,4-tetrahydro-2-naphthoic acid with sulfur also gave a product melting at 194–196°. The same compound was also obtained by catalytic dehydrogenation of the acid with palladium on charcoal.

An authentic sample of 6-methoxy-2-naphthoic acid prepared by the method of Fries and Schimmelschmidt[3] sintered at 186° and melted at 196°. It displayed the same characteristics when mixed with the dehydrogenation product. (Fries and Schimmelschmidt[3] reported that the acid sintered at 190° and melted at 209°.)

An authentic sample of 6-methoxy-2-naphthamide, prepared from the authentic acid by the method of Shriner and Fuson,[5] melted at 220–221° (lit.,[3] 219°). The amide prepared from the dehydrogenation product melted at the same point as also did a mixture of the authentic and dehydrogenation samples.

Summary

The reaction between potassium cyanide and γ-anisyl-γ-butyrolactone resulted in the formation of γ-anisyl-β-cyanobutyric acid. The successful conversion of this cyano acid to 6-methoxy-4-keto-1,2,3,4-tetrahydro-2-naphthamide and 6-methoxy-1,2,3,4-tetrahydro-2-naphthoic acid has been described.

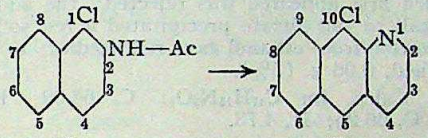
Derivatives of 10-Chlorobenzo(g)quinoline

BY FRANCIS H. GERHARDT[1] AND CLIFF S. HAMILTON

Several series of benzoquinolines have been prepared in this Laboratory and studied as intermediates for possible antimalarials.[2] In this particular investigation some nitro and amino derivatives of 10-chlorobenzo(g)quinoline were synthesized.

1-Chloro-2-acetamidonaphthalene (I) was subjected to the Skraup reaction to give 10-chlorobenzo(g)quinoline (V).[3] By the same Skraup



I V

procedure, the 5-nitro- (II), 6-nitro- (III), and 8-nitro- (IV) derivatives of (I) yielded, respectively, the 6-nitro- (VI), 7-nitro- (VII) and 9-nitro- (VIII) derivatives of (V). The action of fuming nitric acid on (V) gave chiefly (VI), together with a smaller amount of (VIII).

(II), (III) and (IV) were prepared by chlorination of the corresponding nitroacetamidonaphthalenes by the same procedure[4] used to prepare (I). They were also formed by the nitration of (I); thus the position of the chlorine atom was established.

Morpholine and piperidine condensed with (V) in sealed tubes in poor yields; no reaction occurred with diethylamine. The lability of the chlorine atom of (V) was not markedly increased by the introduction of a nitro group into the benzo ring. Morpholine condensed with (VI) and with (VII) under reflux in poor yields; no reaction occurred with diethylamine in sealed tubes. (VI) was reduced to 6-amino-10-chlorobenzo(g)-quinoline with iron and dilute acetic acid.

Treatment of (V) in chloroform with chlorine gave the dichlorobenzo(g)quinoline reported by Koeberle and Ploetz.[3] This compound was proved to be 5,10-dichlorobenzo(g)quinoline by its oxidation to the known benzo(g)quinoline-5,10-dione.[5]

Experimental

Preparation of Naphthalene Intermediates.—(I), (II), (III) and (IV) were prepared by the direct chlorination of the corresponding acetamidonaphthalene derivative in acetic acid according to the procedure of Franzen and Stäuble,[4] the resulting compounds being recrystallized from ethanol, forming white needles.

1-CHLORO-X-NITRO-2-ACETAMIDONAPHTHALENE, $C_{12}H_9ClN_2O_3$

X	M. p., °C.	Yield, %	Percentage composition: Carbon Calcd.	Carbon Found		Hydrogen Calcd.	Hydrogen Found	
5	183–185	80	54.45	54.28	54.66	3.43	3.48	3.46
6[a]	221–223	76	54.45	54.55	54.48	3.43	3.40	3.47
8	188–190	65	54.45	54.59	54.63	3.43	3.57	3.66

[a] Pale yellow.

Treatment of (I) with fuming nitric acid (d. 1.49) at −10° gave a mixture of (II) and (IV) which was separated by fractional crystallization from ethanol. No depression in melting point resulted when samples of (II) obtained by nitration and by chlorination were mixed; mixtures of samples of (IV) from the two sources also exhibited no melting point depression.

The action of fuming nitric acid (d. 1.49) on a solution of (I) in glacial acetic acid at room temperature resulted in some (III). Samples of (III) prepared by nitration and by chlorination exhibited no depression in melting point when mixed.

10-Chlorobenzo(g)quinoline (V).—Sulfuric acid, glycerol, arsenic acid and (I) were heated according to the procedure of Koeberle and Ploetz.[3] The crude product was extracted with acetone, the extract treated with charcoal and added dropwise to water with rapid stirring. (V) was obtained as cream-colored crystals; m. p. 138–140°; yield, 34%.

6-Nitro-10-chlorobenzo(g)quinoline (VI).—To 10 ml. (0.23 mole) of fuming nitric acid (d. 1.49) cooled to −18° in a snow–hydrochloric acid bath was added 2 g. (0.01 mole) of (V) in small portions. After fifteen minutes the solution was poured into 200 ml. of water. The precipitate which separated was filtered, washed with sodium bicarbonate solution to remove oxides of nitrogen, and extracted with 100 ml. of boiling ethanol. The extract was set aside (see preparation of (VIII) below) and the residue recrystallized from ethanol to give (VI) as fluffy yellow needles; m. p. 211–212°; yield, 1 g. (45%).

Anal. Calcd. for $C_{13}H_7ClN_2O_2$: C, 60.36; H, 2.72. Found: C, 60.29, 60.31; H, 2.44, 2.73.

(VI) was also prepared by subjecting (II) to the same Skraup procedure used to prepare (V). The two samples of (VI) exhibited no depression in melting point when mixed.

7-Nitro-10-chlorobenzo(g)quinoline (VII).—A mixture of 32 g. (0.12 mole) of (III), 50 ml. (0.66 mole) of glycerol and 100 ml. of 70% sulfuric acid (1.6 mole) was heated to gentle reflux by means of an oil-bath. A solution of 30 g. (0.13 mole) of arsenic acid in 75 ml. of 70% sulfuric acid (1.2 mole) was added in the course of thirty minutes. Heating was continued for another thirty minutes and the cooled mixture poured into 800 ml. of water and allowed to stand a few hours. The solution was filtered through a cellite pad and the filtrate neutralized with dilute sodium hydroxide. The crude product was extracted with acetone, the extract treated with charcoal and slowly poured into water. The resulting yellow solid was recrystallized three times from ethanol; yellow needles; m. p. 243–245°; yield, 1.2 g. (4%).

Anal. Calcd. for $C_{13}H_7ClN_2O_2$: C, 60.36; H, 2.72. Found: C, 60.60, 60.36; H, 2.90, 2.81.

9-Nitro-10-chlorobenzo(g)quinoline (VIII).—See preparation of (VI), above. Upon cooling, the alcoholic extract of the nitration product deposited a yellow solid; yellow crystals from ethanol; m. p. 209–211°; yield, 0.3 g. (12%).

Anal. Calcd. for $C_{13}H_7ClN_2O_2$: C, 60.36; H, 2.72. Found: C, 60.46, 60.61; H, 2.86, 2.92.

A mixture of some of this material and (VI) melted from 161–190°. However, these yellow crystals did not lower the melting point of the product obtained by subjecting (IV) to the same Skraup procedure used to prepare (V).

10-Morpholinobenzo(g)quinoline (IX).—In a sealed tube 2 g. (0.01 mole) of (V), 15 ml. (0.17 mole) of morpholine, and a few crystals of potassium iodide were heated at 150° for thirty-six hours. The reaction mixture was poured into 100 ml. of water and the resulting gummy precipitate dissolved in 5% hydrochloric acid. The acid solution was treated with charcoal and dilute sodium hydroxide added until the solution was barely acid. The unreacted (V) was removed by filtration and the filtrate made alkaline. The greenish-yellow solid was recrystallized twice from ethanol; bright yellow prisms; m. p. 160–161°; yield, 0.15 g. (6%).

Anal. Calcd. for $C_{17}H_{16}N_2O$: C, 77.24; H, 6.10. Found: C, 77.10, 77.34; H, 6.19, 6.16.

10-Piperidinobenzo(g)quinoline (X).—In a sealed tube 2 g. (0.01 mole) of (V) and 12 ml. (0.13 mole) of piperidine were heated at 150° for thirty-six hours. The reaction mixture was treated as in the preparation of (IX). Recrystallization of the product from ethanol gave bright-yellow needles; m. p. 97–99°; yield, 0.2 g. (8%).

Anal. Calcd. for $C_{18}H_{18}N_2$: C, 82.42; H, 6.91. Found: C, 82.27, 82.22; H, 7.07, 7.01.

5,10-Dichlorobenzo(g)quinoline (XI).—According to the procedure of Koeberle and Ploetz,[3] 3 g. of (V) was dissolved in chloroform and chlorine slowly bubbled in. The precipitate formed was treated with ammonium hydroxide and recrystallized twice from ethanol; yellow needles; m. p. 213–215°; yield, 2.5 g. (71%).

Anal. Calcd. for $C_{13}H_7Cl_2N$: C, 62.92; H, 2.84. Found: C, 62.86; H, 2.91.

In their patent[3] Koeberle and Ploetz neither characterized this chlorination product nor proved its structure. Refluxing (XI) with chromium trioxide in glacial acetic acid gave a tan solid which was recrystallized from benzene as tan needles; m. p. 278–280°. This product did not contain chlorine and its melting point agreed with that reported[5] for benzo(g)quinoline-5,10-dione. Hence, the chlorination product was 5,10-dichlorobenzo(g)quinoline.

6-Nitrobenzo(g)quinoline-5,10-dione (XII).—A mixture of 0.6 g. (0.002 mole) of (VI), 0.2 g. (0.002 mole) of chromium trioxide and 20 ml. of glacial acetic acid was refluxed for twenty-five hours. The reaction mixture was poured into water and the precipitate recrystallized twice from ethanol; pale tan crystals; m. p. 243–245°; yield, 0.25 g. (42%).

Anal. Calcd. for $C_{13}H_6N_2O_4$: C, 61.42; H, 2.34. Found: C, 61.52, 61.37; H, 2.35, 2.54.

6-Amino-10-chlorobenzo(g)quinoline (XIII).—Five grams (0.019 mole) of (VI), 3.2 g. (0.057 mole) of reduced iron powder, 80 ml. of glacial acetic acid, and 25 ml. of water were refluxed one hour. The mixture was diluted with about twice its volume of water, made alkaline, and extracted with three 100-ml. portions of chloroform. The combined extracts were washed with two 50-ml. portions of 5% hydrochloric acid and the acid solution treated with charcoal and neutralized with dilute sodium hydroxide. The precipitate was recrystallized from ethanol as orange needles; m. p. 181–183°; yield, 1.3 g. (30%).

Anal. Calcd. for $C_{13}H_9ClN_2$: C, 68.22; H, 3.97. Found: C, 68.09, 68.07; H, 3.94, 4.06.

6-Nitro-10-morpholinobenzo(g)quinoline (XIV).—One gram (0.004 mole) of (VI), 10 ml. (0.11 mole) of morpholine, and a pinch of copper bronze were refluxed five hours. The reaction mixture was poured into 300 ml. of water and the crude precipitate dissolved in 30 ml. of 5% hydrochloric acid. The acid solution was treated with charcoal and dilute sodium hydroxide added. The greenish precipitate which first appeared was rejected; the addition of more alkali to the filtrate precipitated a red solid. Recrystallization from ethanol gave red needles; m. p. 156–158°; yield, 0.06 g. (5%).

Anal. Calcd. for $C_{17}H_{15}N_3O_3$: C, 66.02; H, 4.88. Found: C, 66.25; H, 4.73.

7-Nitro-10-morpholinobenzo(g)quinoline (XV).—A mixture of 0.5 g. (0.002 mole) of (VII), 6 ml. (0.07 mole) of morpholine and a pinch of copper bronze was refluxed six hours. The reaction was worked up just as in the preparation of (XIV). The product was recrystallized from ethanol as tan platelets; m. p. 202–204°; yield, 0.02 g. (3%).

Anal. Calcd. for $C_{17}H_{15}N_3O_3$: C, 66.02; H, 4.88. Found: C, 66.24; H, 4.64.

Summary

10-Chlorobenzo(g)quinoline was condensed with morpholine and with piperidine. Nitration of 10-chlorobenzo(g)quinoline was found to give chiefly 6-nitro-10-chlorobenzo(g)quinoline, together with a small amount of 9-nitro-10-chlorobenzo(g)-quinoline.

6-Nitro-, 7-nitro- and 9-nitro-10-chlorobenzo-(g)quinoline were prepared from the new naphthalene intermediates, 1-chloro-5-nitro-, 1-chloro-6-nitro- and 1-chloro-8-nitro-2-acetamidonaphthalene, respectively.

6-Nitro- and 7-nitro-10-chlorobenzo(g)quinoline were condensed with morpholine. 6-Nitro-10-chlorobenzo(g)quinoline was reduced to 6-amino-10-chlorobenzo(g)quinoline.

Factors Determining the Course and Mechanism of Grignard Reactions. XIV. Replacement of Halogen Atoms of Aromatic Halides with Hydrogen Atoms by the Action of Grignard Reagents and Cobaltous Chloride

BY M. S. KHARASCH, D. C. SAYLES AND E. K. FIELDS

It is well established that aliphatic and aromatic Grignard reagents do not react, even at elevated temperatures, with monohalogenated and dihalogenated aromatic compounds. However, an energetic reaction occurs when cobaltous chloride is added to such a reaction mixture. Thus, butylmagnesium bromide reacts with phenyl bromide in the presence of 5 mole per cent. of cobaltous chloride to yield the following compounds:

Compound	Yields in % of amount calculated
Benzene	44
Butane and butylene	83
Butylbenzene	3
Biphenyl	3
Polyphenyls	11[1]

In order to ascertain the scope and general utility of this reaction, a number of dihalogenated aromatic compounds and monohalogenated polycyclic compounds were treated with Grignard reagents in the presence of cobaltous chloride.

TABLE I

Discussion

The results summarized in Tables I and II indicate that, although Grignard reagents do not react with aromatic halides (monohalogenated and dihalogenated hydrocarbons), a reaction leading to the replacement of a halogen atom by a hydrogen atom takes place in the presence of cobaltous chloride. The wide applicability of this method is indicated by the variety of halogenated substances which react as indicated. Thus, bromobenzene, *p*-bromobiphenyl, 1- and 2-bromonaphthalenes, 9-bromophenanthrene, 9-bromoanthracene, 2-bromofluorene, and 3-bromoacenaphthene give the corresponding hydrocarbons when treated with Grignard reagents in the presence of cobaltous chloride. Furthermore, ortho-, para- and meta-dichloro- and dibromobenzenes, 2,2′-dibromobiphenyl and 2,4-dibromoanisole give the corresponding monohalogen derivatives, or, if an excess of Grignard reagent is used, the corresponding hydrocarbons. The yields (40–55%) reported in the tables are not necessarily those that could be obtained under optimum experi-

mental conditions; hence, no significance should be attached to slight variations in the figures recorded. However, the differences noted between dichloro- and dibromobenzenes are probably real; they indicate a greater resistance of the chloro compounds to reduction.

The replacement of the halogen atom by a hydrogen atom probably proceeds by a free radical chain mechanism in which the cobalt subhalide acts as the chain carrier.

R = Aliphatic radical; R′ = Aromatic radical

(a) $RMgX + CoCl_2 \longrightarrow RCoCl + MgXCl$
(b) $RCoCl \longrightarrow R\cdot + CoCl\cdot$
(c) $R'\cdot Br + CoCl\cdot \longrightarrow R'\cdot + CoClBr$
(d) $R'\cdot + C_2H_5OC_2H_5 \longrightarrow R'H$

The compounds formed from the aliphatic free radical R (produced in reaction b) and those formed from the ether molecule (reaction d) have already been discussed.[1a] Of interest, although fully expected, was the non-selective replacement of a halogen atom in 2,4-dibromoanisole by a hydrogen atom.

The dimerization of some aromatic radicals by the action of alkyl or aryl halides and cobaltous chloride on the Grignard reagents of these radicals has already been reported.[1b] It has now been found that *p*-biphenylmagnesium bromide,[2] and 9-phenanthrylmagnesium bromide, when treated with ethyl bromide and 5 mole per cent. of cobaltous chloride, give quantitative yields of bixenyl and biphenanthryl, respectively. These results taken in conjunction with those reported in Tables I and II substantiate a previous statement[1b] that the dimers of aromatic radicals are not formed in ether solution (or for that matter in other solvents) by the combination of the two free aromatic radicals; they are formed by some other mechanism which we hope to discuss in the near future. On the other hand, free radicals formed from weakly electronegative radicals do dimerize in ether solution.[3]

Experimental

Hydrocarbons.—The hydrocarbons used were purchased from the Eastman Kodak Company. They were purified by fractional distillation under reduced pressure and by crystallization from suitable solvents.

Bromohydrocarbons.—1-Bromonaphthalene and 2-bromonaphthalene were prepared in the usual manner. *p*-Bromobiphenyl was obtained from the Eastman Kodak Company. Phenanthrene dibromide was prepared by the procedure of Austin.[4] It was converted by heat into the 9-bromophenanthrene; this compound was purified first by distillation (b. p. 237–242° under 22 mm. pressure) and then by crystallization from ligroin (m. p. 63°). A similar procedure applied to anthracene yielded the 9-bromoanthracene (m. p. 100°). 2-Bromofluorene was prepared by the method of Clarkson and Gomberg.[5] 3-Bromoacenaphthene was prepared by the method of Compton and Walter.[6] 2,2′-Dibromobiphenyl was prepared according to the method of Schwechten.[7]

Reaction of Aryl Grignard Reagents with Ethyl Bromide in the Presence of Cobaltous Chloride; Preparation of Bixenyl and Biphenanthryl.—To 0.05 of a mole of the aryl Grignard reagent kept at 5°, five mole per cent. of cobaltous chloride was added. To this mixture, ethyl bromide (0.1 mole) dissolved in a small amount of ether, was slowly added in one and one-half to two hours. The reaction mixture was decomposed by ice and acidulated water (acetic acid), and then worked up in the usual way. Halide ion titrations of the water solution indicated 38% and 40% reactions, respectively. The yield of bixenyl (m. p. 302° after crystallization from nitrobenzene) calculated on the basis of the amount of Grignard reagent used was 60%. However, if this yield is corrected for the bixenyl (20%) present in the Grignard reagent, it is quantitative (40%). The yield of biphenanthryl (40%) was quantitative if calculated on the basis of the Grignard reagent that had reacted. The biphenanthryl thus obtained melted at 180° after crystallization from a mixture of chloroform and methanol.

Reaction of Grignard Reagents with Polycyclic Aromatic Halides in the Presence of Cobaltous Chloride (Table II).—The experimental technique was the same as described in previous papers.[1b] The cobaltous chloride (5 mole per cent.) was added to the Grignard reagent (0.05 mole) at low temperatures; then a solution of the organic halide (0.05 mole) in ether was added at a rate sufficient to maintain a gentle refluxing of the ether solution. The mixture was thoroughly agitated throughout the addition. After the addition was complete, the reaction mixture was refluxed for two hours on a water-bath; it was allowed to stand overnight, and was worked up in the usual way by pouring it onto ice, and extracting the mixture with ether. The aqueous layer was made up to 250 cc. volume; aliquot parts were withdrawn for halide ion titration. The ether solution was evaporated and worked up in the usual way. The results are recorded in Table II.

Reaction of Grignard Reagents with Dihalo Aromatic Compounds (Table I).—The Grignard reagents were prepared from ordinary magnesium turnings. In all cases, except where noted in Table I, the Grignard reagent was added to the halide in ether solution containing half of the total amount of the cobaltous chloride used in the experiment. After half of the Grignard reagent had been added, the other half of the cobalt chloride was added to the reaction mixture. Vigorous stirring and refluxing was maintained throughout the period of addition and for one hour thereafter. The reaction mixture was then treated in the usual manner; the products were separated by fractional distillation, or by crystallization from appropriate solvents.

Summary

1. In the presence of cobaltous chloride (5 mole per cent.), Grignard reagents reduce (a) dihalogenated aromatic compounds to the monohalogenated derivatives, (b) *o*-bromotoluene to toluene, (c) polycyclic aromatic halides to the corresponding hydrocarbons. In all cases some polymeric materials are obtained.

2. A mechanism for the replacement of the halogen atom by a hydrogen atom is suggested.

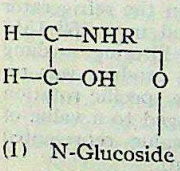
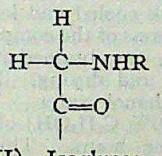
The Reaction of Glucose with Some Amines

BY ELEANOR MITTS AND R. M. HIXON

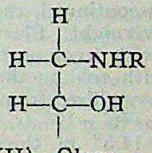
The phenylhydrazine derivatives were recently prepared from several corn sirup dextrins as a check on other methods of determining molecular weights of these large molecules. The ease of hydrolysis of these compounds indicated that they were of a glycosidic structure analogous to similar derivatives prepared by the reaction of phenylhydrazine in organic solvents with simple sugars. The tendency of the phenylhydrazine derivatives to form highly solvated molecules as well as the ease of isomerization detracts from their value for characterization of the dextrins. In connection with the synthesis of Vitamin B_2, detailed studies have been made of the reaction of aromatic amines with glucose. These compounds are N-glucosides (I) and undergo the Amadori rearrangement (II) to form amino ketones. A comparative study of the relative stability of the N-glucosides was made as an indication of nitrogen derivatives better suited for characterizing the dextrins. The data on glucosylalkylamines and their hydrogenation products (III) has been extended.



(I) N-Glucoside



(II) Isoglucosamine formed from (I) by Amadori Rearrangement



(III) Glucamines formed from (I) or (II) by hydrogenation

The available literature indicates that glucose and other monosaccharides react in non-polar solvents to give N-glucosides (I) with ammonia,[1] alkylamines,[1a,2] arylamines,[3] acid amides,[4] hydroxylamine[5] and phenylhydrazine.[6] As a general class, these compounds are labile and undergo rearrangement as well as hydrolysis. In many cases they crystallize with one or more molecules of water, of alcohol, or of amine. The difficulties of isolation or recrystallization seem to depend upon these solvation characteristics as well as upon hydrolysis or isomerization.

With the exception of the first member of the series, 1-aminoglucose or glucose ammonia, hydrolysis of the N-glucosides appears to parallel the basic dissociation constant (K_B) of the nitrogen substituent. The extent of hydrolysis depends upon concentration and temperature. Experiments with representative members of the various series indicate that for dilute aqueous solutions (2% or less) the alkylamines come to equilibrium in about twenty hours with approximately 40% of hydrolysis; in contrast, the glucosyl-*n*-arylamines after approximately ninety hours are only 8% hydrolyzed, while the amide derivatives are not hydrolyzed in water or even by dilute acids at room temperature.

The isomerization of N-glucosides to isoglucosamines (II, the Amadori rearrangement) has been observed with arylamines only. Weygand[7] suggests this type of rearrangement to explain the formation of osazones. The presence of the methoxy group in 2-methylglucose is not sufficient to prevent the formation of the osazone[8]; it is, however, sufficient to prevent rearrangement of the *p*-toluidide. Repeated attempts to induce the Amadori rearrangement in N-acyl and N-alkylamine glucosides met with negative results. In fact, the conditions used for the production of aryl isoglucosamines were found to be ideal for the production of the N-alkylamine glucosides. These conditions were used to prepare *n*-butyl, *n*-amyl and *n*-heptyl glucosylamines and the melting points found were identical to those reported previously by Votoček.[2b]

Catalytic hydrogenation of the N-glucosides of alkylamines has been previously reported.[9] It was found that good yields of N-alkyl glucamines (III) could be obtained in several cases where it was not possible to isolate the intermediate N-glucoside in crystalline form. The glucamines are crystalline solids, soluble in water and quite stable to heat. They may be titrated potentiometrically with dilute acid and are stable to both strong acid or alkali. These compounds, especially those from amines of intermediate molecular weight, lower the surface tension of water noticeably and are good wetting agents. Properties for a number of such compounds are reported in Table I.

Experimental

Glucosyl-*n*-butylamine.—To 10 g. (0.056 mole) of glucose and 2 ml. of 0.5 *N* hydrochloric acid, 9 g. (0.12 mole) of *n*-butylamine was added. This mixture was heated

[a] One per cent. solution in 50% ethanol. [b] Softened earlier.

under reflux on a water-bath at 70° until the glucose went into solution and for ten minutes thereafter. The solution was cooled and 20 ml. of ethanol, then 100 ml. of ether, was added. The needle-like crystals that formed were filtered by suction and washed repeatedly with ether; yield 11 g. The compound was recrystallized from dioxane and washed with petroleum ether. Recrystallization from alcohol and ether usually resulted in the formation of a gelatinous precipitate rather than the desired crystals. The product was dried over phosphorus pentoxide under reduced pressure. The melting point of the crystals was usually about 86–87° but, after repeated crystallization, the melting point was raised to 96–97°. The specific rotation after five minutes was $(\alpha)^{25}D$ −22° (*c*, 2; C_2H_5OH); this changed to a constant value of −7.8° in less than one hour.

Anal. Calcd. for $C_{10}H_{23}O_6N$: N, 5.53. Found: N, 5.48, 5.49.

Glucosyl-*n*-amylamine.—The same procedure as given above was used; yield 11 g. The melting point of the compounds after thorough drying was 96–97°, which was not changed after recrystallization from alcohol–ether. The specific rotation after twelve minutes was $(\alpha)^{25}D$ −22°; this changed to a constant value of −8° (*c*, 2; C_2H_5OH).

Anal. Calcd. for $C_{11}H_{25}O_6N$: N, 5.25. Found: N, 5.28, 5.28.

Glucosyl-*n*-heptylamine.—The same procedure was used for the preparation of this glucosylalkylamine as was employed for the preparation of the *n*-butyl compound. Thirteen grams of white needles, recrystallized from a butanol–Skelly D mixture, was obtained. The compound could also be recrystallized from methanol or methanol–water mixtures, or from water alone if the solution were cooled rapidly enough to preclude appreciable hydrolysis; m. p. 97–98°, $(\alpha)^{25}D$ −13° after ten minutes, changing to a constant value of −7° (*c*, 2; C_2H_5OH).

Anal. Calcd. for $C_{13}H_{29}O_6N$: N, 4.74. Found: N, 4.70, 4.63.

Glucosyldicyclohexylamine.—To 9 g. (0.09 mole) cyclohexylamine was added 10 g. (0.056 mole) of glucose and 2 ml. of 0.5 *N* hydrochloric acid. This mixture was heated on the water-bath at 75° until the solution became homogeneous and for ten minutes thereafter. After the solution was cooled, 20 ml. of ethanol and 100 ml. of ether were added. After thirty-six hours in the refrigerator, 6 g. of crystals was obtained. The compound melted at 97–98°, with softening early. The specific rotation after four minutes was $(\alpha)^{25}D$ −23.5°; this changed to −11.6° in six hours (*c*, 2; C_2H_5OH). On analysis, it was found that two molecules of the amine had combined with the hexose and one molecule of water had been eliminated.

Anal. Calcd. for $C_{18}H_{36}O_5N_2$: N, 7.77. Found: N, 7.60, 7.75.

Efforts to obtain a condensation product from one molecule of glucose and one molecule of the amine were not successful. The second molecule of cyclohexylamine could not be removed by heating the compound at the boiling point of acetone for three hours under reduced pressure. Heating at 100° resulted in the darkening of the compound and after several hours 20.44% of the total weight was lost. Upon analysis, the nitrogen content was found to be 8.26%, indicating that water was removed from the glucosylalkylamine more easily than a cyclohexylamine molecule.

Diglucosylethylenediamine.—To 3.5 g. (0.06 mole) of ethylenediamine in 50 ml. of methanol, 21 g. (0.12 mole) of glucose was added. This mixture was refluxed gently on a water-bath until the glucose went into solution. The refluxing was continued and soon a precipitate appeared on the side of the flask. After two hours, the refluxing was discontinued, the flask cooled and left in the refrigerator overnight. Eleven grams of the compound, m. p. 152–154° (with decomposition), was obtained after filtering, washing with cold methanol, and drying. The product was recrystallized from methanol–water. The specific rotation $(\alpha)^{25}D$ −17° (*c*, 2; 50% C_2H_5OH) changed to a value of +14.5° in thirty-nine hours. This value represented partial hydrolysis as well as mutarotation.

Anal. Calcd. for $C_{14}H_{28}O_{10}N_2$: N, 7.29. Found: N, 7.35, 7.35.

Glucosyl-*n*-hexadecylamine.—Twenty-four grams (0.10 mole) of *n*-hexadecylamine was dissolved by warming in 50 ml. of ethanol and to this was added 18 g. (0.10 mole) of glucose and 50 ml. of ethanol. After the mixture was refluxed for several minutes, the glucose went into solution and the refluxing was continued for fifteen minutes. The precipitate that formed on cooling was filtered and washed with alcohol and ether; yield 31 g., m. p. 106–107° with softening somewhat earlier. The compound was purified by precipitation from hot ethanol. The specific rotation was not determined since the compound was not appreciably soluble in ordinary solvents at room temperature.

Anal. Calcd. for $C_{22}H_{47}O_6N$: N, 3.32. Found: N, 3.28, 3.26.

Glucosyl-*n*-octadecylamine.—Twenty-seven grams (0.10 mole) of *n*-octadecylamine was dissolved in 100 ml. of ethanol, and 18 g. (0.10 mole) of glucose added. This mixture was refluxed until the glucose went into solution and for fifteen minutes thereafter. The precipitate (37.5 g.) that formed on cooling the red-brown liquid was filtered and washed with alcohol and ether, then dried; m. p. 104–105° with softening earlier. The specific rotation was not determined.

Anal. Calcd. for $C_{24}H_{51}O_6N$: N, 3.12. Found: N, 3.01, 3.06, 3.01.

Attempted Condensations of Other Amines with Glucose.—Repeated attempts using the different methods of preparation for glucosylalkylamines were made to obtain pure crystalline condensation compounds from isopropylamine, 2-aminoöctane, and propylenediamine. Solid

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

compounds were obtained by precipitation of the glucose–isopropylamine solution with ether, and by precipitation of the methanol or ethanol solution of propylenediamine and glucose, but the nitrogen analysis was high in all cases and the preparation melted over a range of several degrees. The compounds could not be recrystallized from any of the ordinary solvents. Evidence of reaction of all these amines with glucose was shown by the ease of solution of the sugar in the alcohol containing the anhydrous amine as well as by the analysis of the amorphous products obtained.

Reduction of the Glucosyl-*n*-alkylamines.—All of the glucosyl-*n*-alkylamines prepared were hydrogenated in a Parr type bomb using activated Raney nickel as a catalyst.[10] The physical constants and nitrogen analyses of the compounds are given in Table I. Ten grams of the glucosyl-*n*-alkylamines was dissolved in 200 ml. of solvent (methanol, ethanol or alcohol–water mixtures). The reduction was carried out below 100° (most often 70–83°) at pressures of 800 to 1300 lb. of hydrogen. The amount of catalyst was varied from 2.5 to 9 g. and the time of reaction from seven to fourteen hours. No effort was made to determine the minimum conditions necessary for complete reduction. Good yields were obtained except from glucosyl-*n*-hexadecylamine and glucosyl-*n*-octadecylamine which, after reduction and partial removal of the solvent, gelatinized and were difficult to obtain as solids.

N-Isopropyl-*d*-glucamine, N,N′-propylenediglucamine and N-2-octyl-*d*-glucamine were prepared, even though the corresponding glucosyl derivatives were not isolated in the pure state. A solution of the glucoside of 2-aminoöctane and of isopropylamine was obtained by the same method used for the preparation of the glucosyl-*n*-butylamine, except that after the solution was homogeneous, 75 ml. of ethanol was added and the solutions refluxed for one-half hour. In the reduction of diglucosylpropylenediamine, 12 g. (0.067 mole) of glucose was refluxed with 2.5 g. (0.034 mole) of propylenediamine in 60 ml. of methanol for one hour. Before reduction 150 ml. of 50% methanol was added. Although complete reduction of the diglucosylpropylenediamine occurred, only a very small amount of the reduced compound was isolated.

N-Isopropyl-*d*-glucamine was not pure as was shown by the nitrogen analysis. The compound gelatinized on attempted recrystallization from alcohol, but precipitated from a methanol-ethyl acetate mixture. Since the nitrogen value of the compound was still somewhat low, the impurity was believed to be sorbitol.

Hydrolysis of Glucosyl-*n*-alkylamines.—Glycosyl-*n*-butylamine was selected as a representative compound of this series, and the equilibrium of 0.5000 g. of the compound in 25 ml. of water was followed. From the change in optical rotation, it was evident that equilibrium was reached in twenty-two hours at room temperatures. On the assumption that only one form of the glucosylamine was present, and that it dissociated into glucose and the amine, the amount of the compound that had dissociated was calculated to be 56.9%. Potentiometric titration of the solution at equilibrium indicated that 39.5% of the compound had hydrolyzed. By extraction with ether an amount of the amine equivalent to 44% of the glucosyl-*n*-alkylamine was recovered. It was evident that mutarotation as well as hydrolysis occurred in aqueous solution. In methanol solution, mutarotation but no hydrolysis occurred. The other glucosyl-*n*-alkylamines behaved in much the same manner, the amount of hydrolysis depending upon the concentration and the temperature.

Hydrolysis of Other Amine Derivatives of Glucose.—Glucosyl-*n*-arylamine as well as the N-aryl-isoglucosamines were prepared by the method given by Weygand.[11] The change in rotation of *p*-toluidine-*d*-glucoside in aqueous solution was followed, and the amount of amine liberated after ninety hours was determined by extracting and weighing the extracted amine. Extraction of the 0.008 molar solution of the N-glucoside in water indicated only 8% hydrolysis. The isoglucosamine did not hydrolyze.

1-Aminoglucose was prepared by the method of Ling and Nanji.[12] The compound, after recrystallization from 95% methanol, appeared to be the hydrated compound, m. p. 120–121°, $(\alpha)^{24}D$ +19.1° (0.1001 g. in 1.694 ml. water, 1-dm. tube). Values found in the literature for the melting point of glucose ammonia and 1-aminoglucose vary from 120 to 131°, the rotation from +19.5 to +22.6°.

Anal. Calcd. for $C_6H_{15}O_6N$: N, 7.10. Found: N, 7.01.

1-Aminoglucose is remarkably stable in aqueous solution at ordinary temperatures as evidenced by the very slight change in rotation. This stability was confirmed by potentiometric titration of 1-aminoglucose with dilute acid, and titration of the amine in the presence of a known amount of ammonium hydroxide. After seventy-three hours, no measurable amount of ammonia had been liberated. However, slight acidity or higher temperatures cause immediate hydrolysis.

1-Aminoglucose pentaacetate was prepared from 1-aminoglucose and N-acetyl-1-aminoglucose was obtained from this compound according to the method of Brigl and Keppler.[13] This amide derivative was not hydrolyzed in aqueous solution or in dilute acid. It was hydrolyzed, however, by heating with 1 *N* acid.

Attempted Condensation of Acetamide with Glucose and Acetobromoglucose.—Two grams (0.034 mole) of acetamide was added to 6 g. (0.033 mole) of glucose in 100 ml. of methanol; after a few minutes refluxing on a water-bath, all of the glucose went into solution. The refluxing was discontinued after two hours and most of the solvent was removed under reduced pressure. Although no N-acetyl-1-aminoglucose was obtained even on seeding, the solution of the glucose in the alcohol and the inability to extract with hot chloroform more than one-third of the amide from the solvent-free residue indicated that a reaction had taken place. Such a reaction would be expected, in analogy to the glycosides of urea which have been reported.[4b]

When 10 g. (0.024 mole) of acetobromoglucose prepared by the method of Fischer[14] was refluxed with 4.0 g. (0.068 mole) of acetamide in 20 ml. of chloroform, crystals appeared in the solution after approximately thirty minutes. On analysis for bromine it was found that the crystals were diacetamide hydrobromide that sublimed 95–100° and melted 138–139°. No crystals of pentaacetyl-1-aminoglucose were obtained when the filtrate was seeded.

The Amadori Rearrangement.—Although this rearrangement was easily effected on N-glucosides of the arylamines, neither the alkylamine nor acylamine derivatives of glucose formed the rearranged product. In fact, the best method of preparation of the glucosylalkylamines from the low molecular-weight alkylamines was a procedure that was used for the preparation of the isoglucosamines in the aryl series. A further attempt to effect the rearrangement or partial rearrangement of the glucosylalkylamines was made by refluxing 1 g. of glucose in 10 g. of *n*-butylamine for three hours. Although the resulting gold-colored solution reduced methylene blue fairly rapidly (rapid reduction of methylene blue was used as evidence for the formation of isoglucosamine), only impure crystals of glucosyl-*n*-butylamine could be obtained after rapid removal of excess amine and precipitation with alcohol-ether. No evidence of any kind was obtained to indicate that the N-acyl derivative underwent even partial rearrangement.

Amine Derivatives of 2-Methylglucose.—The phenylhydrazine derivative of 2-methylglucose was prepared by allowing 1.65 g. of phenylhydrazine in 1 ml. of water to stand overnight in the presence of 0.55 g. of the monosaccharide (m. p. 150–155°) and one drop of glacial acetic acid. This derivative melted 176–177° and had a methoxyl content 11.1% as compared to the calculated value of 10.93%. Glucose phenylosazone was obtained by refluxing the phenylhydrazine derivative of 2-methylglucose with phenyl-

hydrazine and glacial acetic acid in aqueous solution as had been reported by Brigl and Schinle.[8] The analysis for the glucose phenylosazone is as follows.

Anal. Calcd. for $C_{18}H_{22}O_4N_4$: N, 15.64; OCH_3, 0.00. Found: N, 15.93; OCH_3, 0.40.

The *p*-toluidide of 2-methylglucose was prepared by heating 1.04 g. of the monomethyl sugar (OCH_3, 15.27%) with 0.72 g. of *p*-toluidine and 0.30 ml. of water. The mixture was heated on a water-bath until the solution became homogeneous and for ten minutes thereafter to insure complete reaction. After cooling, 2 ml. of 95% ethanol and 4 ml. of ether was added. Cooling in the refrigerator yielded a precipitate (0.15 g.) that was identified as unchanged 2-methylglucose. The mother liquor was evaporated to 1.5 ml. and left overnight; needle-like crystals (0.55 g.), m. p. 150–151° after purification, were obtained.

Anal. Calcd. for $C_{14}H_{21}O_5N$: OCH_3, 10.95. Found: OCH_3, 10.7.

Prolonged refluxing in the water–ethanol solvent with dilute acetic acid and with dilute hydrochloric acid gave no evidence for the Amadori rearrangement; crystals of the glucoside were isolated in all cases.

Summary

Physical properties are reported for a number of glucosylalkylamines and the corresponding glucamines.

The glucamines formed from primary amines of intermediate molecular weight are good wetting agents.

An approximation of the degree of hydrolysis of the various N-substituted glucosides was made by comparison of changes in rotation, by potentiometric titration and by extraction of the hydrolyzed amine. With the exception of the first member of the series, 1-aminoglucose, ease of hydrolysis appears to parallel the K_B of the nitrogen substituent.

An attempt was made to effect the Amadori rearrangement of the glucosylalkylamines and the acyl derivatives of 1-aminoglucose. No rearranged product could be isolated in either case.

The *p*-toluidide and phenylhydrazine derivative of 2-methylglucose were prepared. The methoxyl group on the second carbon atom prevented rearrangement of the *p*-toluidide, but glucose phenylosazone was prepared from the phenylhydrazine derivative of 2-methylglucose.

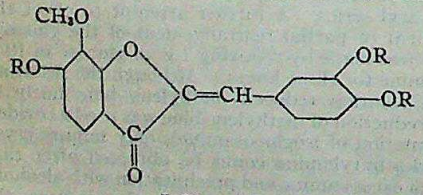
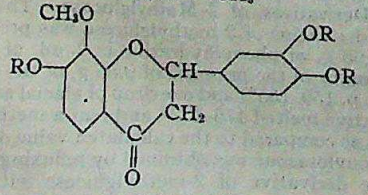
Anthochlor Pigments. V. The Pigments of *Coreopsis grandiflora*, Nutt. II

BY T. A. GEISSMAN AND CHARLES D. HEATON

In the preceding paper of this series,[1] structures were proposed for leptosin, leptosidin and a flavanone, constituents of the flower petals of *Coreopsis grandiflora*, Nutt. Leptosin and leptosidin are related as glycoside and aglycon, and to the latter was assigned the structure of 7-methoxy-3′,4′,6-trihydroxybenzalcoumaranone (I). The position of the sugar residue (presumably glucose) in leptosin was assumed to be 6, on the basis of certain distinctive color reactions of the glycoside. The structure of the flavanone was considered to be II, both because of the correspondence in the positions of the hydroxyl and methoxyl groups in this structure and in that chosen for leptosidin, and because of the similarity between certain color reactions of the flavanone and those of butin (3′,4′,7-trihydroxyflavanone).



I, R = H
III, R = CH_3



II, R = H
IV, R = CH_3

We have synthesized 3′,4′,6,7-tetramethoxybenzalcoumaranone (III) by the condensation of veratraldehyde with 6,7-dimethoxycoumaranone. The product, crystallizing in bright yellow needles, did not depress the melting point of fully methylated leptosidin. This establishes for the first time the occurrence in nature of a substance possessing the benzalcoumaranone nucleus.

3′,4′,7,8-Tetramethoxyflavanone (IV) has been described by Kostanecki and Rudse,[2] who reported its melting point as 144°. While the trimethyl ether of the naturally-occurring flavanone analyzed correctly for this structure and showed color reactions which left no doubt that it was a flavanone and pointed strongly to the probability that it had structure IV, it melted at 139–140°, a fact which left some doubt as to its identity with the flavanone described by Kostanecki and Rudse. The synthesis of IV has shown that the trimethyl ether of the naturally-occurring flavanone is indeed 3′,4′,7,8-tetramethoxyflavanone. The condensation of gallacetophenone 3,4-dimethyl ether with veratraldehyde yielded 2′-

Digitized by Arya Samaj Foundation Chennai and eGangotri

hydroxy-3′,4′,3,4-tetramethoxychalcone, and this was isomerized to the flavanone by treatment with dilute alcoholic hydrochloric acid. The product melted at 137–139° even after repeated recrystallization from dilute alcohol, and retained a pale yellow color. It did not depress the melting point of the natural substance and gave the same blue-violet color when reduced with magnesium and alcoholic hydrochloric acid. Further study showed that it was contaminated with a small amount of the chalcone, and when this was removed the pure flavanone, m. p. 143.5–144°, was obtained. A mixture of this material and that obtained from the natural source melted at 142.5–143°.

The position of the methoxyl group in leptosidin and in the flavanone, and the point of attachment of the sugar residue in leptosin still rest upon the inferences drawn from the observations previously reported.[1] These inferences carry additional weight in view of the establishment of the disposition of the oxygen atoms in these compounds, but direct proof is still needed and will be the object of further work.

Experimental

6,7-Dimethoxycoumaranone.—To a suspension of 4.0 g. of α-chlorogallacetophenone[3] in 30 ml. of hot water was added 12 g. of sodium carbonate, followed by 10 ml. of dimethyl sulfate, with stirring. After the reaction was complete, an additional 6 g. of sodium carbonate and 3 ml. of dimethyl sulfate were added and the mixture warmed for a few minutes longer. The semi-solid mixture was filtered and the solid removed and stirred with warm alcohol to remove inorganic salts. Upon cooling the alcoholic solution the product separated as reddish crystals. Recrystallized from alcohol, the compound formed light pink crystals, m. p. 122–123°[4] (literature,[5] m. p. 122°).

3′,4′,6,7-Tetramethoxybenzalcoumaranone (III).—A solution of 0.5 g. of veratraldehyde and 0.5 g. of 6,7-dimethoxycoumaranone in 10 ml. of warm alcohol was treated with 3 ml. of 30% aqueous sodium hydroxide solution. Yellow crystals began to form at once and in less than a minute the reaction mixture had set to a crystalline mass. The product (0.68 g., 84%) was collected and recrystallized from aqueous alcohol. The bright yellow needles melted at 156–157° and further recrystallization did not change the melting point. A mixture of the synthetic material with leptosidin trimethyl ether (m. p. 156–157°) melted at 156–157°.

2′-Hydroxy-3′,4′,3,4-tetramethoxychalcone.—A solution of 0.5 g. of gallacetophenone 3,4-dimethyl ether[6] and 0.45 g. of veratraldehyde in 4 ml. of warm alcohol was treated with 2 g. of hot 50% sodium hydroxide solution. The mixture was shaken and kept hot for fifteen minutes, cooled and poured into dilute hydrochloric acid. The oily precipitate solidified on standing. It was recrystallized from dilute alcohol, yielding 0.51 g. of yellow-orange needles, m. p. 121–122° (literature,[2] 119°).

3′,4′,7,8-Tetramethoxyflavanone (IV).—A solution of 0.25 g. of the chalcone in a mixture of 20 ml. of alcohol, 8 ml. of concentrated hydrochloric acid and 25 ml. of water was refluxed for four hours, evaporated to half its volume and poured into dilute hydrochloric acid. The yellow oil which separated soon solidified. After seven recrystallizations from dilute alcohol the flavanone was still pale yellow in color and melted at 137–139° (literature,[2] 144°). A mixed melting point with the fully methylated naturally-occurring flavanone, m. p. 139–140°, was 138–140°. The two substances gave identical colors when reduced side by side with magnesium and alcoholic hydrochloric acid.

The synthetic material was recrystallized from carbon disulfide, and careful examination of the product showed that it was a mixture of yellow-orange rosets and pale yellow needles. A partial mechanical separation of these two substances, followed by recrystallization of the nearly colorless material from carbon disulfide, afforded nearly colorless needles of the pure flavanone, m. p. 143.5–144°. A mixture of this material with the natural substance (m. p. 139–140°) melted at 142.5–143°.

Anal. Calcd. for $C_{19}H_{20}O_6$: C, 66.26; H, 5.86. Found: C, 66.10; H, 5.92.

Summary

Leptosidin trimethyl ether and the trimethyl ether of the flavanone accompanying leptosidin in the flower petals of *Coreopsis grandiflora*, Nutt, have been identified as 3′,4′,6,7-tetramethoxybenzalcoumaranone and 3′,4′,7,8-tetramethoxyflavanone, respectively.

The proof of the structure of leptosidin trimethyl ether establishes for the first time the occurrence in nature of a compound possessing the benzalcoumaranone nucleus.

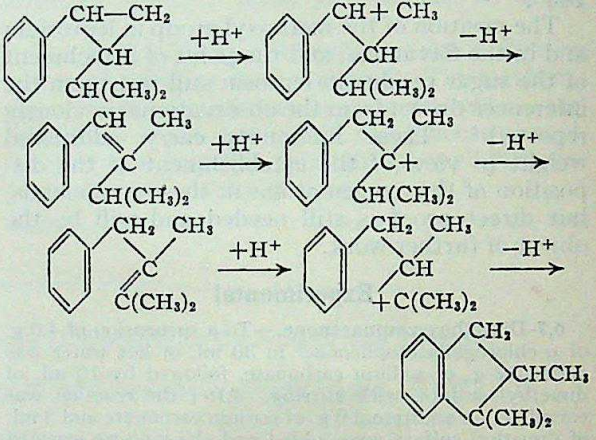
The Action of Sulfuric Acid on 1-Phenyl-2-alkylcyclopropanes[1,2]

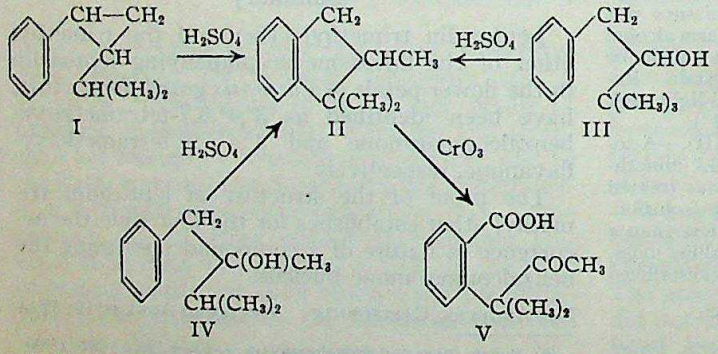
BY DAVID DAVIDSON AND JULIAN FELDMAN

Since the chemistry of the cyclopropane ring resembles that of the olefinic double bond it was of interest to compare the behavior of certain monophenylated cyclopropanes toward sulfuric acid with that of monophenylated olefins, which, if not polymerized, are converted to indans or tetralins.[3]

In the case of 1-phenyl-2-isopropylcyclopropane (I), the action of 90% sulfuric acid produced a low yield of 1,1,2-trimethylindan (II), a product previously obtained by the cyclodehydration of 1-phenyl-3,3-dimethyl-2-butanol (III)[4] and of 1-phenyl-2,3-dimethyl-2-butanol (IV).[5] This product is readily identified by its oxidation to the ketone acid (V). Treatment of 1-phenyl-2-methylcyclopropane[6] and of 1-phenyl-2-ethylcyclopropane with 90% sulfuric acid yielded gummy polymers and only traces of volatile oils.[7]

The foregoing results suggest that the attack on the 1-phenyl-2-alkylcyclopropanes by sulfuric acid begins with the opening of the cyclopropane ring by the addition of a proton to the least substituted carbon atom.[8] The resulting carbonium ion, which may also be obtained from olefins or alcohols, may then undergo its characteristic reactions; *i. e.*, addition to an unsaturated molecule (*polymerization*), decomposition to a smaller carbonium ion and an unsaturated molecule (*depolymerization*), isomerization to another carbonium ion (*rearrangement*), or decomposition into an olefin and a proton (*protolysis*). In the case of 1-phenyl-2-isopropylcyclopropane the changes shown below may be postulated.





Preliminary tests with higher homologs and with milder acid (85% phosphoric acid) indicate that isomerization to olefins actually does occur. Only with the isopropyl derivative are conditions very favorable for cyclization[3]; hence, in the other cases polymerization results.

Experimental

1-Phenyl-2-alkylcyclopropanes.—These hydrocarbons (Table I) were prepared by Kishner's method.[6,7,9] This involves the decomposition of certain pyrazolines in the presence of platinized asbestos and solid potassium hydroxide, the pyrazolines themselves resulting from the condensation of α,β-unsaturated ketones with hydrazine hydrate. The required unsaturated ketones were prepared by condensing benzaldehyde with methyl alkyl ketones in the presence of aqueous sodium hydroxide.[10] Good yields (75–80%) were obtained in each step.

The Conversion of 1-Phenyl-2-isopropylcyclopropane to 1,1,2-Trimethylindan.—While stirring, 14.4 g. of 1-phenyl-2-isopropylcyclopropane was run into 30 ml. of 90% sulfuric acid. Within a half hour the temperature rose to 40° after which it was maintained at 35° for one hour. The residual oil was removed by adding 25 ml. of ligroin, separating from the acid, washing the ligroin layer twice with 5-ml. portions of cold, concentrated sulfuric acid, steam distilling, separating the volatile oil, removing the ligroin by distillation through a short Widmer column, and distilling the residue. This gave 3.2 g. of 1,1,2-trimethylindan, b. p. 208°, d^{20}_4 0.919, $n^{20}D$ 1.5137.

Analyses.[11] Calculated for $C_{12}H_{16}$: C, 89.9; H, 10.1. Found (1-phenyl-2-isopropylcyclopropane): C, 89.7; H, 10.1. Found (1,1,2-trimethylindan): C, 89.7; H, 10.2.

Oxidation of 0.46 g. of the product obtained above by the method of Price, Davidson and Bogert[4] yielded 0.30 g. of the ketone acid (V) which when recrystallized from water melted at 156°. This did not depress the melting point of an authentic sample of the acid melting at 158°. Both samples gave iodoform when treated with sodium hypoiodite.

(11) These analyses were performed by Mr. Saul Gottlieb, Columbia University.

Summary

1. 1-Phenyl-2-isopropylcyclopropane is rearranged by 90% sulfuric acid to 1,1,2-trimethylindan.

2. Under similar conditions 1-phenyl-2-methylcyclopropane and 1-phenyl-2-ethylcyclopropane undergo polymerization.

3. Cyclopropanes obey the modernized Markovnikov rule.

The Isolation of Stigmasterol and β-Sitosterol from the Common Bean, *Phaseolus vulgaris*

BY ARNOLD C. OTT[1] AND CHARLES D. BALL

The content of the "crude fat" of the common or navy bean, *Phaseolus vulgaris*, has been reported by various workers[2] to be between 1.4 and 2.36%. Grimme[3] submitted values for certain physical and chemical constants of the oil among which was an unsaponifiable matter percentage of 5.85. Likiernik[4] appeared to be the only worker to have isolated sterols from any part of the bean. He obtained from the seed coats two substances named by him paraphytosterol and phasol. In harmony with the work of Anderson and Shriner[5] paraphytosterol would appear to be γ-sitosterol, while phasol, m. p. 189–190°, $[\alpha]_D$ + 30.6°, is either a mixture or has not been identified with any of the better known sterols. Attention has been focused on the ether soluble portion of the navy bean by the recent observation of Bowman,[6] who maintains that the bean oil retards the digestion of soluble starch by pancreatic amylase *in vitro*.

In the present work the bean oil, "ether extract," has been found to represent about 2.6% of the bean, of which 5.0 to 6.0% was unsaponifiable matter. This unsaponifiable matter consisted of 55 to 60% crude sterols. Stigmasterol made up about one-fourth of the sterols, while β-sitosterol was found to be present to the extent of 5 to 7% of the total sterols. The separation of the stigmasterol was based on the insolubility of the tetrabromide while the β-sitosterol was obtained from the mother liquors after debromination and fractional crystallization as acetates. No sterols corresponding to α-sitosterols appeared to be present in any appreciable amount. After irradiation the unsaponifiable matter had a vitamin-D activity of about 700 U. S. P. units per g. of unsaponifiable matter, thus indicating the presence in very small amount or amounts of irradiatable sterol or sterols.

(5) Anderson and Shriner, THIS JOURNAL, **48**, 2976 (1926).

(6) Bowman, *Science*, **98**, 308 (1943).

Experimental

1. Extraction of the Beans.—Forty kg. of the common bean, *Phaseolus vulgaris*, was ground in a hammer mill and extracted six times by cold ethyl ether. The extract was filtered and the solvent distilled off in an atmosphere of carbon dioxide. The yield was 0.83 kg. of yellow oil, which represented 1.9% of the original beans.

2. Saponification.—To the entire lot of the oil 4 liters of ethanol and 1 liter of 50% potassium hydroxide were added. The mixture was stirred on the steam-bath for two hours. Water was then added and the unsaponifiable matter was exhaustively extracted from the soaps with "Skellysolve B." The combined extracts were concentrated to 50% concentration of oil and then washed free from alkali. The remainder of the solvent was evaporated; yield, 48.7 g. of a yellow, semi-solid oil. This quantity represented about 5.9% of the crude oil.

3. Preparation of Crude Sterols.—The entire lot of unsaponifiable material was taken up in petroleum ether, b. p. 40–60°, and steam passed into the solution until saturation nearly occurred. The solution was then allowed to stand overnight. The first fraction of crystals, designated Fraction I, consisted of 22.5 g. of colorless crystals; m. p. 138–144°; $[\alpha]^{27}D$ −44.0° (35.4 mg., 2.1 ml. chloroform, l = 1 dm., $\alpha^{27}D$ −0.742°, *average* reading). The Liebermann–Burchard reaction was strongly positive. The mother liquor was evaporated to 300 ml. and allowed to stand for twenty-four hours in the cold. The result was Fraction II, which consisted of 7.2 g. of crystals, m. p. 128–131°; $[\alpha]^{26}D$ −38.0° (38.6 mg., 2.1 ml. chloroform, l = 1 dm., $\alpha^{26}D$ −0.698°, *average* reading). A third fraction of about 2 g. was obtained from the mother liquors of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

fraction II. The total crude sterols amounted to 29–30 g. or about 60% of the unsaponifiable matter.

4. Separation of Sterols.—An unsuccessful attempt was made to separate the sterols as azobenzenemonocarboxylic esters according to the chromatographic method of Ladenburg, Fernholz and Wallis.[7] From their work the separability of sterols on alumina depends primarily upon differences between the number of double bonds, and not upon their position or upon the nature of the side chains. Inference might be implied that the sterols of the common bean are all of the same general type.

One and one-half g. portions from each of Fractions I and II were combined, and acetylated with 60 ml. of acetic anhydride, by refluxing for one and one-half hours. The mixture was concentrated to saturation and after cooling for one hour at 12°, the crude acetates were filtered off. The acetates were brominated by solution in 30 ml. of ethyl ether and the addition of 38 ml. of bromine–acetic acid solution (5 g. bromine in 100 ml. of glacial acetic acid) following the procedure of Windaus and Hauth.[8] After refrigeration the insoluble bromides were filtered and washed with cold ethyl ether. A yield of 1.4 g., m. p. 190–194°, was obtained. Six recrystallizations of the bromides from chloroform–methanol gave a product with a m. p. of 194–196°.

Stigmasteryl Acetate.—To a solution of 1.2 g. of the recrystallized bromides in 12 ml. of glacial acetic acid 1.2 g. of zinc dust was added. The mixture was refluxed for one and one-half hours, filtered hot, diluted with water, and extracted with ethyl ether. The ether layer was washed with dilute sodium sulfite, then with water, and the ether removed by evaporation. The product obtained weighed 580 mg. It was recrystallized four times from ethanol, and twice from 2–1 methanol–chloroform; m. p. 139–140°; $[\alpha]^{25}D$ −54.0° (37.4 mg., 2.1 ml. chloforoform, l = 1 dm., $\alpha^{25}D$ −0.962°, *average* reading).

Anal.[9] Calcd. for $C_{31}H_{50}O_2$: C, 81.88; H, 11.09. Found: C, 81.18; H, 10.73.

Stigmasterol.—Four hundred mg. of the above acetate was hydrolyzed for one hour with 10% alcoholic potassium hydroxide. Water was added and the mixture extracted with ethyl ether. The ether solution was washed with dilute sodium carbonate, and then with water. After removal of the ether, the residue was recrystallized three times from 95% ethanol, m. p. 168–169°; $[\alpha]^{29}D$ −47.3° (28.6 mg., 2.1 ml. chlofororm, l = 1 dm., $\alpha^{29}D$ −0.644°, *average* reading).

Anal. Calcd. for $C_{29}H_{48}O$: C, 84.40; H, 11.72. Found: C, 83.47; H, 11.70.

Stigmasteryl Benzoate.—About 300 mg. of the free sterol was dissolved in 2 ml. of dry pyridine; then 0.6 ml. of benzoyl chloride was added. The mixture was heated for two and one-half hours in a glass-stoppered flask on the steam-bath and allowed to cool. The contents were poured into ice-cold 5% sulfuric acid. The solution was extracted with ethyl ether, washed with dilute sodium carbonate, and then with 10% ethanol. The extract was evaporated on the steam-bath and the residue recrystallized three times from ethanol and once from methanol–chloroform; m. p. 160.5–161.5°; $[\alpha]^{24}D$ −24.5° (152.3 mg., 2.1 ml. chloroform, l = 1 dm., $\alpha^{24}D$ −1.779°, *average* reading).

Anal. Calcd. for $C_{36}H_{52}O_2$: C, 83.65; H, 10.14. Found: C, 83.95; H, 9.83.

β-Sitosteryl Acetate.—The remainders of Fractions I and II were combined with the small amount of the third fraction. This combined fraction was converted into acetates by treatment with 250 ml. of acetic anhydride and refluxing for two and one-half hours. On cooling, a yellow, wax-like cake appeared on the surface, while suspended below colorless crystals were observed. The colorless crystals were dissolved by warming the solution to about 40°, and the colored, wax-like cake removed by filtration. The filtrate was reduced in volume to effect a more complete crystallization, cooled in the refrigerator for one hour, filtered and washed with cold glacial acetic acid. The product obtained (about 10 g.) was brominated as previously described, the brominated products filtered off, and the derivatives in the filtrate debrominated in the usual manner with zinc dust. The debrominated acetates were taken up in sufficient 1–1 acetone–chloroform to effect a solution about one-half saturated. After standing overnight, the solid acetates were removed by filtration. The acetates were subjected to a triangular fractionation[10] first with a 3–1 acetone–methanol mixture and subsequently with a 3–1 ethanol–benzene mixture. From this fractionation appeared: (1) a wax-like material, insoluble in cold concentrated sulfuric acid, with a m. p. of 65–66.5° after thirteen recrystallizations from ethanol–benzene and (2) β-sitosteryl acetate; m. p. 123–124°; $[\alpha]^{28}D$ −38.5° (40.5 mg., 2.1 ml. chloroform, l = 1 dm., $\alpha^{28}D$ −0.744°, *average* reading).

Anal. Calcd. for $C_{31}H_{52}O_2$: C, 81.52; H, 11.47. Found: C, 81.59; H, 10.96.

The first material was no further characterized.

β-Sitosterol.—The above acetate was saponified with 10% alcoholic potassium hydroxide, extracted and washed as usual. The product was crystallized three times from methanol–chloroform; m. p. 136–138°; $[\alpha]^{25}D$ −37.8° (19.2 mg., 2.1 ml. chloroform, l = 1 dm., $\alpha^{25}D$ −0.346°, *average* reading).

Anal. Calcd. for $C_{29}H_{50}O$: C, 83.99; H, 12.15. Found: C, 83.41; H, 11.25.

β-Sitosteryl Benzoate.—Fifty mg. of the free sterol was treated with 0.2 ml. of benzoyl chloride in 1.5 ml. of dry pyridine. The mixture was heated for one and one-half hours on the steam-bath and allowed to stand. The contents of the reaction were poured into cold 5% sulfuric acid and the mixture extracted with ethyl ether. The residue obtained from the ether extraction was crystallized four times from ethanol; m. p. 145–146°; $[\alpha]^{25}D$ −13.5° (19.4 mg., 2.1 ml. chloroform, l = 1 dm., $\alpha^{25}D$ −0.125°, *average* reading).

In Table I are presented the data on the properties of stigmasterol and β-sitosterol and their derivatives as obtained or derived from the common bean, together with a comparison of the corresponding products as obtained from other sources by other investigators.

TABLE I

	M. p., °C.	$[\alpha]_D$ in $CHCl_3$
Stigmasterol (isolated from the common bean)	168–169	−47.3
acetate	139–140	−54.0
benzoate	160.5–161.5	−24.5
Stigmasterol[11]	169–170	−44.7 to 51.0
acetate[11]	141 to 144	−55.6
benzoate[11]	160	
β-Sitosterol (isolated from the common bean)	136–138	−37.8
acetate	123–124	−38.5

β-sitosteryl acetate, the fraction containing the soluble acetates was obtained by evaporation of the solvent on the steam-bath. The residue obtained was taken up in ethanol and hydrolyzed by the addition of alcoholic potassium hydroxide in the manner previously described. The solution obtained was worked up in the same manner as given for β-sitosterol. The product was dried and treated with sufficient 3,5-dinitrobenzoyl chloride in order to yield the corresponding esters. Triangular fractionation was again used in an attempt to isolate one of the three known "α-sitosterols," which according to Wallis and Fernholz[13] differ greatly in the solubilities of their 3,5-dinitrobenzoates. The most insoluble of the 3,5-dinitrobenzoates obtained had a m. p. of 222–223°; $[\alpha]^{28}D$ −17.3° (23.6 mg., 2.1 ml. chloroform, l = 1 dm., $\alpha^{28}D$ −0.195°, *average* reading). The regenerated free sterol melted at 155–157°; $[\alpha]^{28}D$ −55.8° (15.6 mg., 2.1 ml. chloroform, l = 1 dm., $\alpha^{28}D$ −0.415°, *average* reading). The acetate of the free sterol was prepared; m. p. 134–135°. The Liebermann–Burchard reaction was positive. Since all the derivatives of all the "α-sitosterols" have a positive value of relatively high magnitude for their optical rotations, the absence of any appreciable amounts of α-sitosterols is indicated, and the presence of an unknown sterol is indicated. A summary of the properties of this unknown sterol is also included in Table I.

5. Irradiation of the Unsaponifiable Matter.—A portion of the unsaponifiable matter was dissolved in ethyl ether and irradiated with ultraviolet light. Aliquots of this stock solution were taken for assay by the standard biological method. The results of the assay indicated an activity of 700 U. S. P. units per g. of crude unsaponifiable matter.[14]

(13) Wallis and Fernholz, THIS JOURNAL, **58**, 2446 (1936).

Summary

1. The total unsaponifiable matter of the common bean, *Phaseolus vulgaris*, is about 5.9%, or about 0.15% of the air-dry bean.

2. About 60% of the unsaponifiable matter is represented by crude sterols.

3. Stigmasterol and β-sitosterol have been isolated and characterized, the former representing about 25%, and the latter about 6% of the crude sterols.

4. An unidentified sterol with a high negative optical rotation has been isolated.

5. Neither α-sitosterols nor γ-sitosterol, the apparent paraphytosterol of Likiernik, have been found, although the presence of small amounts of these sterols is not precluded.

6. The unsaponifiable matter of the common bean after irradiation has a Vitamin-D activity of 700 U. S. P. units per g.

(14) The authors wish to thank Dr. C. A. Hoppert, Professor of Biological Chemistry, for the Vitamin-D assay.

Studies in the Biphenyl Series. IV. The Iodination of the Acetate, Benzoate and Benzenesulfonate of 4-Hydroxybiphenyl[1]

BY HAROLD R. SCHMIDT, CORA MAY SAVOY[2] AND JOHN LEO ABERNETHY

In connection with an investigation of the bactericidal activity of certain halo-4-hydroxybiphenyls, it was of interest to find a more convenient route to 4-hydroxy-4′-iodobiphenyl than had been used previously. Since it is known that chlorination[3,4,5] and bromination[6,7] of certain esters of 4-hydroxybiphenyl give rise to substitution in the 4′-position of the biphenyl nucleus, and subsequent hydrolysis gives the desired 4′-chloro and 4′-bromo compound, it seemed that iodination of these esters might give rise to the corresponding iodo compounds. Hence, 4-acetyloxybiphenyl, 4-benzoyloxybiphenyl and 4-benzenesulfonyloxybiphenyl were subjected to iodination.

Iodination of 4-acetyloxybiphenyl (I) with iodine in the presence of nitric acid gave rise to 4-acetyloxy-4′-iodobiphenyl (II) when either carbon tetrachloride or glacial acetic acid was used as the solvent. Hydrolysis of the ester gave rise to 4-hydroxy-4′-iodobiphenyl (III) which did not depress the melting point of the known compound prepared from benzidine (IV), by converting IV to 4-amino-4′-iodobiphenyl (V) and then to III, according to the method of van Alphen.[8] Furthermore, acetylation of III produced an ester which did not depress the melting point of the product of iodination of I. It was found that a better yield of the iodinated ester (II) was obtained if nitric acid was added immediately to the reaction mixture rather than dropwise over a period of several hours. The latter procedure gave rise to a considerable amount of nitrated product, along with the iodinated ester.

By means of a similar reaction, 4-benzoyloxybiphenyl (I) was converted to 4-benzoyloxy-4′-iodobiphenyl (II). Benzoylation of III gave rise to this same ester. Hydrolysis of II yielded III. Similarly, iodination of 4-benzenesulfonyloxybiphenyl (I) yielded 4-benzenesulfonyloxy-4′-iodobiphenyl (II), which was proved by benzenesulfonation of III. Hydrolysis of II yielded III.

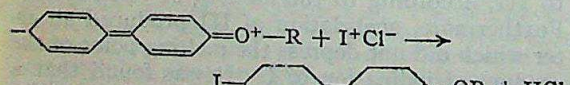
R = —$COCH_3$, —COC_6H_5 or —$SO_2C_6H_5$

Iodine monochloride has been found to be a suitable iodinating agent for many organic compounds which contain strong ortho-para directing substituents. Since iodine monochloride has a very high dipole moment, even in solvents of very low dielectric constant,[9] its ability to make an electrophilic attack on positions of relatively high electron density in aromatic compounds is readily explained. As there would be considerable resonance between the benzene rings of the biphenyl nucleus, particularly when the 4-position contains an acetyloxy, benzoyloxy or benzenesulfonyloxy substituent, and as the 3- and 5-positions are hindered by the ester linkages, it was anticipated that substitution by means of this incipiently ionized iodine monochloride would take place with relative ease. Such was found to be the case when either carbon tetrachloride or glacial acetic acid was used as the solvent.



R = —$COCH_3$, —COC_6H_5 or —$SO_2C_6H_5$.

Substituted esters identical with the ones prepared by iodination with iodine and nitric acid were formed.

Acknowledgment.—The authors are indebted to the Research Institute of the University of Texas for a grant which made this investigation possible.

Experimental

Iodination of 4-Acetyloxybiphenyl.—(a) A mixture of 10 g. of 4-acetyloxybiphenyl, prepared from 4-hydroxybiphenyl, 13.1 g. of iodine (10% excess), 100 ml. of carbon tetrachloride and 3 ml. of concentrated nitric acid was refluxed on a steam-bath for five hours and allowed to cool. The solvent was removed by distillation under reduced pressure, and the solid residue was crystallized from ethanol. After purification by recrystallization from ethanol, the pure 4-acetyloxy-4′-iodobiphenyl, which was obtained as lustrous white plates melting at 155° (cor.), weighed 6.1 g. (38.3% yield).

(b) Ten grams of 4-acetyloxybiphenyl and 13.1 g. of iodine were suspended in 100 ml. of glacial acetic acid, and a solution of 3 ml. of concd. nitric acid in 25 ml. of glacial acetic acid was added dropwise over a period of four hours. The mixture was refluxed during the addition of the nitric acid, and for one hour after. The product was cooled, poured into 800 ml. of ethanol, and recrystallized from ethanol. Pure 4-acetyloxy-4′-iodobiphenyl (2.2 g.) (13.8% yield) with m. p. 155° resulted. The rapid addition of nitric acid yielded a product of yellow needles (m. p. 201°) in greater quantity than the iodo compound. Nitration of 4-acetyloxybiphenyl in glacial acetic acid gave rise to the same yellow needles, m. p. 201°.

(c) Fifteen grams of 4-acetyloxybiphenyl was dissolved in 60 ml. of glacial acetic acid. To this solution 14.5 g. of iodine monochloride (Eastman Kodak Co. grade), dissolved in 20 ml. of glacial acetic acid, was added slowly over a period of one-half hour. The mixture was heated gently on a steam-bath during the addition. After all the iodine monochloride had been added the mixture was heated for three hours with constant stirring. Hydrogen chloride was liberated slowly.

At the end of the reaction period the mixture was cooled and poured into a large quantity of ice water. The oil which separated was dissolved in chloroform and the resultant solution was washed thoroughly with sodium bisulfite solution to remove the free iodine and then with water. After drying over anhydrous sodium sulfate, approximately one-third of the chloroform was removed under reduced pressure. Petroleum ether (b. p. 30–35°) was added to the remainder of the solution and 2.5 g. (10.5% yield) of pale yellow crystals separated. These were found to melt at 155–156° and proved to be 4-acetyloxy-4′-iodobiphenyl.

The remaining solution was concentrated further by the above procedure, yielding another precipitate. This solid was found to be soluble in ethanol which indicated that hydrolysis had taken place during the procedure. An attempt was made to benzoylate this solid. An oil formed which could not be solidified, which suggested that a mixture of several different substances was present. Further attempts to separate these products were unsuccessful.

Hydrolysis of 4-Acetyloxy-4′-iodobiphenyl.—Ten grams of 4-acetyloxy-4′-iodobiphenyl, prepared by the iodination of 4-acetyloxybiphenyl, was suspended in a solution of 50 ml. of water, 50 ml. of ethanol, and 10 g. of potassium hydroxide. The mixture was refluxed for one-half hour, cooled, and poured into 250 ml. of water. The solution was acidified, and the white precipitate which formed was filtered and washed with 2 liters of water. This product, obtained in quantitative yield (8.8 g.), melted at 202° (cor.) and did not depress the melting point of 4-hydroxy-4′-iodobiphenyl prepared from benzidine.

4-Hydroxy-4′-iodobiphenyl.—According to the method of van Alphen,[8] 25 g. of benzidine was tetrazotized, and the product obtained was allowed to stand with an additional 25 g. of benzidine at 15° for three days. The 4-amino-4′-biphenyldiazoic acid formed was treated with potassium iodide and subsequently diazotized and heated. The product was extracted from the reaction mixture with a dilute solution of sodium carbonate. Acidification of the solution yielded 3.5 g. (4.4% yield) of 4-hydroxy-4′-iodobiphenyl, which melted at 202° after crystallization from chloroform and petroleum ether (b. p. 35–55°).

Acetylation of 4-Hydroxy-4′-iodobiphenyl.—To a mixture of 2 g. of 4-hydroxy-4′-iodobiphenyl and 3 ml. of acetic anhydride, 5 drops of sirupy phosphoric acid was added. The mixture was refluxed for five minutes on a steam-bath. Water was added slowly to the hot solution until the excess acetic anhydride had decomposed. The

(9) Fairbrother, *Trans. Faraday Soc.*, **33**, 1507 (1937).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

warm solution was poured into ice water whereupon a precipitate separated. Filtration and recrystallization of the precipitate from ethanol yielded 1.8 g. (79% yield) of pure ester[8] melting at 155–156°. The melting point of a mixture of equal amounts of the above prepared ester and the product obtained on iodination of 4-acetyloxybiphenyl caused no depression.

Iodination of 4-Benzoyloxybiphenyl.—(a) A mixture of 10 g. of 4-benzoyloxybiphenyl, prepared from 4-hydroxybiphenyl, 10.1 g. of iodine (10% excess), 10 ml. of concentrated nitric acid, and 100 ml. of carbon tetrachloride was heated on a water-bath for eight hours. After the solvent was removed by distillation under reduced pressure, the solid residue was crystallized three times from glacial acetic acid. Pure 4-benzoyloxy-4′-iodobiphenyl (10.5 g.) (72% yield) was obtained as white plates which melted at 207° (cor.). When glacial acetic acid was used as the solvent for the iodination the yield was reduced to 45%.

(b) To a warm solution of 14.5 g. of 4-benzoyloxybiphenyl in 80 ml. of glacial acetic acid, 15 g. of iodine monochloride in 40 ml. glacial acetic acid was added in fifteen minutes. The mixture was placed on a steam-cone and heated to a temperature at which hydrogen chloride was liberated. Any iodine monochloride which vaporized was condensed in the lower part of the water-cooled condenser. The reaction was allowed to proceed for three hours, at the end of which time it was cooled and poured into ice water. A gummy mass separated. It was taken up in chloroform, washed with sodium bisulfite and water, and dried over anhydrous sodium sulfate.

When the solution was dry it was filtered and the chloroform removed by distillation under reduced pressure until a solid began to separate. The remaining portion was removed from the flask and white plates were caused to precipitate by the addition of petroleum ether. The solid was suspended and digested in hot ethanol. On filtration, 14.2 g. (67.2% yield) of solid was obtained. Recrystallization from acetic acid raised the melting point of 4-benzoyloxy-4′-iodobiphenyl to 207°.

Anal. Calcd. for $C_{19}H_{13}O_2I$: I, 31.75. Found: I, 31.30.

Hydrolysis of 4-Benzoyloxy-4′-iodobiphenyl.—4-Benzoyloxy-4′-iodobiphenyl (5 g.) was suspended in a solution containing 40 ml. of ethanol, 10 ml. of water and 5 g. of potassium hydroxide. The mixture was refluxed for eight hours, cooled, and diluted with an equal volume of water. After the ethanol had been removed by distillation, the solution was chilled and saturated with carbon dioxide. The white solid which separated was extracted with ether. The ether extract was dried with anhydrous sodium sulfate, and the solvent removed by distillation under reduced pressure. The solid residue was crystallized from a mixture of carbon tetrachloride and petroleum ether (b. p. 35–55°). This product, which weighed 2.9 g. (78% yield), melted at 202°. A mixture of the compound thus formed and 4-hydroxy-4′-iodobiphenyl prepared from benzidine melted at 202°.

The aqueous solution previously saturated with carbon dioxide was acidified and again extracted with ether. After the ether extract had been dried with anhydrous sodium sulfate, the ether was removed by distillation under reduced pressure. Upon recrystallization of the residue from water, 0.7 g. (44% yield) of benzoic acid, m. p. 121.5°, resulted.

Benzoylation of 4-Hydroxy-4′-iodobiphenyl.—A mixture of 1 g. of 4-hydroxy-4′-iodobiphenyl, 10 ml. of pyridine and 1 ml. of benzoyl chloride was refluxed for ten minutes. The solution was allowed to cool to room temperature and poured into 100 ml. of ice water. A precipitate separated which was filtered and digested with ethanol. The yield of 4-benzoyloxy-4′-iodobiphenyl was 1.1 g. (82% yield) and its melting point was 206–207°. A mixture of the product obtained by the action of iodine monochloride on 4-benzoyloxybiphenyl and the above ester did not cause a depression of the melting point.

Iodination of 4-Benzenesulfonyloxybiphenyl.—(a) A mixture of 10 g. of 4-benzenesulfonyloxybiphenyl and 8.9 g. (10% excess) of iodine was suspended in 100 ml. of carbon tetrachloride containing 10 ml. of conc. nitric acid. The suspension was heated on a water-bath for eight hours and allowed to cool. After the solvent had been removed by distillation under reduced pressure, the solid residue was crystallized three times from methanol. The 4-benzenesulfonyloxy-4′-iodobiphenyl, obtained as white needles which melted at 93.5° (cor.), weighed 8.5 g. (60% yield).

Iodination of 4-benzenesulfonyloxybiphenyl was carried out as described above, except that glacial acetic acid was used as the solvent. The same product, 4-benzenesulfonyloxy-4′-iodobiphenyl, resulted in a yield of 51%.

(b) 4-Benzenesulfonyloxybiphenyl (16.7 g.) was suspended in 50 ml. of glacial acetic acid and heated gently on a steam-bath, which caused the ester to dissolve. Fifteen grams of iodine monochloride, dissolved in 20 ml. of glacial acetic acid, was added slowly to the above solution. The reaction was allowed to run for three hours with constant heating and stirring. At the end of this time the solution was cooled and poured into ice water, whereupon a solid separated. The solid was taken up in chloroform after which the iodine was removed with sodium bisulfite solution. The chloroform solution was washed with water and distilled under reduced pressure until approximately one-third of the original volume remained. To this mixture petroleum ether was added causing a precipitate to separate. The solid was recrystallized three times from ethanol, and yielded 5.4 g. (23% yield) of pure 4-benzenesulfonyloxy-4′-iodobiphenyl. The melting point of the above white needle-like crystals was 92–93° (cor.).

Anal. Calcd. for $C_{18}H_{13}SO_3I$: I, 29.10. Found: I, 28.95.

Hydrolysis of 4-Benzenesulfonyloxy-4′-iodobiphenyl.—A suspension of 10 g. of 4-benzenesulfonyloxy-4′-iodobiphenyl in 160 ml. of ethanol, 40 ml. of water, and 10 g. of potassium hydroxide was refluxed for twelve hours, cooled, and diluted with an equal volume of water. The solution was acidified, and the white precipitate which separated was crystallized from a mixture of carbon tetrachloride and petroleum ether (b. p. 35–55°). Six and six-tenths grams of purified product (97% yield), melting point 202°, resulted. A mixture of this compound and 4-hydroxy-4′-iodobiphenyl prepared from benzidine melted at 202°.

Benzenesulfonation of 4-Hydroxy-4′-iodobiphenyl.—Two grams of 4-hydroxy-4′-iodobiphenyl was dissolved in 20 ml. of pyridine and cooled by means of an ice-bath. To this cooled solution, 3 ml. of benzenesulfonyl chloride was added. After the addition the mixture was heated gently on a hot-plate for fifteen minutes, cooled to room temperature and poured into 100 ml. of ice water. The precipitate which separated was filtered and recrystallized from ethanol. The pure product, melting at 93.5° (cor.), weighed 2.7 g. (93% yield). A mixture of the product obtained on iodination of 4-benzenesulfonyloxybiphenyl and the ester as prepared above caused no depression in the melting point.

Summary

Iodination of the acetate, benzoate and benzenesulfonate of 4-hydroxybiphenyl gave rise to substitution in the 4′-position. Both iodine monochloride and iodine and nitric acid were used as iodinating agents. Proof of the structure of these esters was afforded by hydrolysis to the known 4-hydroxy-4′-iodobiphenyl, prepared from benzidine. Furthermore, acetylation, benzoylation and benzenesulfonation of 4-hydroxy-4′-iodobiphenyl gave rise to these same esters.

The ease of iodination of these esters with iodine monochloride has been explained on the basis of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the high dipole moment of iodine monochloride and the resonance between the benzene rings of the biphenyls.

It would appear in each case that iodination with iodine and nitric acid in a carbon tetrachloride solution is the best procedure for iodination of the esters studied.

Pyrolysis of Lactic Acid Derivatives. Production of Phenyl and *o*-Tolyl Acrylate*

BY E. M. FILACHIONE, J. H. LENGEL AND C. H. FISHER

In recent years considerable interest has been shown in the production of acrylic esters by the pyrolysis of esters of acetoxypropionic acid. These esters can be made from lactic acid by the reactions

$$CH_3CHOHCOOH + ROH \longrightarrow CH_3CHOHCOOR + H_2O$$

$$CH_3CHOHCOOR + (CH_3CO)_2O \longrightarrow CH_3CH(OCOCH_3)COOR$$

Methyl acetoxypropionate[1,2] has been pyrolyzed to give high yields of methyl acrylate. Satisfactory yields of acrylic esters have been obtained also by pyrolysis of the benzyl[1] and tetrahydrofurfuryl[3] esters of acetoxypropionic acid. Other esters of acetoxypropionic acid, including the ethyl,[1] butyl,[1] allyl,[4] and methallyl[4] esters, have been pyrolyzed, but the yields of the corresponding acrylic esters are low, since a predominant side reaction takes place, *i. e.*, the aliphatic alcohol radical is decomposed into the corresponding olefin. For example, ethylene, carbon monoxide, acetaldehyde and acetic acid are formed when ethyl acetoxypropionate is pyrolyzed. Because of this or other side reactions, the satisfactory preparation of acrylic esters by the pyrolytic method appears limited to acetoxypropionic esters that have relatively stable alkyl groups.

Recent work[5] has shown that α-acetoxyisobutyric esters can be converted by pyrolysis into methacrylic esters more readily than α-acetoxypropionic esters can be transformed into acrylic esters.

Phenol is thermally stable, and because of their structure phenyl and substituted phenyl esters of acetoxypropionic acid would be expected to be incapable of the side reaction that occurs with ethyl acetoxypropionate and related esters. Results given in the present paper demonstrate that this expectation was reasonable.

Phenyl and *o*-tolyl acetoxypropionates were prepared by the following series of reactions and also by the methods described in the experimental section: (1) Aqueous 80% lactic acid was acetylated with acetic acid, benzene being used as an entraining agent to remove the water of esterification continuously.[6] The yields of acetoxypropionic acid were as high as 77%. (2) Acetoxypropionic acid was converted by means of thionyl chloride into acetoxypropionyl chloride in 80 to 82% yields. (3) Acetoxypropionyl chloride was converted by treatment with phenol (or *o*-cresol) into phenyl (or *o*-tolyl) acetoxypropionate in yields of almost 90%. (4) Pyrolysis of phenyl acetoxypropionate (or the corresponding *o*-tolyl ester) produced the aryl acrylate (75 to 80% yields).

Phenyl α-acetoxypropionate was pyrolyzed at temperatures and contact times that ranged from 440 to 600° and from 0.77 to 20 seconds. A pressure of 18 to 19 mm. was used in one experiment, atmospheric pressure for the others (Table I). The yield of acetic acid was always higher than the yield of phenyl acrylate. Carbon monoxide and carbon dioxide were formed in some experiments in considerable amounts. Styrene, obtained in yields as high as 20%, presumably was formed prior to decomposition of phenyl acetoxypropionate into phenyl acrylate since it has been reported by Skraup and Nietzen[7] that phenyl acrylate yields phenol, acetylene, and carbon monoxide on pyrolysis.

o-Tolyl acetoxypropionate was pyrolyzed at temperatures ranging from 500 to 591° (Table II). *o*-Tolyl acrylate was obtained in yields as high as 75%; the yields of acetic acid were even higher. No real attempt was made to detect *o*-methylstyrene in the reaction products.

Possibly because of the presence of small amounts of phenol or some other inhibitor, the phenyl acrylate purified by distillation showed little tendency to polymerize. Samples of phenyl acrylate that had been washed with dilute sodium

hydroxide solution, however, polymerized readily (mass polymerization at 75°) in the presence of 1% benzoyl peroxide, forming a transparent product that was hard at room temperature but became soft at approximately 60°.

When a sample of *o*-tolyl acrylate isolated from the pyrolysis products by distillation was heated with approximately 1% benzoyl peroxide, a soft and viscous polymer was formed. Samples of the *o*-tolyl ester that had been washed with alkali polymerized readily (mass polymerization at 67°) when treated with 1% benzoyl peroxide. The polymer thus obtained, which was hard at room temperature, softened at approximately 60°.

The authors gratefully acknowledge the assistance of Dr. W. P. Ratchford, under whose direction the pyrolyses were carried out, and also the assistance of the other members of the Carbohydrate Division and of the Analytical and Physical Chemistry Division.

Experimental

Preparation of Acetoxypropionyl Chloride.—A mixture of 4 moles of lactic acid (80%), 28.0 moles of glacial acetic acid, 200 ml. of benzene, and 1 ml. of concentrated sulfuric acid was refluxed, with the continuous removal of water by means of a modified Dean and Stark tube. After twenty-one hours the mixture was neutralized with 4.0 g. of sodium acetate and distilled in vacuum. A 77% yield of acetoxypropionic acid resulted. By heating the acetoxypropionic acid with thionyl chloride (1.1 mole) gradually for approximately two hours to a final temperature of 95°, followed by distilling in vacuum, an 82% yield of acetoxypropionyl chloride was isolated.

Preparation of Phenyl α-Acetoxypropionate.—Phenyl acetoxypropionate was prepared by heating equimolar quantities of phenol and acetoxypropionyl chloride on a steam-bath until evolution of hydrogen chloride ceased. The ester was then isolated in 86 to 88% yields by distillation in vacuum: b. p. 110 to 111° (2 to 3 mm.) and 143° (12 mm.); $n^{20}D$ 1.4860; d^{20}_4 1.134. *Anal.* Calcd. for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81; M_R, 52.70. Found: C, 62.63; H, 6.05; M_R, 52.65.

Phenyl acetoxypropionate was prepared also by (a) the reaction of acetoxypropionyl chloride with aqueous sodium phenolate (65% yield); (b) the interaction of acetoxypropionyl chloride, phenol, and phosphorus oxychloride (30%); and treatment of phenyl acetate with acetoxypropionic acid in the presence of a small amount of concentrated sulfuric acid (45% yield on the basis of unrecovered acetoxypropionic acid).

Preparation of o-Tolyl α-Acetoxypropionate.—A mixture of 1.0 mole of *o*-cresol and 1.0 mole of α-acetoxypropionyl chloride was heated on the steam-bath until evolution of hydrogen chloride ceased. The mixture was then distilled in vacuum, a Claisen flask being used. The *o*-tolyl α-acetoxypropionate boiled at 112 to 113° below 1 mm.; $n^{20}D$ 1.4860; d^{20}_4 1.124. *Anal.* Calcd. for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35; saponification equivalent, 111.1. Found: C, 64.01; H, 6.56; saponif. eq., 111.2.

Pyrolysis.—The pyrolysis of the acetoxypropionates was carried out by allowing the liquid to run into a Pyrex glass tube having a bore of 30 mm. and heated over a length of 13 inches. The vertical tube, packed with short lengths of Pyrex glass tubing, was heated by an electric furnace[2] controlled automatically. The apparatus[2] was swept with nitrogen before the pyrolysis started and also after all the ester had been added. A small amount of hydroquinone was added to the condensate to prevent premature polymerization.

Titration of the crude pyrolysis product showed the amount of acetic acid present. The acrylate and undecomposed acetoxypropionate were isolated by vacuum

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

distillation of the crude pyrolysis product. Styrene was also formed in the pyrolysis of phenyl acetoxypropionate. It was collected with the acetic acid fraction in the distillation and was isolated by adding salt water to the acetic acid fraction.

Further data on the pyrolysis of phenyl and *o*-tolyl acetoxypropionate are given in Tables I and II.

Properties of Phenyl Acrylate and *o*-Tolyl Acrylate.—Phenyl acrylate[7] as obtained by the pyrolysis of phenyl α-acetoxypropionate was a virtually colorless liquid that boiled at 63 to 64° at 1- to 2-mm. pressure and 87 to 94° at approximately 12 mm.; $n^{20}D$ 1.5210; d^{20}_4 1.0762. *Anal.* Calcd. for $C_9H_8O_2$: C, 72.97; H, 5.44; M_R, 41.35. Found: C, 72.77; H, 5.66; M_R, 41.92. Neither the phenyl nor the *o*-tolyl acrylate polymerized readily until it had been washed with dilute alkali.

The *o*-tolyl acrylate was a virtually colorless liquid: b. p. 55 to 57° at 0.5 mm.; 78 to 79° at 3 mm.; $n^{20}D$ 1.5160; d^{20}_4 1.050; MR (calcd.) 45.96; MR (obs.) 46.59.

Summary

1. Satisfactory methods have been developed for converting lactic acid into α-acetoxypropionyl chloride, phenyl α-acetoxypropionate and *o*-tolyl α-acetoxypropionate.

2. Pyrolysis of the phenyl and *o*-tolyl esters of acetoxypropionic acid yielded phenyl and *o*-tolyl acrylate, respectively. Styrene also was formed in the pyrolysis of phenyl acetoxypropionate.

3. Relatively hard resins were obtained by polymerizing phenyl and *o*-tolyl acrylate.

Polarographic Behavior of Aniline Oxidation Products

BY DAVID LESTER AND LEON A. GREENBERG

A recent paper by Levitan, Kolthoff, Clark and Tenenberg[1] describes the polarographic behavior of some of the oxidation products of sulfanilamide. For some time we have been interested in the possible use of the polarograph for the analysis of the intermediary products of the metabolism of aniline and therefore investigated the behavior of β-phenylhydroxylamine, *p*-aminophenol, and azoxybenzene at the dropping mercury electrode. Since we concluded at that time that this method of analysis was better replaced by specific and more sensitive colorimetric methods in the case of the first two compounds, our study was not pursued further.

Our study, however, yielded results which appear to be at variance with those published on the hydroxylamino derivative of sulfanilamide. We find that in 0.07 *M* phosphate buffer (*p*H 6.3) β-phenylhydroxylamine does not give a cathodic wave but does give an anodic oxidation wave with an $E^1/_2$ *vs.* the S. C. E. of −0.02 volt. Levitan, Kolthoff, Clark and Tenenberg do not mention an anodic wave but do find a cathodic wave in 0.1 *M* sodium hydroxide. It has been our experience with β-phenylhydroxylamine that in the presence of alkali it is converted quite completely and rapidly to the azoxybenzene derivative, which then exhibits a cathodic wave; it is therefore impossible to polarograph alkaline β-phenylhydroxylamine solutions. It would be noteworthy if hydroxylaminobenzenesulfonamide, through the presence of a sulfonamide group, would not undergo this same transformation. This point is supported by the fact that the half-wave potentials for the hydroxylamino and azoxy derivatives of sulfanilamide are practically identical. It is unfortunate that the electrode reduction of the azoxy compound had to be carried out in 50% methanol, thus making impossible comparisons of the diffusion currents.

With our apparatus (Fisher Scientific Co. Electropode) and capillary an anodic diffusion current of 5.23 μa. per 0.001 *M* solution was found for hydroquinone and *p*-aminophenol with the 0.07 *M* phosphate buffer (*p*H 6.3). Since it is known that two electrons are involved in this reaction, two electrons are probably also involved in the anodic oxidation of β-phenylhydroxylamine, which gives a diffusion current of 5.3 μa. per 0.001 *M* solution. We have found that with the same buffer, but containing 20% ethanol, the diffusion current of azoxybenzene is 7.5 μa. per 0.001 *M* solution, with an $E^1/_2$ *vs.* the S. C. E. of −0.63 volt. Since the addition of alcohol decreases the diffusion current, it is quite likely that four electrons or more may be involved in the reduction: thus $C_6H_5NONC_6H_5 \rightarrow C_6H_5NHNHC_6H_5 + H_2O$, that is, the reduction to hydrazobenzene and water.

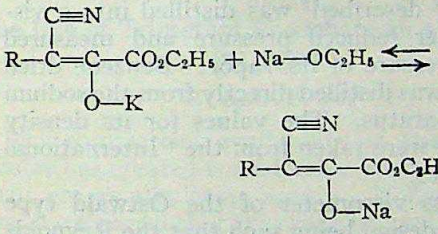
causing the condensation of ethyl phenylacetate with ethyl carbonate or ethyl oxalate. Accordingly mixtures of sodium and potassium ethoxides have been applied to nitriles that do not satisfactorily condense with ethyl oxalate under the influence of sodium ethoxide alone, there being the possibility that once the potassium derivative is formed it might undergo double decomposition with sodium ethoxide and thus avoid to some extent the use of potassium.



Fleischauer[2] was unable to isolate cyanopyruvic ester from the condensation products formed by the action of sodium ethoxide on a mixture of methyl cyanide and ethyl oxalate although he did show that a small amount had been formed. Wislicenus and Silberstein[3] using potassium ethoxide obtained an 83% yield of cyanomethylpyruvic ester from propionitrile. Later investigators[4] have used potassium ethoxide. Thus it would appear that the activation of the α-hydrogen in aliphatic nitriles by the nitrile group alone is not sufficient to permit a satisfactory reaction if sodium ethoxide is the condensing agent.

In phenylacetonitrile, which readily condenses,[5] this hydrogen is also in the reactive position with respect to the double bond in the ring. It is significant also that ethylene cyanide reacts readily with two moles of oxalic ester to give a fair yield of the diketo ester while trimethylene cyanide reacts with only one mole.[6] This difference may be understood if one considers that the hydrogen of the second methylene group in the case of ethylene cyanide is activated also by the double bond of the enolic form present as the salt. In the case of trimethylene cyanide these two influences activate different hydrogen atoms.

(2) Fleischauer, *J. prakt. Chem.*, [2] **47**, 375 (1893).
(3) Wislicenus and Silberstein, *Ber.*, **43**, 1825 (1910).
(4) Borsche and Manteuffel, *Ann.*, **512**, 97 (1934).
(5) Erlenmeyer, Jr., *Ber.*, **22**, 1483 (1889).
(6) Michael, *Am. Chem. J.*, **30**, 156 (1903).

The results of our experiments indicate that with valeronitrile a very poor yield (13%) of cyano-*n*-propylpyruvic ester is obtained with sodium ethoxide as the sole condensing agent, that if one-tenth of the sodium ethoxide is replaced by potassium ethoxide the yield is raised to 31% and that the yield is 55% if potassium ethoxide is the sole condensing agent. On this basis the yield should be increased to approximately 17% by the substitution of the equivalent weight of potassium for 10% of the sodium, whereas the yield is actually increased to 31%. An equimolecular mixture of sodium and potassium ethoxides gave a 79% yield of cyanomethylpyruvic ester which is almost as good as that obtained by Wislicenus and Silberstein who used potassium ethoxide. According to the procedure we employed the greater solubility of the sodium enolate causes no error in isolating the product. The ethylation of cyanopropylpyruvic ester yields the ether of the enol form which confirms more recent results.[4,7]

Preparation of Alkylcyanopyruvic Esters.—In a typical experiment, 14.0 g. of sodium was caused to react with absolute alcohol (182 cc.) dissolved in 805 cc. of absolute ether. The potassium (23.8 g.) was then added to the cooled mixture. After all of the metal had reacted a solution of 67.1 g. of propionitrile in 178.1 g. of ethyl oxalate was added at once and the whole was thoroughly mixed. A deep red color developed within a half hour. The amount of precipitate appearing after standing for four days was much less than it was when the equivalent amount of potassium ethoxide was used. The reaction mixture was then quickly mixed with a freezing mixture prepared from 115 cc. of hydrochloric acid (d. 1.19) and 440 g. of finely crushed ice. The ether layer was dried over sodium sulfate and distilled, finally under diminished pressure. Upon standing several months in a closed container the esters partially decomposed to a yellow oil. Redistillation of such a sample gave oxalic ester, the alkylcyanopyruvic ester and a high boiling residue that did not contain nitrogen. The sample for the analysis of cyanoethylpyruvic ester was prepared by cooling an ether–ligroin solution in an ice–salt mixture.

Ethyl 3-Cyano-2-ethoxy-2-hexenoate.—This compound was prepared in 52% yield by alkylating cyano-*n*-propylpyruvic ester in alcohol with sodium ethoxide and ethyl sulfate. The unalkylated ester was removed by extraction with sodium carbonate solution; b. p. 137–139° (9.3 mm.); 114° (1 mm.).

Reaction of Potassium Chromate with an Indium Salt

BY M. F. STUBBS[1]

The yellow precipitate formed by adding a chromate to a solution of an indium salt first described by Winkler[2] has been assumed to be indium chromate,[3] although Friend[4] points out that indium chromate does not appear to have been analyzed. In view of the present availability of indium, we have now carried out this precipitation and have made observations on the resulting changes in the *p*H of the solution.

Pure indium sulfate was prepared by the method of Seward[5] using 99.98% pure indium[6] and other reagents of analytical reagent quality. To the indium sulfate at 0.02 *M* concentration having an initial *p*H of approximately 2.5 as measured with a Model No. 3 *p*H Electrometer (Coleman), calibrated against the buffer solution furnished by the manufacturer, standard 0.2222 *M* potassium chromate solution was added at room temperature in small amounts from a buret with stirring.

A definite yellow turbidity appeared at *p*H 3.30, complete flocculation of the yellow precipitate taking place at 3.36–3.42, further additions of the chromate resulting in a steady rise in the *p*H. A typical titration curve is shown in Fig. 1. The results are in agreement with the observation of Moeller[7] that attempts to bring a simple indium salt to the neutral point result in the precipitation of hydrous indium hydroxide at *p*H 3.41–3.43.

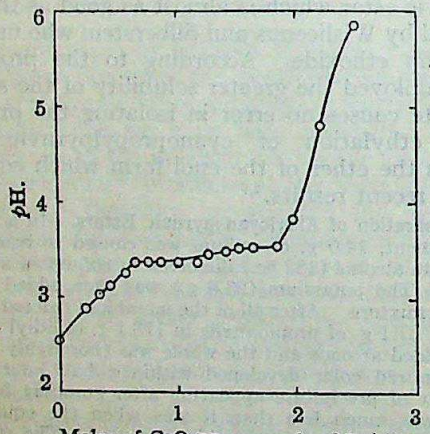

Fig. 1.

The yellow precipitate was then filtered and washed repeatedly until free of chromate. Prolonged washing, however, failed to remove the yellow color. After drying overnight at 110° to convert any hydrous indium hydroxide to indium hydroxide,[8] the precipitate was analyzed for indium by dissolving in dilute sulfuric acid and precipitating with ammonium hydroxide. This process was repeated and the indium hydroxide ignited to oxide. The combined filtrate was analyzed for chromium by acidifying with sulfuric acid, adding excess ferrous ammonium sulfate and back-titrating with standard potassium dichromate in the presence of phosphate ion with diphenylamine sodium sulfonate as indicator.

Anal. Calcd. for $In_2(CrO_4)_3$: In, 39.74; Cr, 27.02. Calcd. for $In(OH)_3$: In, 69.23. Found: In, 63.74, 63.55, 63.48; Cr, 2.16, 2.87, 2.94.

These observations indicate either that the precipitate originally formed is a mixture of indium hydroxide with indium chromate (or a basic indium chromate), or that the indium chromate as precipitated is very largely hydrolyzed during the washing process.

The Viscosities of Dimethyl and Trimethylamine at 15, 25 and 35°

BY ELIJAH SWIFT, JR., AND DEXTER LEIGH WOLFE[1]

The viscosities of dimethyl- and trimethylamine have been measured at three different temperatures using benzene as a standard.

Procedure.—A sample of the amine purified as previously described[2] was distilled into a viscometer under reduced pressure and measured under the pressure of its vapor. Benzene dried over sodium was distilled directly from the sodium into the apparatus. The values for its density and viscosity were taken from the "International Critical Tables."

An all-glass viscometer of the Ostwald type was used, its design being such that the Reynolds number was well below the critical value, and the surface tension correction[3] was minimized. The viscometer was sealed during measurements, so the upper bulb was filled by inverting the instrument beneath the surface of the water in the thermostat. It was not possible to get the same volume each time, so a correction was made for the working volume,[2] as calculated from the weight of material in the instrument and its density[1] at each temperature. At least three measurements of the time of efflux were made at each temperature, using a stop watch calibrated against a standard clock. The temperature was controlled[1] to ±0.02°. Two fillings with different material were made with each compound and with benzene.

The average difference in time between the two runs made on a liquid at the same temperature was 0.2% and the greatest difference 0.5%. The equation used to calculate the viscosities was

$$\eta = \eta_0 \frac{dt}{d_0 t_0} + \frac{mV}{8\pi l} \frac{d}{t} \left(\frac{t^2}{t_0^2} - 1 \right)$$

where the symbols have the usual meanings. The value of m was taken as 1.12,[4] the correction

amounting to about 4% at the greatest. Because of uncertainty in the value of m for this particular instrument, the calculated viscosities are probably reliable to only 1%.

The results obtained are given in Table I.

TABLE I

The Use of Trimethyl Phosphate as a Methylating Agent

BY A. D. F. TOY

The commercial availability of trialkyl phosphates has created considerable interest regarding their use as alkylating agents. Noller and Dutton[1] have shown that they may be used to alkylate phenols, and more recently Billman, Radike and Mundy[2] have applied them successfully to the alkylation of amines.

The present paper reports the methylation of aliphatic alcohols with trimethyl phosphate.

The reaction proceeds readily on heating, but the yield of methyl ether is only 50–60% based on the alcohol used, and not all of the available methyl groups of the phosphate ester are utilized. A fraction of the alcohol is converted into olefins and another part appears in the form of mixed alkyl acid phosphates. By employing an excess of the alkylating agent the yield of methyl ether may be increased.

With the procedures used the method is limited to alcohols boiling above 160°, because with lower boiling compounds the reaction proceeds too slowly.

[g] The compound obtained is ethylene glycol monomethyl ether: Palomaa, *Ber.*, 35, 3300 (1902).

Experimental Part

Two general procedures were followed, both employing commercial grade trimethyl phosphate.

Method I.—The alcohol and the trimethyl phosphate were boiled under reflux until the temperature of the liquid phase reached a constant minimum. The volatile components were distilled, the last portions being removed under reduced pressure, and the desired methyl ether was isolated by careful fractionation of the distillate. The time required for the reaction was twenty to thirty hours.

Method II.—The reactants were boiled in a Claisen flask connected to a water-cooled receiver, and the temperature of both the liquid and the vapor phase was measured. After one hour the temperature of the liquid was 15–20° below the initial temperature. More heat was applied, so that the ether distilled as it was formed, and the temperature of the liquid phase was maintained 3–10° below the initial temperature. The reaction was complete when distillation ceased or when the residue began to decompose. The last traces of volatile material were removed by distillation under reduced pressure and the product was isolated as above.

The results of runs with various alcohols are listed in the table. Analyses were by Mr. Russell Bell of this Laboratory.

Among the volatile by-products, small amounts of olefins, methyl alcohol and unchanged starting material were found. The non-volatile residue was an alkali-soluble mixture of alkyl acid phosphates resembling those obtained by the action of phosphorus pentoxide on alcohols.[3]

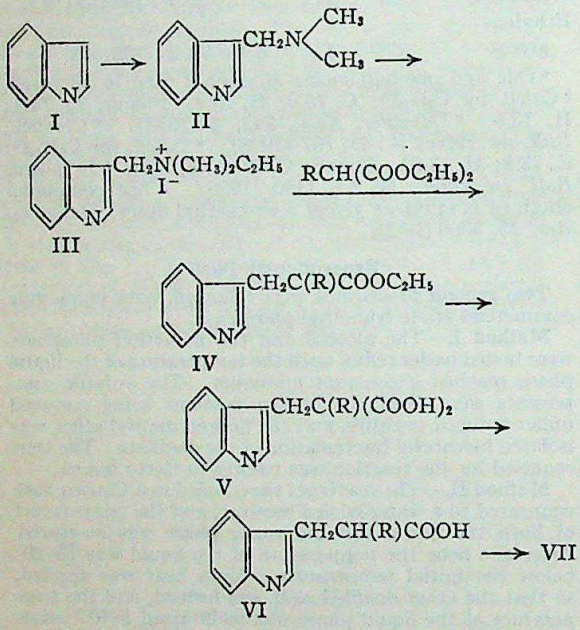
COMMUNICATIONS TO THE EDITOR

A NEW SYNTHESIS OF TRYPTOPHAN

Sirs:

In view of the recent communication of Snyder, *et al.*,[1] on the use of gramine methiodide as an alkylating agent, we wish at this time to record our experience in this field.

Tryptophan (VII) was synthesized by the procedure outlined in the following equations



The condensation was carried out successfully when R = H, $HNCOCH_3$ or $HNCOC_6H_5$. The ethyl α-carbethoxy-β-(3-indolyl)-propionate, (R = H), was hydrolyzed to the malonic acid which melted at 187–189° when pure.[2] The free acid was easily converted to β-(3-indolyl)-propionic acid, which melted at 128–130°.[2]

Ethyl α-carbethoxy-α-acetamido-β-(3-indolyl)-propionate, (R = $HNCOCH_3$), melted at 157° (Calcd. N, 8.09. Found: N, 8.27). Ethyl α-carbethoxy - α - benzamido - β - (3 - indolyl) - propionate, (R = $HNCOC_6H_5$), melted at 142° (Calcd. N, 6.86. Found: N, 7.20).

Hydrolysis of IV in sodium hydroxide solution proceeded quite smoothly. The free acetamido and benzamidomalonic acids (V), m. p. 135–137° (dec.), 85–90° (dec.), respectively, were used inthe crude form since some decarboxylation accompanied purification, thus rendering the preparation of analytical samples difficult. Complete decarboxylation was effected by heating at 180–200° until the evolution of carbon dioxide ceased.[2] The structures of the acetyl and benzoyltryptophan so prepared were confirmed by direct comparison with authentic specimens. The free amino acid was obtained from the above derivatives by hydrolysis according to procedures described in the literature. The over-all yield of tryptophan based on indole as the starting material was as high as 35% of the theoretical. Details of the procedure will be published at some future date.

LOW ANGLE X-RAY SCATTERING FROM CHRYSOTILES

Sir:

It is becoming increasingly evident that studies of low angle scattering of monochromatic X-rays will prove valuable in the study of sub-optical–microscopic structures. Bernal and Fankuchen in their virus studies,[1] Bear in his collagen studies,[2] Warren for carbon black[3] and Kratky in studies of proteins and of fibers,[4,5] found such significant small angle scattering. We have now studied various chrysotiles with X-rays using a standard technique for the wide angle scattering and the apparatus and technique employed in the study of dry gels of tobacco mosaic virus[1] for the low angle work. Copper characteristic radiation filtered through nickel foil was used. In the low angle work a fine slit system to define the X-ray beam and a 30 cm. specimen to film distance permitted the study of the small angle scattering down to angles corresponding to 500 Å. The specimens were stationary thin slabs of chrysotile mounted so that the X-rays passed through the thin direction of the specimen. The wide angle diagrams are substantially alike and all showed an undifferentiated low angle equatorial scattering. The use of a fine slit system[1] resolved this scattering into clearly differentiated lines. In each of the four samples studied to date, at least two lines were always visible, the ratio of their Bragg spacings being $\sqrt{3}$. This suggests strongly that these chrysotiles are composed of parallel fundamental fibrils—hexagonally packed in cross section. The diameters of the fibrils can be computed from the Bragg spacings (on the hypothesis

	Diam. of fibrils in Å.
Canadian chrysotile	195
"harsh" chrysotile (U. S. A.)	250
"soft" chrysotile (U. S. A.)	226
Chrysotile (Italy)	218

It seems possible that the explanation of the variations in mechanical properties of the chrysotiles can be explained on the basis of the differences in their low angle scattering (and consequently on differing fundamental fibril diameter). An extensive survey of asbestos-like materials is now in progress.

BROOKLYN, NEW YORK M. SCHNEIDER

RECEIVED JANUARY 28, 1944

GLIOTOXIN, THE ANTIBIOTIC PRINCIPLE OF *GLIOCLADIUM FIMBRIATUM*[1]

Sir:

We find that the antibiotic substance gliotoxin is produced by at least three different organisms.

Professor Harold Raistrick of the London School of Hygiene and Tropical Medicine has isolated from a species of *Penicillium* (as yet not completely identified) a crystalline substance which appeared to be identical with gliotoxin from *Gliocladium fimbriatum*.[1] He had independently reached the conclusion that it should be represented by the formula $C_{13}H_{14}N_2O_4S_2$ (private communication to J. R. J., London, October 11, 1943). Professor Raistrick has kindly furnished us a sample of his crystalline material and a comparison with our gliotoxin has shown that the two substances are identical.

The sample from Professor Raistrick on examination with a polarizing microscope was monoclinic hemimorphic, crystallizing as flattened rods elongated parallel to the "b" axis. It showed the forms: basal pinacoid, 001; orthopinacoid, 100; hemiclinodomes, 011 and $01\bar{1}$, and hemiprisms, $\bar{1}10$ and 110. The crystallographic angle β is 79° with the interfacial angle, $011:01\bar{1}$, equal to 109°. The optic axial plane is perpendicular to 010 with α, the obtuse bisectrix, 34° from "a" in the obtuse angle β. The optic axial angles are $2V = 53°$ and $2E = 90°$. The refractive indices are α, 1.644 ± 0.001; β, 1.658 ± 0.001; β' (component of β in the plane 100), 1.655 ± 0.002; and γ, 1.708 ± 0.001. This description agrees in every respect with the previously published crystal structure of gliotoxin[1]; hence Professor Raistrick's material is identical with gliotoxin.

Determination of the decomposition point[2] showed 218° (uncor.), and a mixed decomposition point with gliotoxin, melting with decomposition at 219°, was 218°. In a determination of specific rotation, a very characteristic constant of gliotoxin, 6.1 mg. of the sample in 1 ml. of chloroform gave $\alpha = -1.71 \pm 0.06°$, $[\alpha]^{20}D$ $-280 \pm 10°$. This is in reasonably good agreement with the values previously found for gliotoxin: $[\alpha]^{19}D$ -239 (C, 0.51 in $CHCl_3$)[2]; $[\alpha]^{26}D$ $-255 \pm 15°$ (C, 0.103 in $CHCl_3$).

Furthermore, identification of gliotoxin as a product of the fungus *Aspergillus fumigatus* has been accomplished by Dr. O. Wintersteiner.[3]

Since gliotoxin has been isolated from cultures of *Gliocladium fimbriatum*, *Aspergillus fumigatus* and a species of *Penicillium* not yet identified, it may prove to be an antibiotic product of still other fungi.

NEW BOOKS

Dictionary of Science and Technology in English–French–German–Spanish. By MAXIM NEWMARK. Philosophical Library, Inc., 15 E. 40th St., New York, N. Y. 1943. viii + 386 pp. Price, $6.00.

Like a four-color mechanical pencil, a four-language dictionary creates at first sight an impression of ingenuity, compactness, and efficiency, but after a little use one begins to wonder whether a set of old-fashioned single-purpose pencils or dictionaries is not generally more convenient. The present dictionary is constructed in four parts, of which the first is a *numbered* alphabetical list of English words, each followed by its approximate equivalent in French, German, and Spanish. Then come three alphabetical lists of French, German, and Spanish words, respectively, each followed by the *number* of the English word to which it corresponds. Thus compactness is obtained at the expense of convenience, for in order to find the meaning of a foreign word (the most frequent purpose for which such a dictionary is wanted) it is necessary to look in two places. It appears that additional compactness is obtained at the expense of reasonable completeness. As a test, a single sentence of four lines was selected at random from a standard German text on a physico-chemical subject, and found to contain three words not in the Dictionary—verlaufen, darstellen, bestätigen, by no means rare words. In fairness it should be said that the author is particularly interested in achieving up-to-date coverage of technological terms.

It would seem that this book might be useful where for some reason compactness is at a premium, or where there may be occasional need to translate from one foreign language to another.

A. S. COOLIDGE

The Chemistry of Large Molecules (Frontiers in Chemistry, Volume I). By R. E. BURK, Director of Research, The Standard Oil Co., Cleveland, Ohio, and OLIVER GRUMMITT, Morley Chemistry Laboratory, Western Reserve University, Cleveland, Ohio. Published under the Auspices of Western Reserve University. Interscience Publishers, Inc., New York, 1943. 313 pp. 26 figs. 15.5 × 23.5 cm. Price, $3.50.

The chapters of this book represent lectures presented during 1942 as one of the Frontiers in Chemistry series sponsored by Western Reserve University. This is the first of these series to be published. Other volumes will follow. It is the purpose of these lectures to bring together reports summarizing progress in related fields of research.

This volume consists of eight chapters. In the first chapter, "The Mechanism of Polyreactions" by Professor H. Mark, mechanisms of various types of polymerization are discussed. The second chapter, "The Investigation of High Polymers with X-Rays," also by Professor H. Mark, reviews broadly the occurrence, origins and effects of crystallinity in chain polymers. Diffusion, dialysis and viscosity of dilute polymer solutions and the dependence of these on molecular size and shape are discussed by the late Dr. E. O. Kraemer under the title "The Colloidal Behavior of Organic Macromolecular Materials." The fourth chapter on "The Ultracentrifuge and its Application to the Study of Organic Macromolecules," also by Dr. Kraemer, presents an excellent summary of the essentials of ultracentrifuge methods and the results which have been obtained on proteins and on filamentous molecules. "Elastic-Viscous Properties of Matter" by Drs. A. Tobolsky, R. E. Powell and H. Eyring is rather more diversified than other chapters. The statistical mechanics of chain configuration and of mixing of long chains with small molecules are included as well as applications of the transition state theory of viscous flow to the flow of polymer molecules by segments, theory of rubber elasticity, creep in metals, viscosity of suspensions and polymer solutions and thixotropic phenomena. In 27 pages Dr. R. M. Fuoss presents the most significant results of recent investigations carried out chiefly by Fuoss and collaborators on "The Electrical Properties of High Polymers" and their relationship to chemical structure and mechanical properties. Similarly, Professor C. S. Marvel summarizes recent work for which he and his associates are largely responsible on "Organic Chemistry of Vinyl Polymers." The final chapter (65 pp.) by Dr. Emil Ott on "Chemistry of Cellulose and Cellulose Derivatives" represents an exceptionally well organized, concise summary of a very broad field.

In view of the scope and purpose of these lectures, it is clear that the book is to be regarded neither as a text nor as a reference work. From the point of view of the casual reader who desires to be informed on recent accomplishments and current problems, but who cannot (or at least does not) find the time to become an expert on all phases of the subject, this may be looked upon as a point of merit. Too often scientific books strive to be either comprehensive of the entire field or to be complete in all details. This book can be recommended to readers desiring to be brought up to date on the broader aspects of recent developments in the phases of the subject covered by these eight chapters. The book should find a welcome place among the current flood of books which continue to appear on high polymers.

The bibliographies at the end of each chapter should be useful to readers who will want to delve farther into the subject. Numerous diagrams and figures are included. The editing and printing are well done and errors are few. A subject index is given at the end of the volume.

P. J. FLORY

Physical Biochemistry. By HENRY B. BULL, Ph.D., Associate Professor of Physiological Chemistry, Medical School of Northwestern University. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1943. iv + 347 pp. Illustrated. 14.5 × 22 cm. Price, $3.75.

This book represents "an attempt to reorient to some extent" the character of "instruction in physical chemistry for premedical and for graduate students in the biological sciences." The general pattern of the presentation is indicated by the chapter headings: Atoms and Molecules, Energetics, Reaction Kinetics, Electrostatics and Dielectrics, Ions in Solution, Electromotive Force Cells, Acids and Bases, Oxidation-Reduction, Electrical Conductance, Electrokinetics, Surface Activity, Colloidal Solutions, Viscosity and the Flow of Liquids, Diffusion, The Ultracentrifuge, Osmotic Pressure, Membranes and Cell Penetration, Colloidal Structures. Under these headings are found discussions of a number of topics which I have not seen previously treated in comparable detail in any book addressed to a similar audience. These include: the transition state theory of reaction kinetics; some aspects of electrostatics, including dielectric constants, dipole moments, and dielectric increments; semiquinones; a very full discussion of electrokinetics, including the Tiselius electrophoresis apparatus; the relation between viscosity and molecular asymmetry in solutions of large molecules; streaming birefringence; sedimentation and diffusion in their relation to molecular size and shape; and the evaluation of pore size in membranes. The chapter on surface activity goes into much detail, and covers nearly forty pages. Numerous references to the original literature, often to very recent papers, are given as footnotes to the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

text; and the student is urged to read at least a few of them.

All of these topics are interesting and important, and are in the forefront of interest to many investigators today. For the teacher who is presenting important topics in physical chemistry to biological and premedical students, however, the question of relative emphasis remains a difficult problem. In the opinion of this reviewer, it is essential that the student should obtain a firm grasp of the fundamentals of chemical thermodynamics, the significance of the mass law, acid–base equilibria and oxidation–reduction potentials, and the elements of reaction kinetics especially in relation to enzyme action. All these topics are treated by Bull, but in some cases with a brevity which might leave most students without a firm grasp of the subject. It would seem essential to supplement the use of the text, and the recommended outside reading, by the working of numerous quantitative problems requiring the application of the fundamental principles. A set of such problems might be a valuable addition to the book in future editions. For instance, the extensive table of free energies of formation in Chapter II is excellent in itself, but the student is not likely to appreciate it unless he uses it in solving problems. The discussion of thermodynamics in this chapter would benefit from considerable amplification, with fuller explanation of the fundamental concepts, if the student is really to acquire the ability to use thermodynamics effectively in his thinking. The exposition of the activity concept (p. 26), which occupies less than a page, is one example of this; and the short paragraph on entropy and probability (p. 19) may mystify the student more than it enlightens him.

Raoult's law is not introduced until p. 293; in view of its importance, it might be well to place it near the beginning, in Chapter II (Energetics); and also to place Chapter XVI (on osmotic pressure and colligative properties) immediately after Chapter II.

Some equations, such as those involving electrokinetic potentials (p. 157 ff.), and the Langmuir adsorption equation (p. 206), are derived step by step, while others, sometimes simpler and more fundamental, are given without derivation. This is true for instance of the equation for the osmotic work involved in concentrating a component of a system (p. 20), or the Michaelis–Menten equation for enzyme kinetics (pp. 54–55). The student ought certainly to understand the derivation of such equations, if he is to obtain full educational value from a course of this sort.

Occasionally the discussion leaps suddenly from quite simple to much more complicated topics. For instance, on p. 60, a very simple discussion on the elements of electrostatics is followed abruptly by Poisson's equation. I fear that most students will fail to see the significance of the latter when so presented.

It is easy to find points for criticism in a book of this type, for the choice of topics and the manner of their presentation offer most formidable difficulties to an author who attempts to present physical chemistry to biologists and students of medicine. Bull's treatment has broken new ground in several respects, and I believe that it will have a definite influence on the character of instruction of this sort in the future.

JOHN T. EDSALL

A Text-Book of Inorganic Chemistry. By FRITZ EPHRAIM. English Edition by P. C. L. THORNE and E. R. ROBERTS. Fourth Edition, Revised and Enlarged. Interscience Publishers, Inc., 215 Fourth Avenue, New York, N. Y., 1943. (Gurney and Jackson, London, W. C. 1, England, and Oliver and Boyd, Ltd., Tweeddale Court, Edinburgh.) 924 pp. $8.75.

Earlier editions of this book have been reviewed in THIS JOURNAL, **57**, 593 (1935), and **63**, 1171 (1941). This edition differs only slightly from the preceding one. It contains ten additional pages and the revisions have been relatively minor.

The popularity of this text is shown by the increasing frequency with which new editions have appeared, only four years having elapsed since the publication of the last edition. This popularity is easily understood, for to the student familiar only with the usual order of presentation of the bewildering array of the facts of inorganic chemistry, it is certainly illuminating to have them presented in the less usual order adopted here.

ARTHUR B. LAMB

Industrial Chemistry. By WILLIAM THORNTON READ, Dean of the School of Chemistry, Rutgers University, 3rd ed., John Wiley & Sons, Inc., New York, N. Y.; Chapman & Hall, Ltd., London, 1943. 631 pp. 92 illus. 14 × 20 cm. $5.00.

This book gives a general descriptive survey of the more important chemical industries. It is intended primarily for students in their junior or senior year in college who are specializing in chemistry and assumes a knowledge of chemistry which may be expected of a student who has taken introductory courses in general descriptive, analysis, physical, and organic chemistry. At this stage of his career the most important problems facing such a student are the selection of his future wife and a decision as to the kind of job he would like to hold twenty or thirty years later. Shall it be Mary, Sue, or Betty, and shall he go into medicine, or electronics, or sanitary engineering, or chemistry? If we assume that he has selected Betty and has decided to become a professional chemist he is now ready to begin serious work in preparation of his career. He will tentatively set his ambition on the future title of Professor, Research Director, Chief Chemist, Factory Superintendent, Sales Manager, Purchasing Agent, or President of a chemical manufacturing company. This book is designed as a textbook in a course which should help him to reach a wise decision and start the process of fitting himself for an executive position where he will have the responsibility and authority to make decisions on matters of policy. Such an official must make his decisions and put them into effect on the basis of foresight and then a year or a decade later the wisdom of his decisions will be judged by hindsight. A good batting average requires exceptional ability and training, and a little luck may not come amiss.

The success of a factory built to manufacture chemicals is not assured merely by a simple and direct chemical process with good yields and good machine design. It is not enough to make a chemical efficiently but it must also be salable at a profit. The factory may succeed technically but fail financially because it is built in a poor location or it is too big for its markets and therefore cannot operate steadily. A suit for patent infringement may result in an injunction stopping all operations. A foreign war may cut off an imported raw material or a change in tariff make it too expensive. A new scientific discovery or a new invention may make the process of manufacture, or the product itself, obsolete. Persistent disloyalty among employees may outweigh the most skillful chemical engineering. Therefore the young chemist who hopes to rise to positions of executive responsibility should train himself to be a broad man capable of understanding, weighing and anticipating the significance of many outside influences upon the industry with which he is connected. A good knowledge of chemistry and chemical engineering is not enough. He may need some sound knowledge of thermodynamics, electronics, geology, biology, marketing, law, foreign relations, psychology and labor relations. His college course should give him a good start on his education and above all get him in the habit of reading and thinking on many subjects. A textbook of industrial chemistry should, therefore, not be too narrowly confined to chemistry and chemical engineering and should stimulate the student to think on broad lines. This book of Read's meets these specifications to a substantial degree but misses many good opportunities to give practice in con-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

sidering the comparative advantages and disadvantages of alternative procedures or methods. Thus, for example, it is mentioned that both platinum and vanadium oxide are used as catalysts in the contact process of making sulfuric acid but the student is not encouraged to think about the comparative advantages of these catalysts. Similarly, there are now two competing methods of making caustic soda—the electrolytic, and the treatment of Solvay soda with lime—but these are described in different chapters without any discussion of this interesting competitive situation.

The dramatic interest, significance and pedagogic effectiveness of the book could be appreciably increased by more attention to the historical development of the chemical industries. In the chapter on sulfuric acid, the contact process is discussed first, followed by the lead chamber process. Why not follow the historical order by discussing the chamber process first and then the contact process and thus give more realism to the half page devoted to the "Comparison of Contact and Lead Chamber Processes?"

In the chapter on Fixed Nitrogen the order of discussion is: fractional distillation of liquid air, helium, by-product ammonia from coal, ammonia synthesis, calcium cyanamide, the arc process, nitric acid from ammonia, nitric acid from Chile saltpeter, and sodium nitrate from caliche. This horrible scrambling of the historical sequence of development of these processes sacrifices much of the interest and significance. The ammonia synthesis is discussed without mentioning Haber's name or any allusion to the fact that this process was available to Germany during World War I and in combination with the Ostwald Process made Germany independent of Chilean saltpeter whereas England, France and the United States were compelled to rely upon Chilean saltpeter, which was dangerously threatened by the German submarines. The frantic efforts to escape this menace by the construction of the Muscle Shoals plant or the reasons for the choice of the cyanamide process do not rate even a mention. The later controversies over the disposal of this plant and the dam which eventually resulted in the great T. V. A. projects are ignored although they have had great influence on the development of the chemical industries in America. And why discuss the making of nitric acid from ammonia, then from Chilean nitrate and finally the recovery of Chilean nitrate from caliche?

The American potash industry is described before the German. There is no adequate presentation of the industrial difficulties created in America when German potash was cut off in 1915. Why was it that with potash prices averaging more than ten times the previous level for the four years of World War I the U. S. production in 1918 was only 20% of the prewar imports and all except two of the eighty-eight producers in 1918 have gone out of the potash business? And yet in the interval before World War II an American potash industry has arisen which can now care for every need. This extremely interesting and significant story is entirely missing.

The chapter on rubber contains no allusion to the acute situation created by the Japanese capture of Singapore or to the revolutionary changes which are being forced on the American rubber industry. There is no reference to the Baruch–Conant–Compton Report itself, or to its subject matter, or to subsequent developments. The discussion of synthetic rubber is extremely weak for a book dated August, 1943. Why not encourage the students to form an opinion on the prospects of survival of this new industry?

The author avoids mentioning the name of companies so completely that it shows a definite policy. Trade names of materials and even names of great inventors or personalities are used extremely sparingly. He does mention the name of Goodyear, Solvay, Baekeland, Acheson, Hall, and a few others. Glover and Gay-Lussac are towers rather than men. He avoids mentioning Liebig, Nobel, Perkin, Baeyer, Ostwald, Knietsch, Haber, Bergius, Hyatt, Sabatier, Onslager, Burton, Wesson, Dow, and Carothers.

It is perhaps unavoidable that at the time they graduate from college young chemists will be more familiar with the personalities of professional baseball players than of the great chemists and know more about the achievements of football teams than of teams of chemists and engineers representing our great chemical companies. But why encourage this weakness in our educational system? Why describe Neoprene and Nylon without mentioning the du Pont Company? Or the recovery of bromine and magnesium from the ocean without mentioning the Dow Chemical Company?

These criticisms refer to relatively minor matters since they concern missed opportunities rather than actual blunders. The book contains a great deal of information clearly and accurately presented. Any young chemist, whether still a student or at the beginning of his industrial career can broaden his knowledge and substantially improve his prospects of professional advancement by a study of this book.

A comparison of the third edition with the second shows that the changes are relatively minor and are scattered throughout the book.

GRINNELL JONES

Inorganic Qualitative Analysis. Semi-micro Technique. By HAROLD A. FALES, Ph.D., Professor of Chemistry at Columbia University, and FREDERIC KENNY, Ph.D., Professor of Chemistry at St. Francis College, Brooklyn. D. Appleton–Century Company, Inc., 35 West 32nd St., New York, N. Y., 1943. ix + 237 pp. 15 × 22 cm. Price, $2.65.

This book, which is intended for a one-semester course, follows much the same pattern as most contemporary texts in this field. The first 150 pages deal with theoretical topics, and the remaining 75 pages are devoted to systematic schemes of analysis employing semi-micro technique.

The usual theoretical topics are discussed, including types of compounds, strong and weak electrolytes, hydrolytic equilibria, solubility product, complex ions, and oxidation–reduction theory. The characteristics of electrolyte solutions and of various types of ionic equilibria are thoroughly and clearly presented. Each of the theoretical chapters concludes with a comprehensive set of problems, which in general appear to be well chosen. Among the few exceptions may be noted the fictitious equation $S = \sqrt[5]{K/108}$ on p. 72 for the relation between the molar solubility S in pure water and the solubility product K of lead phosphate, which is unrealistic and misleading because it ignores the extensive hydrolysis of the phosphate ion. Fortunately, there appear to be few synthetic examples of this sort; most of them display excellent didactic judgment.

In the reviewer's opinion the chapter on oxidation–reduction theory is outstandingly good, particularly the sections on pp. 139–145 which discuss a number of examples of oxidation–reduction equilibria that are important in qualitative analysis.

The semi-micro laboratory procedure provides for the detection of the usual twenty-four metallic elements, and the scheme of analysis adheres closely to the classical Noyes and Bray system with a few minor modifications. The various group analyses are summarized in clearly executed tabular diagrams. Equations are given for all reactions, and happily these have been written with a realistic appreciation of the ionic or molecular states of the substances involved.

Unfortunately the analytical chemistry of the non-metallic elements is almost completely ignored, and all that one finds is tests for four anions (chloride, sulfate, nitrate, and carbonate) on pages 221–222. The reviewer fails to appreciate the point of view which this neglect implies; certainly the importance of the analytical chemistry of the non-metallic elements warrants the inclusion of systematic schemes for anion analysis in even a one-semester course in qualitative analysis. It is true that in the past the laborious and time-consuming features of the classical macro procedures provided a more or less cogent argument for

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

limiting one-semester courses to cation analysis, but surely the development of relatively rapid semi-micro techniques has invalidated this argument. Also the fact that anion analysis is somewhat less systematized and generally presents chemically more complex situations than cation analysis cannot be denied, but these attributes are actually more advantageous than disadvantageous from a didactic viewpoint. A student cannot be expected to acquire even a modicum of critical chemical sense, or a true perspective toward analytical chemistry, unless he is given an opportunity to wrestle with a few difficulties. It is hoped that in future editions of this otherwise sound text anion analysis will receive the attention it deserves.

JAMES J. LINGANE

Manometric Methods as Applied to the Measurement of Cell Respiration and Other Processes. By MALCOLM DIXON, Ph.D., Sc.D., F.R.S., University Lecturer in Biochemistry in the University of Cambridge. Second edition. The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1943. xiv + 155 pp. Illustrated. 13 × 19.5 cm. Price, $1.75.

This useful and standard manual gives an up-to-date account of all the most common methods in use in biochemical laboratories for following the time course of oxygen uptake and carbon dioxide output by cell and tissue enzyme systems. The author writes "It has of course not been possible to include every modification of manometer which has been described in the literature: my aim has been to select those forms which are already in fairly general use or likely to become so." In this aim he has been extremely successful. The book contains full instructions for, and precautions in, the use of the chief biochemical manometers, *i. e.*, the Barcroft and the Warburg apparatus and their various adjuncts and accessories. It also describes in detail the various methods of calibration, including an original theoretical treatment of the author not published elsewhere.

In the edition just published the main new features consist of short descriptions of (i) the beautiful, but rather special, ultra-micro-methods introduced since 1933, (ii) the recently developed modifications of the standard types, (iii) further applications of the methods. The older features have been thoroughly revised and brought up-to-date, and the list of references expanded. The book can be confidently recommended to all biochemists and might also be of occasional service in "pure" chemical departments.

F. J. W. ROUGHTON

Organic Chemistry. By C. W. PORTER AND T. D. STEWART, Members of the Faculty of the College of Chemistry in the University of California. Ginn and Company, Statler Office Building, Park Square, Boston, Mass., 1943. v + 577 pp. 15.5 × 23 cm. Price, $4.00.

All text-books for a year's instruction in elementary organic chemistry will necessarily present certain essential facts in the subject. The chief interest is in how the facts are presented. The beginning of this text is a preview of the whole subject in the first chapter. The student is hurriedly introduced to hydrocarbons of all kinds, alcohols, aldehydes, ketones, acids, esters, amines, amino acids, halogen-containing compounds and ten varieties of sulfur compounds. The tetrahedral atom, atomic dimensions, optical isomers, physical properties, solubility, chemical reactivity, atomic structure, isotopes, radioactive and heavy atoms, and the electronic valence pass rapidly in these first twenty-six pages. The object of this generalized survey is, to some extent, to overcome "the practical difficulty of learning an enormous number of new names and facts in a short time" by presenting the more commonly used new ideas "in anticipation of more detailed treatments."

There may be many, including the reviewer, who will question whether such an aerial photograph will mean much to a student who is unacquainted with any part of the detailed view; or doubt whether reference to the fact that sulfur is present in thiamine or vitamin B, or that Nylon is an amino acid, will have any real significance to a student when these subjects are not mentioned again until the latter half of the text. For those who favor such a method of instruction, however, the authors have given a very good preview.

The remainder of the text follows the more conventional order of hydrocarbons, alcohols, ethers, halides, aldehydes and ketones, acids, etc. The current interest in hydrocarbons as sources of organic compounds is stressed. The trend toward compounds of biological interest receives due attention by a considerable amount of space allotted to pyrimidines, purines, sulfa drugs, alkaloids, sterols, vitamins and enzymes.

The book is divided into 489 pages of discussion, 26 of supplementary notes and appendix, and forty-one pages of very good problems. The chapters are not numbered, but otherwise clearly indicated. The work is relatively free from errors, though the omission of a bond in the formula for quinine is unfortunate. In general the work is a very satisfactory addition to the collection of texts available for elementary organic chemistry.

AVERY A. MORTON

Plants and Vitamins. By W. H. SCHOPFER, Director of the Botanical Institute, University of Bern, authorized translation by NORBERT L. NOECKER. Chronica Botanica Company, Waltham, Mass., and G. E. Stechert and Co., New York, N. Y., 1943. xiv + 293 pp. Illustrated. 18 × 27 cm. Price, $4.75.

As may be guessed from the title, this book covers a relatively large field including the synthesis of vitamins by plants and the responses of plants including microörganisms to vitamins.

Some of the chapters (24 in number) have to do with specific organisms, *e. g.*, yeasts, lactic acid bacteria, etc.; others have to do with specific vitamins, and others deal with more general topics. The author has not been signally successful in the organization of the material.

It is unfortunate, due primarily no doubt to war conditions, that the literature has been reviewed completely only up until 1941, and that from this point on the review is incomplete. Inasmuch as the field covered by this book has undergone very active investigation in recent years, and many important matters have been clarified during the interval involved in its translation and publication, this book cannot be recommended as a critical and up-to-date summary.

For those whose interests are in plant physiology and to whom the vitamin field is largely unfamiliar, Professor Schopfer's book will be especially valuable.

JOURNAL OF THE AMERICAN CHEMICAL SOCIETY

Published monthly by the American Chemical Society at Easton, Penna.

Editorial Office: Chemical Laboratory of Harvard University, 12 Oxford St., Cambridge 38, Mass.

Assistant to the Editor (Proof and Make-up): Allen D. Bliss, Department of Chemistry, Simmons College, 300 The Fenway, Boston 15, Mass.

Business Office: American Chemical Society, 1155 16th St., N.W., Washington 6, D. C.

Advertising Office: American Chemical Society, 332 West 42nd St., New York 18, N. Y.

The American Chemical Society and the Editors of the *Journal of the American Chemical Society* assume no responsibility for the statements and opinions advanced by contributors to THIS JOURNAL.

Remittances and orders for subscriptions and for single copies, notices of changes of address and new professional connections, and claims for missing numbers should be sent to the American Chemical Society, 1155 16th Street, N.W., Washington 6, D. C. Changes of address for the *Journal of the American Chemical Society* must be received on or before the 18th of the preceding month.

Claims for missing numbers will not be allowed (1) if received more than sixty days from date of issue (owing to the hazards of war-time delivery, no claims can be honored from subscribers outside of North America), (2) if loss was due to failure of notice of change of address to be received before the date specified in the preceding paragraph, or (3) if the reason for the claim is "missing from files."

Annual subscription—$8.50 to non-members, $3.00 to members. Postage to countries not in the Pan American Union, $1.50; Canadian postage, $0.50. Single copies—current issues $0.75, back numbers $0.80; special rates to members.

The American Chemical Society also publishes *Chemical Abstracts*, *Industrial and Engineering Chemistry* (Industrial and Analytical Editions), and *Chemical and Engineering News*. Rates on request.

NOTICE TO AUTHORS OF PAPERS

Manuscripts for THIS JOURNAL should be submitted to the Editor ready for publication, typewritten (double space), with 2–3 cm. margins, on a good quality, durable paper, preferably of 8.5″ × 11″ size. In addition to the original typewritten copy, one or more carbon copies should be submitted so that the time required for examination by the Editorial Board may thus be considerably shortened. Care should be taken that all pages in a manuscript, including tables (but not the diagrams) be numbered consecutively. In preparing manuscripts authors are requested to observe, for reasons of economy, the utmost conciseness consistent with clarity of presentation. The manuscripts should be addressed to specialists in their particular field rather than to the general reader. Extensive reviews of the literature cannot be accepted. When well-known or previously published procedures have been followed in the experimental work they should only be designated or referred to.

Form of Presentation.—There should be one or more introductory paragraphs setting forth the occasion, significance and main objectives of the investigation and the method of attack. This should be followed by the experimental results and a discussion of them, either *seriatim* or at their conclusion. Finally, there should be a brief summary of the main achievements of the investigation. Sometimes, particularly when the subject matter is involved and there are many details which, though essential for a successful repetition of the experiments, are unnecessary for the main account of the investigation, these details can with advantage be relegated to an appendix or supplement, just preceding the Summary. In intermediate cases it is often advisable to retain a single, straightforward presentation but to intercalate sections in fine print giving the experimental details of procedure. This has the great advantage of keeping the experimental details close to the more general statements based upon them and yet at the same time permitting the reader if he wishes to pass over this section without inconvenience.

It will be of great assistance to the Editor's Office if the style, arrangement and orthography of the manuscripts are made to conform to the usages of the JOURNAL as exemplified in its recent issues and as set forth in the following paragraphs.

Center headings should be employed sparingly; side headings should be indented and run into the text to which they apply, using period and dash. References to the literature and all footnotes regardless of their nature (except those in tables) should be numbered in one consecutive series, repetition of notes being avoided by using simply the superscript number corresponding to the original reference. They should follow immediately in separate lines the line of text containing the text words to which they refer, and may be set off by short rules above and below. The items in the references to the literature should conform to the uniform usages of the Journal as regards order and punctuation, and to the abbreviations as given by *Chemical Abstracts* in its "List of Periodicals Abstracted." The names of all simple compounds rather than their formulas should be used whenever they occur in the text. Periods of time (unless fractional) should be written in words and quantities of material in Arabic numerals, unless occurring at the beginning of a sentence. Letters used to represent quantities in mathematical expressions should be underscored to indicate that they are to be printed in italics, and Greek or other unusual characters should be written plainly or should be explained by annotations. Simple fractional expressions should be written with a slant line rather than in the conventional manner, so that only a single line of type is required. All subscripts and superscripts should be carefully made and placed (the degree sign ° or a small o should not be used to represent zero). For economy, except in unusual circumstances the abbreviations %, °A., cm., cc., ml., g., Å., m. p., f. p., b. p., cal., kcal., expt. and Fig., should be used rather than the words.

Figures and graphs should be carefully prepared line drawings on plain white drawing paper, blue drawing cloth or coördinate paper printed in blue only. The

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

originals are preferable, but clear, well-prepared photographic prints or photostats are acceptable. Illustrations are most conveniently handled when made in the conventional 8.5″ × 11″ manuscript size; if they are of necessity larger, and therefore liable to damage in mailing, duplicate rough sketches or photographic prints of smaller size should be furnished for dispatch to the Referees. Diagrams should be designed to occupy a single column width and should therefore be tall rather than wide. Particular attention should be given to the correct proportions of the various parts of the figure, especially the experimental points, and if any letters, numbers, or legends must be placed on the diagram to their proportions also. In graphs the frame and actual curves should be ruled and inked more heavily than the coördinate lines, and these latter should not be too close together. Experimental points should always be given and should be indicated not by crosses but by circles or other symbols carefully drawn with drafting instruments. Where feasible it is often helpful to have the diameter of the circles indicate the precision of the measurements. The numbers and legends on coördinate axes are set up in type by the printer; the author, therefore, should place them in pencil outside the axes. The numbers and titles of figures should be placed below the diagrams, or on the back, or collected on a separate sheet. Small photographic prints should be mounted on cardboard and any composite series of photographic prints should be mounted in the order and arrangement desired. Each piece of illustration copy should be marked on the margin or back with the name of the author and brief title of the article (for identification purposes).

Tables.—Tables should not be used indiscriminately as they are much more expensive, line for line, than running text. If reasonably possible, they should be designed to occupy fully a single column (3 inches), which will take 50–75 characters and spaces. Tables occupying the full width can be used, but they are undesirable for the same reasons advanced with regard to page wide figures; their preparation should follow the same principles as for those of single width. Care should be taken to avoid any arrangement which unduly increases the depth of a table, and column heads should be made as small as possible, using abbreviations liberally. Lines of data should not be numbered nor run numbers given unless these numbers are needed for reference in the text. Columns should not be used to contain only one or two entries, nor should the same entry be repeated numerous times consecutively, since these cases may be taken care of more economically in footnotes, or by entries following the title of the table. Data should not be included in one column which are deducible easily by simple arithmetic from data in another column. Tables should be interspersed in the manuscript as near as possible to the places where they are referred to in the text, and need not be placed alone on separate sheets.

Formulas and Equations.—Empirical and structural formulas and mathematical and chemical equations should be arranged to fill adequately the width of a single column. This will often require a continuation of the equation in additional lines, and although this is a disadvantage it is in general preferable to intrusion into the adjoining column. Subscripts and superscripts, especially the latter, should be written with care and the conventional fractional arrangements should not be used in exponents. Organic structural formulas should be arranged to fill the space economically, and arrows should be used horizontally or vertically, not diagonally, wherever possible.

Notes do not differ fundamentally from Articles. They describe fragmentary or less complete studies and hence particular attention must be given to brevity and conciseness of presentation. Summaries are not included. They are collected in a special section near the end of each number of the Journal.

New Compounds.—This department is for brief accounts of new substances which do not appear of sufficient importance to justify separate publication and cannot be described appropriately as part of any other Article or Note. These accounts should report the preparation of the new compound succinctly, yet fully enough so that the operations can be duplicated. Significant properties, formulas and analytical data to establish the identity and purity of the substance should be given. Material appearing in this classification will not be accepted for subsequent publication.

Communications to the Editor are designed to afford prompt, brief, preliminary publication in our Journal of new and significant observations or discoveries. Their total length may in no case exceed 500 words or the equivalent. They will be given as rapid editorial consideration as possible, but at best it will usually be out of the question to include them in a given issue of the Journal if they arrive at the Editor's office later than the 20th of the preceding month. Communications like other contributions should be self-sustaining; that is, they should present experimental or other evidence adequate to establish the *prima facie* credibility of the results or conclusions stated or to permit their appraisal by an expert in the field although because of the 500-word limit a complete presentation cannot usually be expected. These requirements make Communications on many subjects impracticable, particularly those of an involved or theoretical nature.

Communications differ from ordinary Articles or Notes in that their publication does not prevent the re-publication of their subject matter in a later, more complete article in the Journal. In view of this special provision and their expedited publication, it is clear that the contribution made by the Communication should be of special interest or timeliness; mere abstracts of forthcoming articles cannot be accepted. Proof and reprint order will be sent to authors whenever possible, but as this cannot always be done, a memorandum as to the reprints desired should accompany the manuscript.

Microfilm Supplements.—By arrangement with Science Service material supplementary to articles in THIS JOURNAL, such for instance as extensive tables, graphs or calculations, can be distributed at small cost as American Documentation Institute Documents in the form of microfilms with images 25 mm. high on standard 35-mm. film or photoprints 6 × 8 inches legible to the unaided eye. Such material must, however, have been submitted to the Editor of the Journal and must have been approved by him for publication. Attention will then be called to these documents by means of footnotes at appropriate points in the text of the article concerned.

[CONTRIBUTION FROM THE DEPARTMENT OF VITAL ECONOMICS OF THE UNIVERSITY OF ROCHESTER]

Thiamine Inactivation by the Chastek-Paralysis Factor. Inhibition[1] of Thiamine Inactivation

BY ROBERT R. SEALOCK AND RUTH L. GOODLAND

Evidence of the enzymatic nature of the destruction of thiamine by the fish principle or Chastek-paralysis factor has been presented previously.[2] In an effort to obtain more conclusive evidence concerning the enzyme hypothesis, the effect of the usual enzyme inhibitors on the fish principle was studied. Included among the substances used were heavy metal ions, iodine, pyrophosphate, sulfite and cyanide. In the concentrations commonly employed with enzyme reactions several of these were found to interfere[3] with the determination of thiamine by the diazotized aminoacetophenone method of Melnick and Field.[4] Further analysis[3] of the interference indicated that only a few of the inhibitors might be used in the thiamine-fish principle experiments, and in some instances it is evident (Table I) that inhibition of thiamine destruction did occur. On the other hand, it was also apparent that the interference with the analytical method limited the usefulness of these reagents.

TABLE I

INHIBITION OF THIAMINE DESTRUCTION

Inhibitor	Concentration, moles/liter × 10^3	Inhibition, %
Cupric sulfate	1.0	50.0
Zinc chloride	1.0	41.3
Ferric chloride	1.0	45.6
Potassium cyanide	1.0	23.8
Sodium fluoride	1.0	13.1
Iodoacetic acid	1.0	4.3
Cysteine	0.1	56.7
	.01	9.9
Sodium sulfite	.01	9.5

The inhibition of enzyme reactions, however, is not limited to reagents of this type for there are numerous classical examples of inhibition with compounds whose chemical structures are similar to those of the substrate molecules. The effect of various compounds, resembling the thiamine molecule in one or more features, on the destruction of thiamine by the fish principle was therefore investigated. In Table II in which the compounds are listed it is evident that certain ones

[a] These compounds were very kindly made available by Dr. H. T. Clarke. [b] Clarke, THIS JOURNAL, **66**, 652 (1944). [c] Clarke and Gurin, *ibid*, **57**, 1876 (1935). [d] Obtained through the courtesy of the Medical Department of Merck and Co., Inc. The authors are also indebted to this company for a generous supply of thiamine for these studies.

possess the property of greatly retarding the destruction of the vitamin.

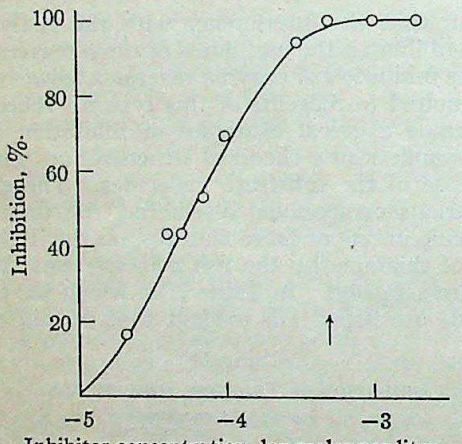

Fig. 1.—Inhibition of thiamine destruction: inhibitor, *o*-aminobenzyl-4-methylthiazolium chloride; the arrow indicates thiamine concentration (5×10^{-4} *M*).

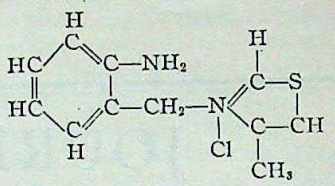
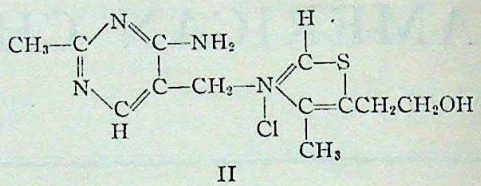
Comparison of the results obtained with the aminobenzyl- or aminoethyl-thiazolium compounds and the corresponding nitro- and phthalimido- derivatives emphasizes the importance of the amino group even though it is attached to the thiazole ring by three carbons in the one case and by two in the other. That this group is not the sole decisive point in the inhibition is evidenced by the distinctly lessened effect obtained with the aminopyrimidines. It appears more likely from the data of Table II that the amine in combination with the thiazolium portion of the molecule furnishes the stronger inhibition. This point will be considered in more detail in a later communication.

Since the most pronounced inhibition occurs with *o*-aminobenzyl-4-methylthiazolium chloride (I) and because of the similarity of its structure to that of thiamine (II)[5] the effect of the former compound was investigated in greater detail.



I



II

Experiments with a wider range of concentrations yielded the results shown in Fig. 1, in which is plotted the per cent. inhibition of thiamine destruction against concentration of the aminobenzyl compound. The character of the curve obtained is suggestive of the fundamental relationship involved.

For the purpose of further experimentation the assumption was made that the disappearance of thiamine in the presence of the fish principle occurs by a mechanism similar to that adopted for the majority of enzyme reactions.[6] In these it is believed that the substrate (in this case thiamine) combines with the enzyme (fish principle) to form an active complex which decomposes to yield the products of the reaction and the regenerated enzyme, the velocity of the reaction being directly proportional to the concentration of the active complex. In addition, inhibitor compounds resembling the substrate molecule are believed to combine in the same way with the enzyme protein in the place of the substrate and thus competitively retard the enzyme reaction. It may also be assumed that a similar situation applies with the aminobenzyl derivative with the consequent decrease in thiamine destruction. The validity of these assumptions may be tested by the use of methods originally derived from the law of mass action by Michaelis and Menten.[7] Representation of the formation of the enzyme-substrate complex by the expression

$$E + S \rightleftarrows ES \qquad (1)$$

leads to the Michaelis–Menten equation

$$v = V(S)/(K_S + (S)) \qquad (2)$$

where v is the initial velocity of the reaction, V the maximal velocity, S the substrate concentration and K_S the dissociation constant. The last term (K_S) corresponds to the substrate concentration of half-maximal velocity and is commonly known as the Michaelis constant.

(5) The similarity in spatial arrangement is even more striking when the comparison is made with atomic models.

(6) Haldane, "Enzymes," Longmans, Green and Co., London, 1930.

(7) Michaelis and Menten, *Biochem. Z.*, **49**, 333 (1913).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

By inversion of the above equation Lineweaver and Burk[8] obtained the form

$$1/v = K_S/V(S) + 1/V \qquad (3)$$

with which, by plotting $1/v$ against $1/(S)$, the more exacting linear treatment of the data is possible. With the slope and intercept values so obtained, the Michaelis constant and maximal velocity are readily calculated.

The latter authors, representing the case with an inhibitor present by the expression

$$2E + S + I \rightleftharpoons EI \text{ (Inactive)} + ES \text{ (Active)} \qquad (4)$$

have derived a second equation similar to the first and also of linear form

$$1/v = \frac{1}{V}\left(K_S + \frac{K_S(I)}{K_I}\right)\frac{1}{(S)} + \frac{1}{V} \qquad (5)$$

Included are the additional terms for inhibitor concentration, (I), and the enzyme-inhibitor dissociation constant, K_I. It is evident from equation (4) that the enzyme of the inactive enzyme-inhibitor complex is no longer able to catalyze the reaction involving the substrate. Again, by plotting the values of $1/v$ and $1/(S)$ of the inhibitor experiment, one may obtain, as Lineweaver and Burk have shown, a straight line the intercept of which is identical with that of the experiment without the inhibitor, but the slope of which is increased by the term, $K_S(I)/VK_I$ of equation (5). In this case the inhibition may be considered competitive. On the other hand, if in the two cases the slope remains the same but the intercept is increased in the presence of the inhibitor then non-competitive inhibition is occurring.

In order to determine whether the decreased thiamine loss in the presence of the aminobenzyl thiazole was due to competition between the former and the latter for the fish principle molecule, an experiment was designed so that the analytical treatment of Lineweaver and Burk might be applied. From solutions containing five different concentrations of thiamine and the same amount of fish principle, aliquots were removed at intervals for thiamine analysis. Similar solutions to which the inhibitor had been added were also analyzed, the over-all time in both cases being sufficiently short so that a plot of the thiamine destruction yields a straight line. From the amounts of thiamine destroyed at the different times the initial velocity of destruction (slope of best straight line through each set of values) in each solution was calculated using the method of least squares. Comparison of the initial velocities recorded in Table III again demonstrates the decreased activity of the fish principle in the presence of the aminobenzyl compound. Also recorded are the values for the amount of thiamine destroyed in each solution at sixty minutes. These may be compared to the values for the same time obtained by calculation. The decreased inhibition (increased destruction) with decreasing ratio of inhibitor to thiamine concentration apparent in Table III further confirms the fundamental relationship suggested by the results shown in Fig. 1.

TABLE III

INHIBITION OF THIAMINE DESTRUCTION

Thiamine concentration, moles/liter × 10^4 Without inhibitor	Destruction: Initial velocity, v, moles/liter/min. × 10^8	Destruction: At 60 minutes, moles/liter × 10^6 Obs.	Destruction: At 60 minutes, moles/liter × 10^6 Calcd.
1.0	0.746	42.8	44.8
2.5	.992	56.6	59.5
5.0	1.12	68.0	67.4
10.0	1.26	74.0	75.6
20.0	1.36	70.0	81.6
With 0.2 × 10^{-4} *M* inhibitor			
1.0	0.136	9.2	8.2
2.5	.285	18.0	17.1
5.0	.618	44.0	37.1
10.0	.758	46.0	45.5
20.0	1.29	76.0	77.4

The reciprocals of the initial velocities and substrate concentrations were plotted as shown in Fig. 2, the best straight lines being calculated by the method of least squares. From the calculation, the values of slopes and intercepts recorded in Table IV were obtained. Since the intercepts of the two straight lines coincide and the slopes are widely divergent, we may consider in the terms of Lineweaver and Burk that the inhibitory action of the aminobenzylthiazole is specific and competitive rather than general and non-specific. In addition, it is evident that the reaction involving thiamine and the fish principle exhibits features previously encountered only in the case of enzymatic reactions.

SUMMARY OF CONSTANTS

	Inhibitor Absent	Inhibitor Present
Slope	62.0	693
Increase in slope, $K_S(I)/VK_I$		631
Intercept	7.47×10^5	4.90×10^5
Maximal velocity, V[a]	0.134×10^{-5}	0.204×10^{-5}
Michaelis constant, K_S[b]	0.831×10^{-4}	
Inhibitor constant, K_I[b]		0.0197×10^{-4}
Affinity constants		
$1/K_S$	1.20×10^4	
$1/K_I$	50.7×10^4	

[a] Moles/liter/minute. [b] Moles/liter.

sponding constant for the inhibitor-fish principle complex have been calculated (Table IV). The reciprocals of the latter may be regarded as affinity constants. The ratio of $1/K_I$ to $1/K_S$ is 42.2, from which it is reasonable to believe that the inhibitor compound combines somewhat more firmly with the fish principle than does thiamine.

It may be further concluded from the above results that *o*-aminobenzyl-4-methylthiazolium chloride possesses the functional groups which allow its combination with the fish principle. There is considerable probability that these are the same as those responsible for the combination of thiamine with the fish principle. Of interest in this connection is the absence of the hydroxyethyl- side chain from the inhibitor molecule. From this it may be argued that it is unimportant in the combination process. This point is also supported by comparison of the results contained in Table II.

The term inhibition has assumed in recent times considerable importance in connection with the water soluble vitamins. The elucidation of the antagonism between *p*-aminobenzoic acid and the sulfa drugs in bacterial metabolism has stimulated numerous investigations involving analogs of other members of the vitamin-B complex. In general, the antagonisms encountered involve competition with or inhibition of the positive physiological functioning of the vitamin in question. In contrast, the above experiments deal with the inhibition of vitamin destruction, a destruction which results from the action of a substance of biological origin. This substance, the fish principle, may be an important metabolic factor in the fish organism; however, with our present knowledge it can hardly be regarded as a positive agent engaged in promoting the physiological action of thiamine. It may even be suggested that similar destructive agents affecting other vitamins may occur in nature, in which case the search for specific inhibitor analogs should prove profitable.

Experimental

The fish principle used in these experiments was prepared from acetone desiccated powder of carp viscera[1] by four or five extractions with 10% sodium chloride in 0.2 *M* phosphate buffer of *p*H 7.4. The combined supernatants obtained by centrifuging were diluted with the same solvent so that 2 ml. contained the activity of 100 mg. of original powder and were adjusted to *p*H 7.4 before being used. In the inhibition tests 2 ml. of the extract plus the desired volume of inhibitor and water to make a total volume of 4 ml. were placed in test-tubes. One ml. of 25×10^{-4} *M* thiamine was added and the tubes were incubated for two hours at 37.5°. The reaction was stopped by the addition of 5 ml. of 20% trichloroacetic acid. After thirty minutes the flocculated protein was removed by centrifugation and 2 ml. was analyzed for thiamine,[4] comparison being made with an unincubated control to which the trichloroacetic acid had been added immediately following the thiamine. The per cent. inhibition was calculated by comparison with incubated tubes containing no inhibitor.

For the experiment involving the Lineweaver–Burk treatment 28 ml. of extract of the fish principle equivalent to 700 mg. of desiccated powder was placed in one flask and 28 ml. of extract and inhibitor in a second flask. After warming to 37.5°, 7 ml. of the proper concentration of thiamine also at 37.5°, was added to both flasks. Five ml. was removed at intervals for determination of the thiamine remaining, the reaction being stopped as described above. In all, five aliquots were removed from each flask, those from the two lower concentrations of thiamine at fifteen-minute and the others at twenty-minute intervals.

Summary

The destruction of thiamine by the Chastek-paralysis factor of fish tissues could be markedly decreased by the addition of cupric, zinc and ferric ions. Cyanide, fluoride, iodoacetate, sulfhydryl and sulfite were less effective. Other common enzyme inhibitors could not be tested since they interfered with the determination of thiamine by the diazotization method.

Compounds resembling the thiamine molecule in one or more features were also tested for inhibitory action. Among these, *o*-aminobenzyl- and *β*-aminoethyl-4-methylthiazolium chloride were found to be strongly inhibitory. Substitution of the amino group of these two by the nitro and phthalimido groups, respectively, abolished the inhibition in the case of the former and greatly reduced it in the case of the latter.

Other thiazoles and various 4-aminopyrimidines were either without effect or exhibited considerably lessened inhibition.

In the case of the aminobenzyl-methylthiazole, the extent of the inhibition proved to be dependent upon the ratio of its concentration to that of thiamine.

Use of the Lineweaver-Burk method showed that this compound specifically inhibited thiamine destruction by competing with the vitamin for the fish principle. The same method yielded a Michaelis constant of 0.831×10^{-4} mole per liter for thiamine and a similar constant of 0.0197×10^{-4} for the inhibitor.

The data presented show that the fish principle behaves with inhibitor substances as do many enzymes. This finding may be interpreted as additional evidence of the enzymatic nature of the fish principle.

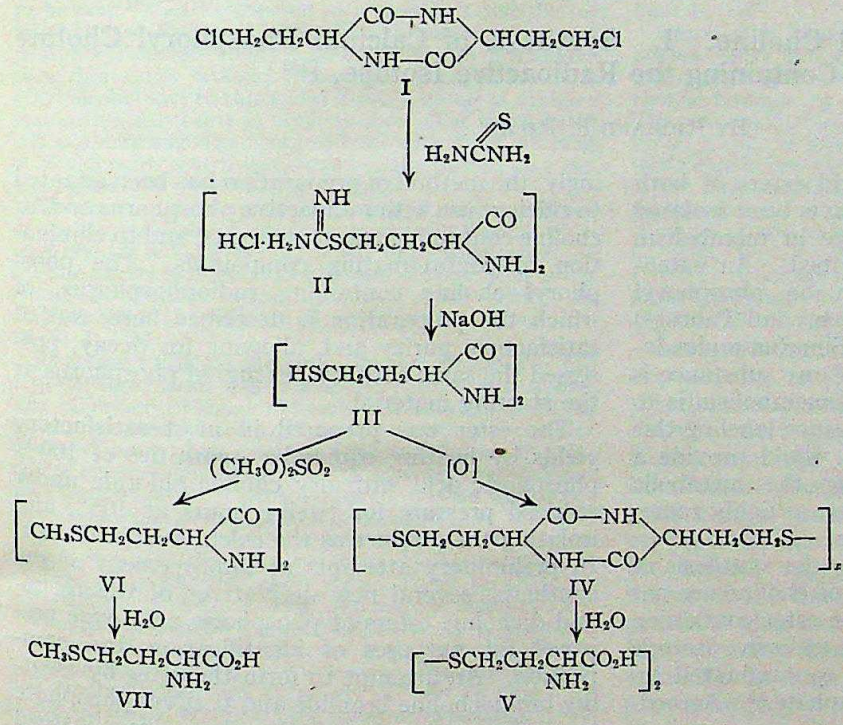
A New Synthesis of Homocystine and a Further Improvement in the Synthesis of Methionine

BY H. R. SNYDER AND GEORGE W. CANNON

In a study of the utilization of 3,6-bis-(β-chloroethyl)-2,5-diketopiperazine[1] (I) in the synthesis of amino acids it has been found that the substance (I) reacts with thiourea to give nearly quantitative yields of the bis-isothiouronium chloride (II). The ready availability of this salt is of interest because it should provide a convenient source of a number of important derivatives related to homocysteine, such as the diketopiperazine (III), homocystine (V), S-benzylhomocysteine and methionine (VII). Except for methionine,[1] these substances have been prepared most conveniently from benzyl β-chloroethyl sulfide through the malonic ester synthesis.[2,3,4]



Some of these possible transformations have been tested. Homocystine (V) was obtained in excellent yields by subjecting the isothiouronium salt to mild alkaline hydrolysis, followed by air oxidation in the presence of ferric chloride and finally by acid hydrolysis. Neither the diketopiperazine of homocysteine (III) nor the polymeric anhydride (IV) of homocystine was isolated.

Treatment of the isothiouronium salt with aqueous alkali followed by methyl sulfate gave poor yields of the anhydride of methionine (VI). However, when a mixture of the salt and methyl sulfate, suspended in ice-water, was decomposed by the gradual addition of aqueous sodium hydroxide, the diketopiperazine VI was produced in high yields. The crude product was of suitable quality for use in the preparation of *dl*-methionine. This method of converting the dichlorodiketopiperazine (I) to *dl*-methionine is more convenient than the earlier procedure,[1] in which the reaction of I with sodium methylmercaptide was employed.

Experimental

(a) **3,6-Bis-(β-isothiouroniumethyl)-2,5-diketopiperazine Chloride (II).**—A mixture of 47.8 g. (0.2 mole) of 3,6-bis-(β-chloroethyl)-2,5-diketopiperazine,[1] 33.5 g. (0.44 mole) of thiourea, and 500 cc. of absolute ethanol was heated under reflux for twenty-four hours. The reaction mixture was cooled in an ice-bath and the product collected by filtration; weight (air-dried) 77 g. (98%). It could be recrystallized from water to give a white solid which darkened at 250° and melted with decomposition at 255°.

Anal. Calcd. for $C_{10}H_{20}O_2N_6S_2Cl_2$: C, 30.69; H, 5.15. Found: C, 30.61; H, 5.29.

(b) **Homocystine (V).**—A solution of 8 g. (0.2 mole) of sodium hydroxide in 40 cc. of water was added dropwise to a stirred mixture of 19.5 g. (0.05 mole) of the isothiouronium salt and 100 cc. of water at room temperature. The stirring was continued for a total of one hour. Two crystals of ferric chloride were added to the mixture and air was bubbled through it for forty-eight hours. The mixture then was concentrated to dryness under diminished pressure. The residue was dissolved in 250 cc. of concentrated hydrochloric acid, and the solution was heated under reflux for three hours. It was then again concentrated to dryness under diminished pressure. The residue was extracted with several portions of boiling absolute ethanol. The combined alcoholic extracts were treated with Norite and then with an excess of pyridine. The solution was allowed to stand in a refrigerator over-night and the product was collected by filtration; it weighed 10 g. (74.5%). After several recrystallizations from water it darkened at 250° and decomposed without melting at 258–263° (lit.[5] 260–265°).

(c) **Methionine Anhydride (VI).**—A mixture of 19.5 g. (0.05 mole) of the diisothiouronium salt and 100 cc. of water was placed in a 500-cc. three-necked flask fitted with a reflux condenser, stirrer, and dropping funnel. The flask was immersed in an ice-bath and 15.1 g. (0.12 mole) of dimethyl sulfate was added at once to the reaction mix-

ture. A solution of 11 g. (0.275 mole) of sodium hydroxide in 40 cc. of water was then added dropwise over a period of twenty minutes. The stirring was continued for a total of one hour, and the product was collected by filtration. The mother liquor was cooled overnight in a refrigerator and a small additional amount of product was obtained. The combined crops of the product weighed 13.5 g. (100%). After one recrystallization from ethanol, the methionine anhydride weighed 10.1 g. (75%) and melted at 226–227.5°. A mixed-melting point determination with an authentic sample of methionine anhydride was not depressed. It was of sufficient purity to give *dl*-methionine in 85–95% yields. Direct hydrolysis[1] of the crude product gave 10 g. (65%) of crude *dl*-methionine.

Summary

3,6-Bis-(β-chloroethyl)-2,5-diketopiperazine is converted quantitatively to the bis-isothiouronium salt by treatment with thiourea in boiling ethanol.

Treatment of the bis-isothiouronium salt with dilute alkali, followed by oxidation with air in the presence of ferric chloride and hydrolysis with acid, provides a convenient synthesis of homocystine.

Decomposition of the bis-isothiouronium salt with alkali in the presence of methyl sulfate produces *dl*-methionine. This method of converting the dichlorodiketopiperazine to *dl*-methionine is superior to that previously described.

Metabolism of Phosphoryl Choline. I. Synthesis of Calcium Phosphoryl Choline Chloride Containing the Radioactive Isotope, P^{32} [1]

BY RICHARD F. RILEY

Although monophosphoric acid esters of both choline[2] and ethanolamine[3,4] have been isolated from normal tissues, their place in metabolism has not been adequately described. An extension[5] of available information on phosphoryl choline (Smith,[6] Welch and Welch,[7] and Taurog[8]) therefore appeared of interest. Since an undue increase in tissue concentration of any substance is to be avoided where its normal metabolism is to be followed (ref. 9, p. 292) and since labeling this molecule with radiophosphorus would provide a convenient means of following the metabolic path of that portion of the ester, a highly radioactive preparation was desirable.

The published procedures for the synthesis of the monophosphoric acid ester of choline are not well suited to preparation of the ester containing radiophosphorus. They permit extensive isotope dilution[2,10,11] or yield products contaminated by the diester and inorganic phosphate.[12] Accordingly, the method of preparation has been adapted to efficient use with radioactive phosphorus and/or choline containing tracer elements, and to elimination of contaminating compounds. The phosphoryl choline containing radiophosphorus, of which the preparation is described here, was of satisfactory purity and, allowing for decay, possessed the same activity per mg. of phosphorus as the starting material.

The ester was prepared in most satisfactory yields by heating equimolar quantities of 100% phosphoric acid with dry choline chloride under reduced pressure for twelve hours at 165°, and isolating the product as the calcium chloride salt. In preliminary attempts at improvement of the synthesis, several new derivatives of the mono- and dicholine esters of phosphoric acid were prepared for purposes of identification and comparison. An attempt to form the ester by treating bromocholine bromide and trisilver phosphate or disilver monophenyl phosphate gave instead excellent yields of neurine. It was also found that choline hydroxide and phosphoric acid may be esterified in refluxing toluene to give a satisfactory product, although in rather low yield and with considerable decomposition.

Experimental

Calcium Phosphoryl Choline Chloride Containing P^{32}.—150 mg. of phosphoric acid containing P^{32} in 6 ml. of water was introduced into a pear-shaped flask of 35 ml. capacity. The flask was fitted with a standard taper 24 stopper and two outlets with glass stopcocks. The dilute acid was evaporated to 100% phosphoric acid by immersion in an oil-bath which was gradually raised to 180° as a stream of dry air was passed through the flask. Only 0.005% of the activity was lost by this evaporation. When complete, 214 mg. of pure dry choline chloride was well mixed with the phosphoric acid and about 1 g. of phosphorus pentoxide, mixed with asbestos contained in a Soxhlet thimble,

supported over the reactants. The contents were maintained for twelve hours at 165° under vacuum. On cooling, the products were taken up in a few ml. of water, 100 mg. of calcium chloride added and the solution brought to the phenolphthalein end-point with saturated calcium hydroxide solution and worked up by the method of Plimmer and Burch[11]; yield 306 mg. or 63% of thin colorless rectangular plates. Unreacted phosphate, recovered as calcium phosphates during the isolation, was salvaged for further use by conversion to magnesium ammonium phosphate. The total recovery of radiophosphorus as the ester and magnesium ammonium phosphate was 96%. *Anal.* Calcd. for $C_5H_{13}O_4NPCaCl\cdot 4H_2O$: C, 18.2; H, 6.37; N, 4.25. Found: C, 18.11; H, 6.42; N, 4.19.

By isotope dilution, the product was found to contain 0.02% contaminating inorganic phosphorus and < 0.05% by colorimetric analysis. Calcium phosphoryl choline chloride prepared in this fashion contains negligible amounts of the diester, as indicated by analysis and the fact that measurable quantities of the insoluble diaurichloride could not be obtained from larger scale preparations utilizing non-isotopic phosphorus.

Phosphoryl Choline Reineckate.—3.37 g. of recrystallized phosphoryl choline aurichloride, prepared according to Jackson,[12] was decomposed with powdered silver by the procedure of Dudley.[13] The dilute aqueous solution of phosphoryl choline chloride so obtained was evaporated to a thin sirup, brought to incipient precipitation with ethyl alcohol and to this added a 100% excess of acidified ammonium reineckate in ethyl alcohol. The precipitated salt was centrifuged and washed twice with 20-ml. portions of alcohol with centrifugation and finally filtered on a sintered glass filter; yield 2.17 g. or 99%.

The compound does not precipitate well from an aqueous or acetone solution (*cf.* choline reineckate) although when once dried it redissolves only slowly in these solvents. It is quite insoluble in ethyl alcohol and dioxane after it has once been obtained in the dry state. *Anal.* Calcd. for $C_{14}H_{36}O_8N_8S_4P_2Cr$: N, 16.37; P, 9.05. Found: N, 16.28; P, 8.54.

Phosphoryl Choline Mercuric Chloride Complex.—0.75 g. of the aurichloride was decomposed with silver as above. The phosphoryl choline chloride, contained in 5 ml. of water, was precipitated as the mercuric chloride complex by the addition of an excess of a saturated alcoholic solution of mercuric chloride. The complex was recrystallized once from warm 80% alcohol, filtered, washed with absolute alcohol and dried; yield 1.08 g. or 76% as beautiful long white needles, singly and in clusters. It is more soluble in water than the mercuric chloride complex of choline; m. p. 180–184° cor. *Anal.* Calcd. for $C_5H_{16}O_4NP\cdot 3HgCl_2$: N, 1.40; P, 3.10. Found: N, 1.45; P, 3.26.

Phosphoryl Choline Phosphotungstate.—A preparation of characteristic composition was not obtained although phosphotungstic acid gave a water-insoluble microcrystalline product which was extremely difficult to filter. It contained 0.91% N; yield 71% based on N analysis.

Dicholine Phosphate Reineckate.—This was prepared by the same procedure given for the monoester: 0.35 g. of the diaurichloride gave 0.23 g. of reineckate; very slightly soluble in water, acetone, ether and chloroform; insoluble in ethyl alcohol. This salt probably is of variable composition. That obtained showed N, 19.70; P, 3.92; yield 79% based on P analysis.

Dicholine Phosphate Mercuric Chloride Complex.—This was prepared by the same procedure given for the monoester complex: 0.30 g. of the diaurichloride gave 0.13 g. of a fluffy crystalline powder on recrystallization of the crude product from hot water; m. p. 202–207°; N, 0.89; yield 13% based on N analysis.

Direct Esterification of Choline Hydroxide by Phosphoric Acid in Toluene.—Ten grams of choline chloride was dissolved in 50 ml. of water and stirred in the dark with a calculated excess of silver carbonate until the filtrate gave a negative test for halogen. It was filtered and the calculated quantity of barium hydroxide added. The solution was filtered from barium carbonate and the filtrate evaporated down under nitrogen with reduced pressure. The sirup obtained was distilled with toluene to remove further water, 3.83 ml. of 100% phosphoric acid added slowly and distillation continued until no more water came over with the toluene, further toluene being added as required. On cooling the toluene was decanted from the residue which was washed with two small portions of absolute alcohol and dried in the air. The residue was taken up in 10 ml. of water, filtered and precipitated by addition of 10 volumes of absolute alcohol. The precipitated sirup was taken up in water, 8.0 g. of calcium chloride added and the solution neutralized to phenolphthalein with saturated calcium hydroxide solution. The filtrate[14] from this solution was evaporated under reduced pressure on the steam-bath to a thin sirup and precipitated by the addition of 200 ml. of absolute alcohol. The crystalline product on drying in air following a second precipitation weighed 3.2 g. or 24%. The product was obtained as thin fragile rectangular plates or needles depending on the rate of crystallization. Analysis showed this to be the calcium chloride salt of Plimmer and Burch.[11] *Anal.* Calcd. for $C_5H_{13}O_4NPCaCl\cdot 4H_2O$: P, 9.46; N, 4.25; H_2O, 21.86. Found: P, 9.2; N, 4.10; H_2O, 21.4; ionic P, 0.07.

Reaction of Bromocholine Bromide and Silver Phosphates.—Five grams of trisilver phosphate suspended in 300 ml. of absolute alcohol reacted with 2.95 g. of bromocholine bromide by refluxing for six hours in the dark. The reaction mixture was cooled, filtered to separate silver bromide and the filtrate, after decolorization with Norite, worked up in two parts to give the picrate and aurichloride of the main reaction product; yield 65%. The neurine picrate melted at 270° and the aurichloride at 243°. *Analysis* of the picrate showed: calcd. for $C_{11}H_{14}O_7N_4$: C, 42.05; H, 4.49; P, 0.00. Found: C, 42.17; H, 4.36; P, 0.00. A similar experiment employing disilver monophenyl phosphate in place of the trisilver phosphate gave an 89% yield of neurine isolated as the picrate.[15]

Acknowledgments.—The author takes this opportunity to thank Dr. Harold C. Hodge of this department for his help and advice throughout the development of this work. Dr. Donald Ketchum of the Eastman Kodak Company and Mr. Robert Bauman of the University of Rochester kindly carried out the combustion analyses reported here. We also wish to acknowledge the helpful suggestions of Dr. Arnold Weissberger of the Eastman Kodak Company and express our thanks to Dr. Robley D. Evans of the Massachusetts Institute of Technology, who made available the high activity sample of radiophosphorus employed.

Summary

1. An economical method for the preparation of phosphoryl choline containing isotopic elements has been developed and applied to the synthesis of the ester containing highly active radiophosphorus.

2. Several new derivatives of the mono- and dicholine phosphoric acid esters have been described.

ROCHESTER, N. Y. RECEIVED DECEMBER 31, 1943

A New Method for the Measurement of Tyrosinase Catecholase Activity. II. Catecholase Activity Based on the Initial Reaction Velocity

BY WILBUR H. MILLER,[1] M. FRANK MALLETTE, LLOYD J. ROTH AND CHARLES R. DAWSON

In a previous publication[2] a new technique for the determination of the catecholase activity of the phenol oxidizing enzyme, tyrosinase, was described. This technique was referred to as the chronometric method since it involves the measurement of the time necessary for a given quantity of the enzyme to produce *o*-benzoquinone in the catechol–enzyme system just in excess of that necessary to oxidize a small amount of ascorbic acid also present in the system. The end-point time, time of appearance of excess *o*-benzoquinone, is indicated by a blue coloration at the point where the reaction mixture is continuously sampled dropwise into an acidified starch–iodide indicator solution.

Because it seemed advisable for purposes of comparison to continue the activity data in a form previously used in this and other laboratories, the chronometric method was calibrated against the direct manometric method of measuring the catecholase activity. That is, the end-point times obtained using various amounts of the enzyme with a prescribed amount of ascorbic acid in the system were correlated with the activity of the enzyme as based on oxygen uptake measurements made during the enzymatic oxidation of catechol in the absence of ascorbic acid. A simple equation was thus given for the calculation of the activity from the end-point time, based on the calibration value of 34 catecholase units for an end-point of sixty seconds using a 250-cc. reaction volume. This value (34 units) was obtained after a statistical treatment of a large number of one minute reading experiments using an appropriate dilution of the enzyme in the direct manometric method.[3] It was pointed out that such activity measurements made by the chronometric method were much more reproducible than those obtained using the manometric method and could be obtained with considerably less effort.

A difficulty in obtaining a reliable measure of the catecholase activity of tyrosinase with the usual Warburg manometer technique rests on the fact that during the enzymatic oxidation of catechol the enzyme frequently is very rapidly inactivated. In such a case the course of the oxygen uptake is at no time linear in form, and rate measurements are therefore difficult to obtain. This difficulty generally becomes more and more evident as the purity of the enzyme, or freedom from extraneous inactive protein material, is increased. The limitations of the respirometer method are such that accurate readings of oxygen uptake are not possible during the initial phases of the reaction, hence rate measurements during the first two to three minutes of the reaction are subject to an experimental error estimated by Parkinson and Nelson[4] to be about 20–30%. On the other hand, end-point times by the chronometric method can be obtained with good precision at any time within the interval of twenty to one hundred and fifty seconds after initiating the enzymatic oxidation of catechol.

An application of the chronometric method to a study of this inactivation of the enzyme occurring during the initial phases of the enzymatic oxidation of catechol reveals that the different types of tyrosinase preparations[5] differ markedly in the degree of inactivation of the enzyme that occurs during the first sixty seconds of the reaction.[8] This of course means that catecholase activities based on rate measurements made after the reaction has progressed for a short time are influenced by the degree of enzyme inactivation that has occurred up to that time. In other words, a measurement of the rate of oxidation (activity) made at sixty seconds using a preparation that does not inactivate during this time will give a true value of the original activity of the enzyme. However, the measurement made at sixty seconds for a preparation that has undergone serious inactivation during the first minute of the reaction will, of course, yield an activity value lower than the true activity of the original enzyme preparation.

It is apparent that to compare on a common basis the catecholase activities of tyrosinase preparations differing in the degree of enzyme inactivation that occurs during the initial phases of the enzymatic oxidation of catechol, the activities must be based on the initial reaction velocity. In terms of oxygen uptake, or in terms of *o*-benzo-

(5) Preparations of tyrosinase from the common mushroom *Psalliota campestris* vary in their ratio of catecholase to cresolase activity depending on the method of isolation and purification employed. Those which are relatively much more active with catechol than with *p*-cresol have been termed high catecholase preparations to distinguish them from the so-called high cresolase preparations in which the two activities are more nearly comparable. These preparations have properties that are quite different[3,4,6,7] and the question of whether or not they are mixtures of two enzymes, or result because of modification of one enzyme protein during processing, etc., has not yet been definitely settled.

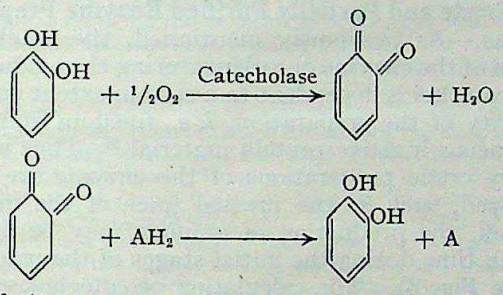
quinone production, the initial reaction velocity is dO_2/dt or dQ/dt where $t \cong 0$. The lack of precision inherent in the manometric method makes the determination of dO_2/dt at $t \cong 0$ impracticable, but a slight modification of the chronometric technique as previously described yields the value of dQ/dt at $t \cong 0$ with good precision. It is the purpose of this communication, therefore, to describe how the true catecholase activity of the enzyme, based on the initial reaction velocity and hence not influenced by the inactivation characteristics of the preparation, may be obtained using the chronometric method.

The Initial Reaction Course.—As previously indicated, when catechol is enzymatically oxidized in the presence of ascorbic acid,[9] no detectable amount of *o*-benzoquinone exists in the solution, and the reaction mixture remains perfectly colorless until the moment the ascorbic acid (AH_2) has all been converted to dehydroascorbic acid (A)



If the experiment is set up a number of times using different amounts of ascorbic acid with a given amount of enzyme and catechol, a series of end-point times (time of appearance of *o*-benzoquinone in system) is obtained. In this way the production of *o*-benzoquinone (or its equivalent—the disappearance of ascorbic acid) can be measured as a function of time for a given amount of the enzyme. The method is, therefore, nothing more than an indirect titration of the *o*-benzoquinone, performed in such a manner that the quinone is never present in the reaction mixture until the instant of its detection. This eliminates from consideration the many complex side reactions which make the direct titration of *o*-benzoquinone unsuitable for measuring the enzyme activity.[11] By using small amounts of ascorbic acid in the system the *o*-benzoquinone production can be followed during the very early stages of the reaction with good precision.

The data given in the form of Curves I, II and III in Fig. 1 show, in terms of quinone production, the initial reaction course during the enzymatic oxidation of catechol as catalyzed by three

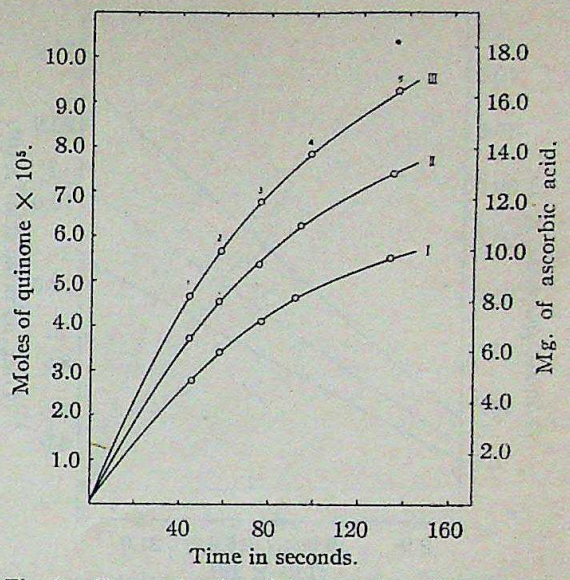


Fig. 1.—Curves showing the production of *o*-benzoquinone during the initial phase of the enzymatic oxidation of catechol. Aerobic oxidation catalyzed by three different amounts of a purified high catecholase preparation of tyrosinase.[12] Each experimental point obtained and checked (see experimental section) using a 250-cc. reaction volume containing 50 mg. of catechol (optimum) and ascorbic acid as shown; *p*H 5.5; temp., 25°. Enzyme employed was tyrosinase preparation C143F1, diluted 1:10 and then this sub-dilution further diluted 1:100 just before using; total dilution 1:1000. Curve I, 6 cc.; Curve II, 8 cc.; Curve III, 10 cc. The undiluted enzyme had a dry wt. of 5.9 mg./cc.,[13] contained 0.07% Cu,[14] 475 cresolase units/cc.,[3] and was stable for a long period when stored at refrigerator temperature. In the 1:10 dilution it was stable for several days at low temperature. See experimental section for method of obtaining data.

different amounts of a purified, typical, high catecholase preparation of tyrosinase.[5] Besides enzyme and ascorbic acid, as shown, the original reaction mixtures for each experimental point contained catechol in optimum concentration for this type enzyme preparation, *i. e.*, 50 mg. in a 250-cc. reaction volume, added at zero time to the buffered enzyme–ascorbic acid mixture (*p*H 5.5) to initiate the reaction. The oxidations were carried out at 25°. Other experimental details are given in the legend of the figure and the experimental section.

Because the catechol concentration remains constant during the reaction and is present in large excess in comparison to the amount of *o*-benzoquinone formed, the drop in rate of production of quinone that is evident in each case can only be attributed to serious inactivation of the enzyme in the early stages of the reaction.

(9) The ascorbic acid functions only as a reducing agent and does not significantly inhibit or accelerate the enzyme action. Its oxidation is not catalyzed by the enzyme under these conditions, nor does it affect the inactivation of the enzyme.[2,10]

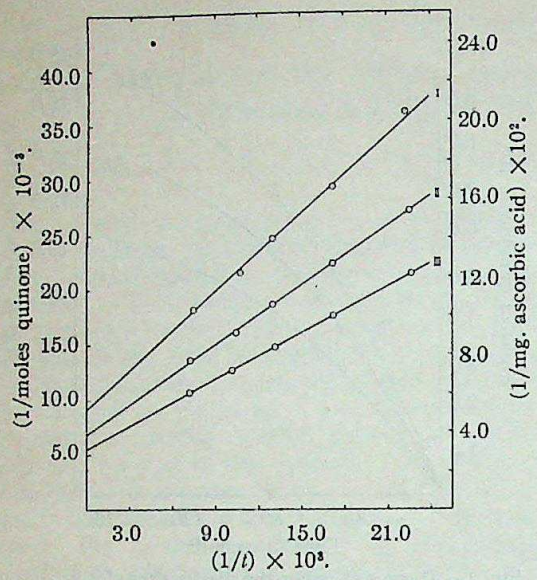

Fig. 2.—Reciprocal plot of data in Fig. 1. The linear curves (I, II and III) are expressed by Equation 2 and therefore verify that the initial reaction course during the enzymatic oxidation of catechol follows Equation 1. The most probable curve was established in each case by the method of residuals[15] using large-scale plots.

The Initial Reaction Velocity.—When the reciprocal of the quinone is plotted against the reciprocal of the time, linear curves are obtained as shown in Fig. 2. This fact indicates that during the initial stages of the enzymatic oxidation of catechol by a purified high catecholase preparation of tyrosinase the *o*-benzoquinone is produced in accordance with the following equation

$$Q = at/(b + t) \qquad (1)$$

since the linear curves are expressed by the reciprocal equation

$$1/Q = b/a(1/t) + 1/a \qquad (2)$$

where Q is the *o*-benzoquinone, and a and b are constants which may be evaluated by determining the slope and intercept of the linear curves of Eq. 2.

Differentiation of Eq. 1 in respect to t gives equation 3.

$$\frac{dQ}{dt} = \frac{ab}{(b + t)^2} \qquad (3)$$

and it follows that when $t \cong 0$

$$\frac{dQ}{dt_{(t \cong 0)}} = a/b \qquad (4)$$

Thus the initial reaction velocity (a/b) is the reciprocal of the slope of the linear curves shown in Fig. 2 (see Eq. 2) and may be determined from the experimental data.

The Unit of Catecholase Activity.—In all previous publications from this and certain other laboratories concerning the enzyme tyrosinase, one unit of enzyme activity has been defined as that amount of enzyme that, when catalyzing the oxidation of the phenolic substrate under specified conditions, causes an oxygen uptake of 10 cu. mm. per minute. This rate of oxygen uptake is equivalent to 8.93×10^{-7} mole of quinone per minute or 1.49×10^{-8} mole of quinone per second. Thus in terms of the initial reaction velocity (Eq. 4), which may be expressed as moles of quinone per second, the catecholase activity is calculated from

$$\text{Catecholase Units} = (a/b)/1.49 \times 10^{-8} \qquad (5)$$

and one unit of catecholase becomes that amount of enzyme which produces *o*-benzoquinone at an initial rate of 1.49×10^{-8} mole of quinone per second. The original definition of a catecholase unit has not been changed, but the portion of the reaction from which the unit is calculated has been shifted.

Crude and Partially Purified Enzyme Preparations.—As previously mentioned, the inactivation of the enzyme occurring during the oxidation of catechol is dependent to a certain extent on the purity of the preparation, *i. e.*, freedom from extraneous inactive protein material.[16] Thus when very crude preparations of the enzyme are employed, such as the pressed juice of the mushroom, the production of quinone may be linear with time during the initial stages of the reaction (see Fig. 3). The calculation of catecholase activity in these cases is, of course, simplified since the slope of the reaction curve is constant and gives directly the initial reaction velocity in moles of quinone per second.

It can be seen that a linear reaction course is nothing more than a special case of the expression as given in Eq. 1. For as the constants a and b become very large, *i. e.*, approach infinity, b becomes very large in respect to t and Eq. 1 approaches the expression for a straight line through the origin, *i. e.*

$$Q = at/b = kt \qquad (6)$$

As the purification of a high catecholase type preparation of tyrosinase is increased, *i. e.*, the activity per mg. dry weight is increased, the inactivation of the enzyme during the initial stages of the oxidation of catechol soon becomes evident. That is, the reaction course generally departs from a linear form after two or three steps in the purification process. It has been our experience in following through a large number of such preparations that the reaction course always follows the expression given by Eq. 1, *i. e.*, the reciprocal plot

(15) H. M. Goodwin, "Elements of the Precision of Measurements and Graphical Methods," McGraw-Hill Book Co., New York, N. Y., 1920.

(16) It should be pointed out that the inactivation characteristics of a tyrosinase preparation during the oxidation of catechol appear also to be dependent on the ratio of the catecholase to cresolase activity of the enzyme.[5] Preparations relatively high in cresolase activity generally are more stable than high catecholase preparations during the oxidation, and several purified high cresolase preparations have been obtained that show no inactivation during the initial stages of the oxidation of catechol.[5]

Digitized by Arya Samaj Foundation Chennai and eGangotri

of quinone versus time yields linear curves of the type expressed by Eq. 2 and shown in Fig. 2. The values of a and b decrease to constant values that are characteristic of the high catecholase type preparation, and further purification has little or no effect on the curvature of the reaction course. In other words, after a certain stage in the purification is reached, further purification has little or no effect on the inactivation characteristics of the high catecholase type preparation. The application of Eq. 1 to a study of the inactivation of the catecholase activity of tyrosinase is to be published later.

The Activity Determination: Experimental.—The chronometric method as originally described made use of a 250-cc. reaction volume. Experience in this Laboratory has shown that the reaction system can be reduced to a 100-cc. volume with advantage if all of the reagents of the system are reduced proportionately, *i. e.*, to 2/5 scale. Much less enzyme, catechol, ascorbic acid and buffer are used up, therefore, per end-point determination; an important factor when a large number of determinations are made per day. The precision of the measurements and working range of enzyme concentration do not appear to be significantly different in the smaller volume. The method as described below is, therefore, for the 100-cc. volume system.

A 300-cc. round-bottom three-neck flask[17] is clamped in position in a 25° thermostat. One neck of the flask is to hold a capillary siphon tube for carrying the reaction mixture dropwise (about 2 drops per second) over into the acidified starch iodide indicator solution. Another neck allows for the introduction of a medium stream of air bubbles which serve to agitate the contents of the flask and also to start the siphon flowing when the third (center) neck is momentarily closed. The center neck of the flask is used for introducing the reagents which are previously maintained at 25° in the thermostat.[18]

In the flask are placed 10 cc. of 0.2 M citric acid—0.4 M secondary sodium phosphate buffer (pH 5.1) and enough water to make the total volume 100 cc. when the other reagents have been added. Just previous to starting the reaction the ascorbic acid and enzyme are added. Usually for the first end-point an accurately known quantity of ascorbic acid (about 3 mg.) is introduced in the form of a 0.1% solution which is also 0.1% in metaphosphoric acid (the latter stabilizes the ascorbic acid to autoxidation but has no effect on the enzymatic reaction). The ascorbic acid and enzyme are rinsed in with a measured quantity of water, and the siphon tube is then adjusted in position. The air bubbler is inserted, and the reaction is initiated about ten to fifteen seconds afterwards by rapidly introducing an aqueous solution of catechol from a small erlenmeyer flask or cylinder. The pH of this final reaction is 5.5. At any convenient time thereafter (usually 5 to 10 seconds) the siphon is started, and the end-point time, the time at which o-quinone is existent in the reaction mixture due to complete removal of reducing agent, is indicated by the appearance of a blue color at the point where the reaction mixture drops into the acidified starch–iodide indicator solution. The indicator solution is a mixture of 5 cc. of 1% starch solution, 25 cc. of 10% potassium iodide solution, and 25 cc. of 2 N sulfuric acid containing 1% pyrogallol. To greatly facilitate the observation of the end-point it is advantageous to use the indicator solution in a small crystallizing dish illuminated from below through white opal glass.. The indicator solution should be stirred slowly at a constant rate during the determination. The effect on the end-point time caused by certain variations in experimental conditions has been discussed elsewhere.[2]

(17) A 500-cc. flask works equally well.

(18) The diluted enzyme is kept at 0–5° at all times. Experience has shown that many tyrosinase preparations, particularly when purified, tend to lose catecholase activity very rapidly when allowed to stand in highly dilute solution at room temperature. Concentrated preparations (in excess of 1 mg. of enzyme protein per cc.) are generally quite stable. To dilute the stock enzyme for activity determination cold water should be used, and the analysis made within a few minutes of the dilution. Several determinations generally can be made on the same dilution if it is kept in an ice-bath at 0–5°.

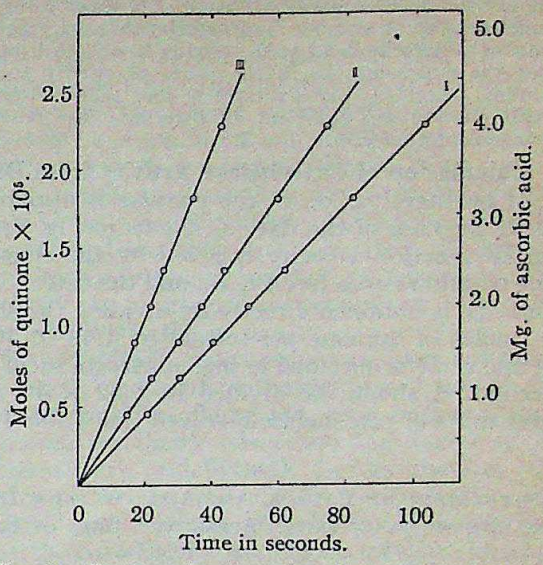

Fig. 3.—Curves showing the linear production of o-benzoquinone during the initial phase of the enzymatic oxidation of catechol when catalyzed by three different amounts of crude extract preparation[19] of tyrosinase from the common mushroom, *Psalliota campestris*. Each experimental point was obtained and checked using 100 mg. of catechol (optimum) in a 100-cc. reaction volume buffered to pH 5.5 as described in the experimental section. Curve I, 1 cc. of a 2:17 dilution of the extract; Curve II, 1 cc. of a 3:18 dilution; Curve III, 1 cc. of a 5:17 dilution. See Table I for calculation of catecholase activities. The undiluted crude extract had a dry wt. of about 6 mg./cc. and contained 23 cresolase units/cc.

To determine the catecholase activity of tyrosinase by this method it is first necessary to establish the optimum concentration of substrate (catechol) to be used, since the rate of oxidation varies with the catechol concentration for different tyrosinase preparations.[2] This is best accomplished by diluting the enzyme so that when 50 mg. of catechol and 3 mg. of ascorbic acid are used an end-point is obtained in the region of forty to sixty seconds. Then using the same amount of enzyme and ascorbic acid the end-point determination is repeated three or four times while varying the original catechol concentration until the quantity giving the shortest end-point time has been determined. Purified high catecholase preparations usually have an optimum catechol concentration in the vicinity of 20 mg. per 100 cc. reaction volume, whereas crude preparations and high cresolase preparations generally show maximum activity and little variation between 100–200 mg. of catechol.

With the optimum catechol concentration established the initial reaction course is then determined by repeating

(19) 1 lb. of mushrooms was passed through a meat grinder into two volumes of cold acetone (chilled with dry-ice) to wash out natural substrates and coloring matter. After filtering immediately, the pulp was frozen with dry-ice for two hours and then broken up and suspended in 600 cc. of water containing a drop of concentrated ammonia solution. After standing overnight at refrigerator temperature the extract and pulp were separated by pressing through

the end-point determination a number of times using the same amount of enzyme and catechol but varying the amount of ascorbic acid used—usually from 1 to 4 mg. so that the end-points lie in the range of twenty to one hundred seconds. Usually three or four such end-points (with checks) are sufficient to determine the reaction course as plotted in Fig. 1 or 3.

Calculation of Catecholase Activity from Data.—If no inactivation of the enzyme is apparent, as in the case of the data as shown in Fig. 3, the initial reaction velocity is given by the slope of the reaction curve (see Eq. 6), and the catecholase activity is obtained directly by dividing the slope in moles of quinone per second by 1.49×10^{-8}. If the slope is obtained in mg. of ascorbic acid per second, it should be divided by 2.62×10^{-3} to give units of catecholase involved (see Table I).

TABLE I

CALCULATION OF CATECHOLASE ACTIVITY FROM DATA. NO ENZYME INACTIVATION APPARENT. DATA OF FIG. 3

Curve	Enzyme diln. factor	Slope, mg. AH_2 per sec.	Units in reaction, slope/ 2.62×10^{-3}	Units/cc., undiluted
I	8.5	0.0388	14.8	126
II	6.0	.0540	20.6	124
III	3.4	.0933	35.6	121
			Average ± a.d.	124 ± 2

If inactivation of the enzyme is apparent, as in the case of the curves in Fig. 1, the best value of the catecholase activity is obtained from the reciprocal plot of the data as shown in Fig. 2. If care is taken to establish the best linear curve through the experimental points (see legend Fig. 2) the reciprocal of the slope of this curve (the initial reaction velocity) is directly proportional to the amount of enzyme taken when the conditions specified above are employed. This proportionality is shown by the data as arranged in Table II.

TABLE II

CATECHOLASE ACTIVITY FROM THE RECIPROCAL PLOT DATA (FIG. 2). ENZYME INACTIVATION APPARENT

Curve	Enzyme, cc.	Slope (b/a), sec. per mole Q	Initial vel. (a/b) moles Q per sec.	Catecholase units $(a/b)/1.49 \times 10^{-8}$	Units/cc.
I	6.0	11.8×10^5	8.48×10^{-7}	56.8	9.47
II	8.0	8.94×10^5	11.2×10^{-7}	75.2	9.40
III	10.0	7.03×10^5	14.2×10^{-7}	95.4	9.54
			Average ± a.d.		9.47 ± 0.05

If only the activity of the enzyme is desired and not the values of a and b of Equation 1 or 2, it is not necessary to plot the reciprocal curve (Fig. 2). The initial reaction velocity can be obtained directly from the original data by inserting the values of two experimental points into the following equation

$$a/b = \frac{(Q_1C_2)(t_2 - t_1)}{(t_1t_2)(Q_2 - Q_1)} \qquad (7)$$

where Q_1 is the moles of quinone formed in t_1 seconds, and Q_2 the moles formed in a longer time t_2. It is generally more convenient to use Eq. 7 in terms of mg. of ascorbic acid rather than moles of quinone, since the data are obtained directly in terms of ascorbic acid. The initial reaction velocity is then converted into catecholase activity in the manner described previously and illustrated in Table I. This method of calculating the activity directly from the original data is much less time-consuming than the method involving the reciprocal plot. However, the results obtained are less reliable since they are based on only two experimental points. For example, using this method for three different pairs of points (1 and 3, 2 and 4, 3 and 5) for each of the three curves of Fig. 1 yields an average value of 9.37 ± 0.33 (3.5%) units per cc. as the activity of the diluted enzyme (compare with Table II).

Discussion

It seems advisable to compare the catecholase activity of tyrosinase as determined by the method described above with that obtained by other methods of determination. Two other methods that are in use are (I) the direct monometric method on catechol,[3,20] and (II) the manometric method using a mixture of hydroquinone and catechol as proposed by Adams and Nelson.[21] Each of these methods (I and II) depends on a rate measurement made at some time after the enzymatic oxidation of catechol has been initiated, and the activity results are, therefore, influenced by what has happened to the enzyme during the reaction previous to that rate measurement. It follows, therefore, that only in the case of an enzyme which shows no inactivation during the initial stages of the reaction can these methods yield results that are comparable to the results obtained with the chronometric method as described above. In the usual case, where inactivation of the enzyme is evident, the chronometric method based on the initial reaction velocity will give considerably higher values of catecholase activity. It follows that no conversion factor is possible to convert catecholase activity as determined by any of these methods into activity as based on the initial reaction velocity unless the nature and degree of inactivation in the early stages of the reaction are also known.

In the direct manometric method on catechol, as used by Gregg and Nelson,[3] the inert protein material gelatin is placed in the reaction system to "protect" the enzyme to some extent against inactivation. More reproducible results are obtained in the presence of gelatin than when gelatin is absent from the system, and the reaction course is somewhat more linear in form during the first two minutes of the reaction when gelatin is employed.[6] The diluted enzyme stands in the buffered reaction system (containing gelatin) during a ten to twenty minute temperature equilibra-

tion period (25°), and then the reaction is initiated by the addition of catechol. Readings of oxygen uptake are taken every minute.

If the activity of a purified high catecholase preparation of tyrosinase is determined by this method and then by the chronometric method as based on the initial reaction velocity, about twice as much catecholase activity will be indicated in the latter case. A good share of this discrepancy between the two methods is due to the considerable inactivation of the enzyme that occurs during the first minute of the reaction, and the rest can undoubtedly be ascribed to the difference in the experimental conditions. The main experimental difference between the two systems lies in the fact that in the chronometric system no gelatin is employed, and the diluted enzyme is not subjected to a long temperature equilibration period prior to the measurement. Both of these factors have been shown to lower the activity of the enzyme, particularly when the activity is based on the first minute reading of oxygen uptake.[6]

The Adams and Nelson manometric method of measuring the catecholase activity of tyrosinase[21] is based on the rate of oxygen absorption while the enzyme catalyzes the oxidation of a small amount of catechol in the presence of a relatively large amount of hydroquinone. Gelatin is also employed in the system. At the time it was proposed, it was believed that the hydroquinone functioned only as a reductant of the *o*-benzoquinone, thereby maintaining a constant concentration of catechol during the measurement. The presence of hydroquinone in the catechol–enzyme system markedly stabilizes the enzyme against inactivation during the oxidation, and the reaction course as followed by oxygen uptake tends to be linear for an appreciable time.[10] Because of the linear reaction course, reproducible rate measurements of the enzymatic oxidation of catechol became possible with the introduction of this substrate mixture, and the method met with favor. It did much to stimulate studies of the catecholase activity of tyrosinase, and made possible the comparison of this activity with the monophenolase activity of the enzyme.

However, these studies have shown that hydroquinone does not act merely as a reductant for the *o*-benzoquinone. Under certain conditions it is oxidized by the enzyme,[22] and previous publications[4,6] have emphasized the fact that the stabilizing effect of hydroquinone against the inactivation of the enzyme varies with the nature of the enzyme preparation. In all cases when hydroquinone is in the system the initial rate of enzymatic oxidation is less than when catechol is oxidized alone, *i. e.*, catecholase activity obtained by this method is always less than that obtained in the direct manometric method on catechol. Apparently the hydroquinone behaves as a competitive inhibitor in the system.

If these effects of hydroquinone were constant, no serious criticism to the continued use of the method could be offered but, as a matter of fact, both the stabilizing effect and the degree of inhibition vary widely with factors such as the purity of the enzyme and the ratio of the catecholase and cresolase activities. It is obvious that the catechol–hydroquinone method does not give a true measure of the catecholase content of any tyrosinase preparation, and the continued use of the method is, therefore, open to serious criticism.

Summary

1. A chronometric method based on the indirect titration of *o*-benzoquinone is described for following the initial reaction course during the enzymatic oxidation of catechol.

2. The precision is such that the initial reaction velocity (dQ/dt at $t \equiv 0$) may be determined and used for calculation of the catecholase activity of the enzyme tyrosinase.

3. The value of catecholase activities based on the initial reaction velocity, particularly when comparing enzymes having different inactivation characteristics, has been discussed.

4. Two other methods now in use for the measurement of tyrosinase catecholase activity have been discussed in comparison with the chronometric method.

5. It is felt that the chronometric method of measuring the catecholase activity of tyrosinase is superior to other methods now in use.

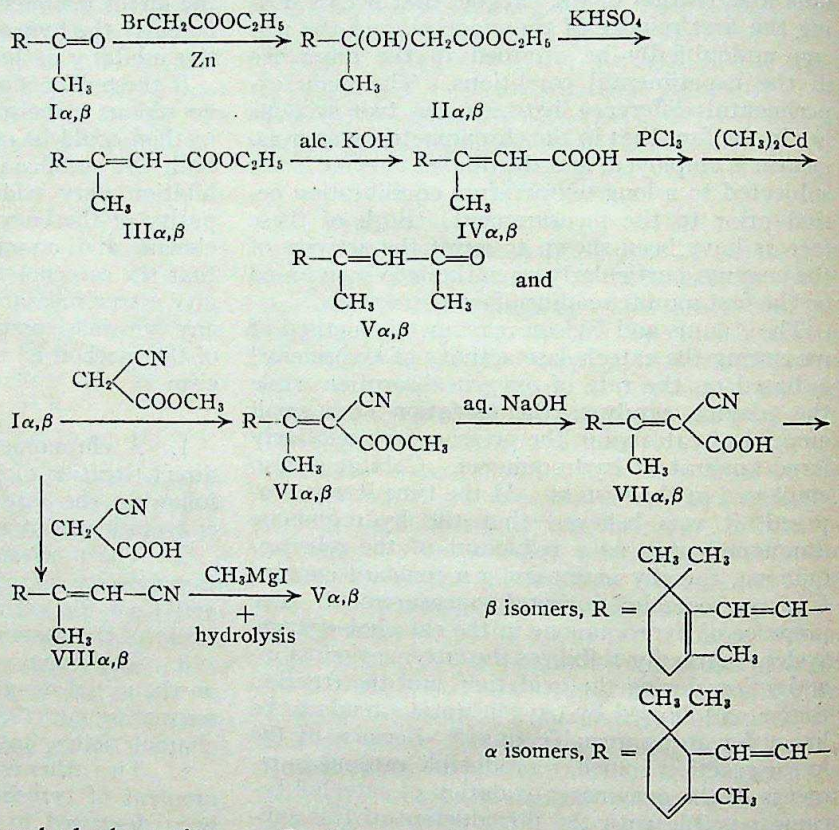
Polyenes. I. The Synthesis and Absorption Spectra of the Ionylideneacetones and Related Compounds[1,2]

BY WILLIAM G. YOUNG, LAWRENCE J. ANDREWS AND STANLEY J. CRISTOL

In a study of synthetic methods for increasing the polyene chain of β-ionone, β-ionylideneacetone has been prepared by two different procedures. Because the absorption maximum of this ketone was found to lie at 285 mμ instead of in the expected range of 300–320 mμ, it seemed possible that during some stage in the preparation of the sixteen carbon ketone the double bond in the β-ionone ring had rearranged to the position which it occupies in α-ionone. Consequently, the preparation of α-ionylideneacetone from α-ionone by the same methods used to prepare the β isomer was undertaken. A comparison of the absorption spectra of α- and β-ionylideneacetone and of the intermediates involved in their syntheses coupled with a critical investigation of the structure of these ketones by hydrogenation, ozonization and hypochlorite oxidation seems to indicate that no isomerization of the ring structure occurred during the synthesis of either sixteen-carbon ketone.

The Preparation of the Ionylideneacetones.—The β-ionone used in these syntheses had absorption maxima at 296 mμ, ε 8600 and 222 mμ, ε 7640; the α-ionone had maxima at 227 mμ, ε 12850 and 296 mu, ε 1950.[3] The reaction paths involved are as follows



Contrary to the report of Karrer and co-workers,[4] the crude product of the Reformatsky

reaction on β-ionone did not dehydrate on distillation. It was always found necessary to heat the hydroxy esters (IIα,β) with potassium bisulfate to obtain the ethyl ionylideneacetates (IIIα,β). The esters were saponified to the corresponding acids (IVα,β). Figure 1 gives the spectra of these esters (IIIα,β). The β compound showed a maximum farther toward the visible than that of the α isomer.[5] Figure 2 gives the spectra of α-ionylideneacetic acid and of liquid and crystalline β-ionylideneacetic acid. The crystalline β acid shows two maxima at 294 mμ, ε 13700 and at 260 mμ, ε 12900 (Karrer[4] reports a flat maximum from 270–310 mμ, ε *ca.* 11200). The cyclocitrylideneacetic acids, prepared for comparison purposes by hypochlorite oxidation of the ionones, show a much larger difference in the positions of their maxima (α isomer, <212.5 mμ, β isomer, 277 mμ) than do the corresponding ionylideneacetic acids.

The ionylideneacetones (Vα,β) were prepared by the action of dimethylcadmium[6] on the acid chlorides of IVα,β.[7] They were also prepared by the reaction of the ionylideneacetonitriles (VIIIα,β) with methylmagnesium iodide.

The transformations of the ionones to the ionylideneacetonitriles were carried out by condensation with cyanoacetic acid[8] using a mixture of ammonium acetate and acetamide as catalysts and removing water formed, by co-distillation with the solvent as the reaction proceeded.[9] The structure of the β-nitrile was proved by conversion of the nitrile to β-ionylideneacetic acid.[4,8] The nitriles

were also prepared by decarboxylation of the ionylidenecyanoacetic acids (VIIα,β) which were obtained by saponification of the methyl esters (VIα,β) produced by condensation of the ionones with methyl cyanoacetate. The spectra of VI, VII, VIII α and β are given in Figs. 3–5. These spectra do not suggest that any of the compounds prepared from β-ionone had isomerized to the α form.

The absorption maxima and extinction coefficients of the polyenes derived from the ionones are given in Table I.

TABLE I

THE ABSORPTION MAXIMA AND EXTINCTION COEFFICIENTS OF THE POLYENES DERIVED FROM THE IONONES

Compound[a]	$\lambda_{max.}$, mμ	$\epsilon_{max.}$[b]
Ethyl β-ionylideneacetate	283	18950
Ethyl α-ionylideneacetate	272, 236	14700, 11800
β-Ionylideneacetic acid (solid)[c]	283	17700
(liquid)	294, 260	13700, 12900
α-Ionylideneacetic acid	267	17650
β-Ionylideneacetone	285	11600
α-Ionylideneacetone	285	14500
Methyl β-ionylidenecyanoacetate	353, 286	12000, 10300
Methyl α-ionylidenecyanoacetate	292.5	16100
β-Ionylidenecyanoacetic acid	332, 275	12500, 8700
α-Ionylidenecyanoacetic acid	286	14300
β-Ionylideneacetonitrile	300, 256	12500, 14500
α-Ionylideneacetonitrile	262.5	18900
β-Cyclocitrylideneacetic acid	277	9240
α-Cyclocitrylideneacetic acid	<212.5	>10100

[a] These compounds were prepared from the commercial ionones. [b] The solvent was 95% ethanol. [c] M. p. 124°.

(5) After this paper was submitted for publication the article of Sobotka, Bloch and Glick, THIS JOURNAL, **65**, 1961 (1943), appeared. These authors found that the barium salt of β-ionylideneacetic acid cleaves to give α-ionone on dry distillation. Their suggestion that the ring double bond isomerization takes place during the Reformatsky reaction on β-ionone does not seem in accord with our findings. There is a much larger difference in the refractive indices of the α- and β-ionylideneacetates prepared in the present work than in those found by Sobotka and co-workers.

The Structure of β-Ionylideneacetone.—The spectra of α- and β-ionylideneacetone are given in Fig. 6. The results obtained for the β isomer were rather surprising in that the position of maximum absorption was at the same wave length as that of the α isomer (though the shapes of the curves were quite different), whereas the increased conjugation of the β isomer would lead to a prediction for the maximum at a higher wave length.[10]

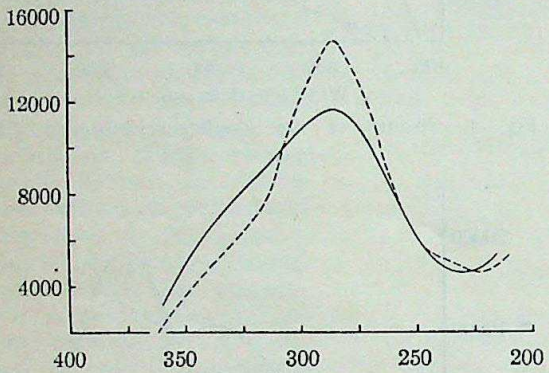

Fig. 6.—Spectra of the ionylideneacetones: – – –, α; ———, β.

The semicarbazone and oxime of the β ketone could not be obtained in crystalline form, although the α isomer formed a crystalline semicarbazone. The presence of the ketone group in the β isomer was shown by reaction with Girard's reagent T[11] and subsequent recovery of the ketone by acid hydrolysis.

On hydrogenation over a platinum oxide catalyst the β ketone, which should have three carbon—carbon double bonds, absorbed 3.06 moles of hydrogen. Under the same conditions, β-ionone absorbed 2.05 moles of hydrogen. Ozonolysis of the ketone according to the method of Karrer and co-workers[12] gave geronic acid (isolated as the semicarbazone) in the same yield as that obtained from β-ionone, indicating that the compound had the β ring structure. No isogeronic acid semicarbazone (arising from an α ring) was isolated, although specific attempts were made to isolate this substance by virtue of its limited solubility in hot ethyl acetate.[12,13] Under the same conditions, ozonolysis of α-ionone or of α-ionylideneacetone gave similar yields of isogeronic acid. Hypochlorite oxidation[14] of β-ionylideneacetone produced a liquid acid which solidified after molecular distillation. This proved to be β-ionylideneacetic acid. These data serve to establish the structure of the β-ionylideneacetone.

(10) This anomalous spectral behavior in a β-ionone derivative has been noted in one other case by Burawoy, *J. Chem. Soc.*, 20 (1941). He compared the spectra of a large number of semicarbazones of unsaturated aldehydes and ketones with those of the parent carbonyl compounds. In general the semicarbazones have absorption maxima farther toward the visible than those of the parent compounds. β-Ionone furnished the sole exception to this rule; it ($\lambda_{max.}$ at 293 mμ) gave a semicarbazone with $\lambda_{max.}$ at 277 mμ.

Experimental Part

Ethyl α- and β-Ionylideneacetates (IIIα,β).—These esters were prepared from 100 g. of ionones by a modification of the method of Karrer[4] for the preparation of the β ester. The petroleum ether–benzene solution of the product from the Reformatsky reaction was distilled from a water-bath to remove the lower boiling solvent. To the residue was added 20 g. of fused and powdered potassium bisulfate after which the removal of the solvent was continued on an oil-bath. Dehydration began when the bath temperature was 150°. After two hours at this temperature the residue was cooled and taken up in ether. The ether solution was washed first with sodium bicarbonate solution then with water and dried over magnesium sulfate. After removal of the ether the ester was distilled under reduced pressure (yield approximately 50%). The properties of the esters were as follows: for ethyl β-ionylideneacetate, b. p. 162.5–164.5° (6 mm.); $n^{20.5}D$ 1.5310. *Anal.* Calcd. for $C_{17}H_{26}O_2$: C, 77.82; H, 9.99; sapon. eq., 262.4. Found: C, 77.42; H, 10.13; sapon. eq., 260.2. For ethyl α-ionylideneacetate, b. p. 162.5° (5–7 mm.), $n^{23.2}D$ 1.5140. *Anal.* Found: C, 77.65; H, 10.31; sapon. eq., 264.8.

In one preparation of ethyl β-ionylideneacetate the dehydration with potassium bisulfate was omitted. Distillation of the crude reaction product gave the hydrated ester (IIβ), b. p. 153.5–155.5° (2–3 mm.); $n^{22.5}D$ 1.4880; sapon. eq. calcd., 280.4; found, 281.5. This material reacted vigorously with acetyl chloride. Dehydration with potassium bisulfate in a manner similar to that previously described gave ethyl β-ionylideneacetate.

α- and β-Ionylideneacetic Acids (IVα,β).—These were prepared from the ionylideneacetates according to the saponification procedure previously described.[4] Forty-five g. of ester produced 37.4 g. of acid (95% yield). The crude acids were purified by low vacuum distillation at 3×10^{-3} mm. (bath temperature 110°). The distilled products were greenish-yellow oils. One small sample of distilled β-ionylideneacetic acid crystallized after standing several days. After the crystalline product was freed from the residual oil using a suction filter, it was recrystallized once from aqueous ethanol and twice from aqueous acetic acid. The white needle-like crystals melted from 122–124° (Karrer and co-workers,[4] 125°). *Neut eq.* of β-ionylideneacetic acid. Calcd. for $C_{15}H_{22}O_2$, 234; found, 241.

The Methyl Ionylidenecyanoacetates (VIα,β).—A mixture of 19.2 g. (0.10 mole) of ionone, 10.0 g. (0.10 mole) of methyl cyanoacetate, 40 ml. of glacial acetic acid, 1.0 g. of acetamide and 1.0 g. of ammonium acetate was heated on an oil-bath at such a rate that the acetic acid solvent and the water formed in the reaction were removed over a period of four hours. The residue was dissolved in ether and the resulting solution was washed with water and dilute aqueous sodium carbonate and dried over magnesium sulfate. The ether was removed and the products were distilled at reduced pressure. Methyl β-ionylidenecyanoacetate was a viscous orange oil boiling at 165–168° (2 mm.), $n^{20}D$ 1.5795 (Wittig and Hartmann[8] give b. p. 171–172° (0.38 mm.)). *Anal.* Calcd. for $C_{17}H_{23}NO_2$: C, 74.69; H, 8.48. Found: C, 74.63; H, 8.64. The α isomer was a viscous yellow oil which boiled at 154.5–157.5° (1.5 mm.), $n^{20}D$ 1.5628. *Anal.* Found: C, 74.57; H, 8.71. The yield of ester was about 50%.

The Ionylidenecyanoacetic Acids (VIIα,β).—Two grams (0.0073 mole) of each ester (VIα,β) was heated on a steam-bath with 18 ml. of 1 *N* sodium hydroxide solution with intermittent shaking until the second phase disappeared. The alkaline solution was extracted with ether and acidified with dilute phosphoric acid. The liberated acid was extracted with ether. After removal of the ether, the β

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

acid crystallized slowly. It was recrystallized from ligroin and benzene giving a yellow solid, m. p. 160–163° with decomposition. *Anal.* Calcd. for $C_{16}H_{21}NO_2$: C, 74.10; H, 8.16. Found: C, 73.87; H, 8.24. Wittig and Hartmann[8] report this acid as an oil. The α acid did not crystallize even after long standing. The recovery of the acids from the esters was about 90%.

The Ionylideneacetonitriles (VIIIα,β).—The nitriles were prepared by the condensation of the ionones with cyanoacetic acid as described above for the reaction of the ionones with methyl cyanoacetate. β-Ionylideneacetonitrile was a yellow oil, b. p. 138–140° (3 mm.), $n^{20}D$ 1.5566. *Anal.* Calcd. for $C_{15}H_{21}N$: C, 83.67; H, 9.83; N, 6.50. Found: C, 82.88; H, 9.97; N, 6.30. The α isomer was a yellow oil, b. p. 147.5–150° (3 mm.), $n^{20}D$ 1.5486. *Anal.* Found: C, 83.14; H, 9.91. The yield of crude nitrile was 69%.

β-Ionylideneacetonitrile was prepared by the decarboxylation of β-ionylidenecyanoacetic acid,[8] and the product was comparable to that prepared directly from cyanoacetic acid and β-ionone.

β-Ionylideneacetic Acid from β-Ionylideneacetonitrile.—β-Ionylideneacetic acid was obtained by hydrolysis of the β nitrile with alcoholic potassium hydroxide according to the directions of Wittig and Hartmann.[8] After three recrystallizations from dilute acetic acid the white solid, m. p. 122–125°, gave no melting point depression with the acid prepared from ethyl β-ionylideneacetate.

The Ionylideneacetones (Vα,β).—The preparation of α-ionylideneacetone was carried out as follows: dimethylcadmium was prepared by the method of Gilman and Nelson[6] by treatment of a solution of 0.20 mole of methylmagnesium iodide in 100 ml. of ether with 18.4 g. (0.10 mole) of anhydrous cadmium chloride. To the well-stirred mixture was added over a one-hour period a solution of 32.3 g. (0.128 mole) of α-ionylideneacetyl chloride[7] in 130 ml. of ether. The reaction mixture was refluxed and stirred on a water-bath for three hours and poured onto a mixture of cracked ice and aqueous ammonium chloride. The ether layer was washed with two 50-ml. portions of water and dried over magnesium sulfate. After removal of the ether the product was distilled under reduced pressure. The main portion (7.0 g.) distilled from 135.5–138° (2.5 mm.), $n^{26.3}D$ 1.5298. *Anal.* Calcd. for $C_{16}H_{24}O$: C, 82.70; H, 10.41. Found: C, 81.05; H, 10.35.

Similarly 1.0 g. of β-ionylideneacetone was prepared from 6.4 g. of β-ionylideneacetic acid. This ketone distilled from 131–132° (2.5 mm.), $n^{18.0}D$ 1.5412. *Anal.* Found: C, 81.86; H, 10.33. Karrer and Morf[7] reported that β-ionylideneacetone prepared by the reaction of β-ionylideneacetyl chloride and methylzinc iodide distills from 105–106° (0.1 mm.), $n^{17.5}D$ 1.5430.

The ionylideneacetones were also prepared as follows: a solution of 35.0 g. (0.16 mole) of β-ionylideneacetonitrile in 40 ml. of ether was added dropwise with stirring to 0.5 mole of methylmagnesium iodide in 200 ml. of ether. Then the solution was heated at gentle reflux for three days and decomposed in the usual manner with aqueous ammonium chloride. The ether layer was washed repeatedly with water, filtered and shaken for several days with 360 ml. of 2 *N* sulfuric acid. It was separated and washed with water and sodium bicarbonate solution and dried over sodium sulfate. After removal of the ether, the product was distilled under reduced pressure. Redistillation gave 9.0 g. of β-ionylideneacetone, b. p. 130.5–133.5° (2 mm.), $n^{20}D$ 1.5452. *Anal.* Calcd. for $C_{16}H_{24}O$: C, 82.70; H, 10.41. Found: C, 82.07; H, 10.58.

Similar experiments with methyllithium gave products with the same properties and with no improvement in yield.

α-Ionylideneacetonitrile and methylmagnesium iodide gave the same yield of α-ionylideneacetone, b. p. 134.5–135° (3 mm.), $n^{20}D$ 1.5433. *Anal.* Found: C, 82.09; H, 10.40.

Attempts were made to prepare a solid semicarbazone or oxime of β-ionylideneacetone, but the products obtained were invariably low melting oils. α-Ionylideneacetone gave a crystalline semicarbazone, m. p. 162.5–164° (after recrystallization from aqueous alcohol). *Anal.* Calcd. for $C_{17}H_{27}N_3O$: C, 70.55; H, 9.40. Found: C, 70.27; H, 9.77. The presence of the carbonyl group in β-ionylideneacetone was demonstrated by reaction with Girard's reagent T according to the procedure of Girard and Sandulesco.[11] The ketone was recovered unchanged from the reagent after hydrolysis with aqueous oxalic acid.[11]

Ozonolysis Experiments.—The ozonolyses were carried out in dilute carbon tetrachloride and glacial acetic acid solution according to Karrer and co-workers.[12,13] The geronic (or isogeronic) acid was recovered as the semicarbazone. One g. of β-ionone gave about 150 mg. of crude geronic acid semicarbazone which, after recrystallization from ethanol, melted at 161.5–163.5° (softened at 151.5°). Karrer[12] gives m. p. 162°. α-Ionone (1.18 g.) gave about 250 mg. of crude isogeronic acid semicarbazone which was insoluble in hot ethyl acetate and which upon recrystallization from alcohol melted at 191–195° (with decomposition). Strain[15] reports m. p. 193–195° for isogeronic acid semicarbazone. One gram of β-ionylideneacetone gave about 200 mg. of crude geronic acid semicarbazone, soluble in ethyl acetate. After recrystallization from ethanol it melted at 161.5–163° (softened at 150°). A mixed melting point with the product from β-ionone showed no depression. α-Ionylideneacetone (1.06 g.) gave 93 mg. of isogeronic acid semicarbazone. After extraction with hot ethyl acetate and recrystallization from ethanol, it melted at 191–194°. A mixed melting point with the product from α-ionone showed no depression.

Hypochlorite Oxidation of β-Ionylideneacetone.—A solution of sodium hypochlorite was prepared by the method of Bogert and Davidson.[14] To a sample of 1.5 g. (0.0065 mole) of β-ionylideneacetone was added slowly 7.8 ml. (0.0195 mole) of the freshly prepared sodium hypochlorite reagent. The ketone was cooled in an ice-bath and shaken during the addition which took twenty minutes. Ten ml. of methanol was added. The odor of chloroform was noted. After the reaction mixture had stood for one hour in the ice-bath and one hour at room temperature, the solvents were removed at reduced pressure. Dilute phosphoric acid was added to acidify the residue, and the oil was extracted with 40 ml. of ether. The acid was extracted from the ether solution with two 20-ml. portions of 5% aqueous sodium hydroxide solution. The residue in the ether solution was recovered. It had an absorption spectrum and refractive index similar to those of the original ketone. The basic extract was acidified with dilute phosphoric acid, and the liberated acid was extracted with two 10-ml. portions of ether. Removal of the ether under reduced pressure left 0.9 g. of crude tan-colored acid. A portion of this acid was submitted to molecular distillation. The fraction distilling at an air-bath temperature of 140° (2.5×10^{-3} mm.) was an extremely viscous oil which crystallized slowly. Two recrystallizations from aqueous acetic acid gave a white solid, m. p. 122–124°. A mixed melting point with a sample of β-ionylideneacetic acid prepared from β-ionylideneacetonitrile showed no depression.

Quantitative Hydrogenation of β-Ionone and β-Ionylideneacetone.—Quantitative hydrogenations of approximately 0.25-g. samples of β-ionone and of β-ionylideneacetone were carried out using 60 ml. of ethanol and 0.1 g. of platinum oxide.[16] The hydrogenations went nearly to completion within an hour but were usually allowed to run for several hours to insure complete reduction of the olefin bonds.

α- and β-Cyclocitrylideneacetic Acids.—These were prepared by hypochlorite oxidation of the ionones by a procedure similar to that described for the oxidation of β-ionylideneacetone. The crude acid from 2.0 g. of β-ionone was a yellow solid weighing 1.53 g. It was obtained as white needle-like crystals after one recrystallization from aqueous ethanol and two recrystallizations from aqueous acetic acid. The properties of β-cyclocitrylideneacetic acid were as follows: m. p. 106–108°; *Anal.* Calcd. for $C_{12}H_{18}O_2$: C, 74.20; H, 9.34; neut. eq., 194. Found: C, 73.83; H, 9.39; neut. eq., 192. On quantitative hydrogenation

over Adams catalyst the acid absorbed 1.96 moles of hydrogen (theoretical value 2.00 moles).

From 4.0 g. of α-ionone was obtained 0.34 g. of a yellow oily acid which would not solidify. No investigation of its physical properties other than its absorption spectrum was made. Considerable unreacted α-ionone (2.57 g.) was recovered in this experiment.

Absorption Spectrum Measurements.—Determinations of the ultraviolet absorption spectra of the polyenes were made on the Beckman Spectrophotometer.

The authors are indebted to Dr. R. O. Clinton and to Mr. J. W. Ralls for the combustion analyses reported in this paper.

Summary

The α- and β-ionylideneacetones have been prepared from both the ethyl ionylideneacetates and the ionylideneacetonitriles, each of which may be prepared conveniently from the ionones. β-Ionylideneacetone shows an absorption maximum farther toward the ultraviolet than might be expected. A study of the spectra of all the intermediates in the preparation of the ionylideneacetones has been made. The structures of the ionylideneacetones have been established by the application of quantitative hydrogenation, ozonization and hypochlorite oxidation procedures.

Generalized Acid-Base Catalysis. I. Condensation of *o*-Benzoylbenzoic Acid in Sulfuric Acid

By W. F. Luder and Saverio Zuffanti

Many of the catalytic effects observed in organic reactions can be explained readily as instances of simple acid-base catalysis if one adopts the conception of acids and bases proposed by G. N. Lewis.[1,2,3] One example is the condensation of *o*-benzoylbenzoic acid to anthraquinone, which has been studied by several authors[4,5,6] without arriving at a completely satisfactory explanation of the effects observed.

Deane and Huffman[6] have extended rate measurements of the *o*-benzoylbenzoic acid condensation into oleum of concentrations up to 29% SO_3 at 75 and 85°. They found that the velocity constant increased steadily up to their maximum sulfur trioxide percentage. In some work under way in this Laboratory on the acidity curve of oleum (to be reported in a later paper of this series), our preliminary measurements indicate the same steady increase at 40° up to 65% SO_3, the maximum concentration so far investigated.

This increase in reaction rate with increased concentration of sulfur trioxide in sulfuric acid is readily understood when considered from the Lewis viewpoint. It is merely due to increased over-all acidity. Sulfur trioxide is a stronger acid than sulfuric acid. Lewis and Bigeleisen[7] have shown that the acidity of sulfuric acid solutions increases with concentration of sulfur trioxide. Close correlation is evident in comparing the Lewis and Bigeleisen plot of Hammett's acidity function[8] with the plot of variation in reaction rate with concentration of sulfur trioxide given by Deane and Huffman.[6] This would indicate that the condensation of *o*-benzoylbenzoic acid is an acid-catalyzed reaction, and that the reaction rate does not depend upon a particular species, but rather upon the acid strength. Probably SO_3, H_2SO_4, and H_3O^{+1} are the three principal species involved, but the question of the exact proportion is unimportant since the over-all acidity can be measured experimentally. Of course it is obvious that in 65% oleum the ratio of SO_3 to H_3O^{+1} is very great.

According to this viewpoint the inhibiting effect of the product anthraquinone and of other substances can readily be explained. Anthraquinone is weakly basic. The oxygen atoms each can donate a share in a pair of electrons to a sufficiently strong acid. The presence of the anthraquinone in such a highly acidic medium simply decreases its acidity and therefore its effectiveness as a catalyst. A similar explanation applies to the other inhibitors tested by Deane and Huffman. This is especially interesting since several of these substances such as $AlCl_3$, HCl, and $CuCl_2$ are typical generalized acid catalysts. Even these acids, strong enough to catalyze Friedel–Crafts and similar reactions, are forced to behave as weak bases by the stronger mixture of sulfur trioxide and sulfuric acid.[3]

In view of this very great acidity of fuming sulfuric acid,[7] the statement of Deane and Huffman[6] that, "The effect of definite added amounts of concentrated hydrofluoric acid will more fully indicate the status of this reaction as a case of acid-base catalysis," is not likely to be upheld. They themselves had already tried a stronger acid than HF[3], namely, $AlCl_3$, and found that it did

not increase the reaction rate in fuming sulfuric acid, but actually decreased it.

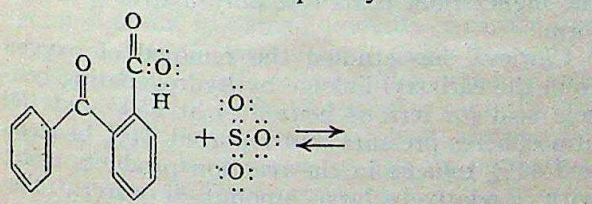
Newman[5] has postulated the formation of the cyclic carbonium ion  as the first step in the condensation. This suggestion is based on the formation of a quantity of pseudo-ester when methyl alcohol was present. The cyclic ion is considered as formed by the reaction of sulfuric acid on the *o*-benzoylbenzoic acid with H_3O^{+1} and $2HSO_4^{-1}$ as the other products. This explanation conforms to the Brönsted theory of acids and bases, but obviously the Brönsted theory cannot explain the large increase in velocity constant as the amount of sulfur trioxide is increased. On the other hand, the observed behavior is exactly what is expected on the basis of the electronic theory of acids and bases. Sulfur trioxide is a much stronger acid[7] (*i. e.*, has a greater tendency to appropriate lone electron-pairs) than H_2SO_4 or H_3O^{+1}.

However, this does not mean that the hypothesis of a cyclic ion is incorrect. The cyclic ion could be formed just as well by sulfur trioxide as by sulfuric acid

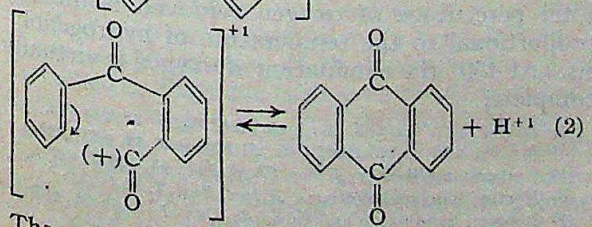
o-Benzoylbenzoic acid + $SO_3 \rightleftharpoons$ (cyclic ion)$^{+1}$ + HSO_4^{-1}

So whether the cyclic ion or some other explanation is adopted, the ability of the Lewis theory to explain the observed catalytic effects is not affected.

An alternative mechanism which we prefer for reasons discussed subsequently is as follows



(1)



(2)

The use of H_2SO_4, H_3O^{+1}, or any other acid species present, in place of the sulfur trioxide in the above equations would serve equally as well since according to the Lewis theory acids coördinate with lone electron-pairs. In equation (1) the sulfur trioxide behaves as a typical acid[2] by coördinating with the oxygen electron-pair to split off the OH^{-1} group thus leaving the carbon atom electron-deficient. This makes the carbon atom acidic since it now has a great tendency to appropriate a lone electron-pair to complete its octet again. The two possibilities are: the formation of the cyclic ion and the formation of anthraquinone according to equation (2) above. Both reactions undoubtedly take place since Newman seems to have demonstrated conclusively the existence of a large proportion of the cyclic ion at low temperatures. But since the reaction under discussion is the formation of anthraquinone, it seems unnecessary to involve the cyclic ion. We prefer to regard its formation as a side reaction to, rather than the first step in, the production of anthraquinone.

The reasons for this preference are: (1) it fits the experimental facts equally as well as Newman's explanation; (2) it is simpler and more direct; (3) it is in accord with the newer explanation of the mechanism of acylations[3,9]; (4) when the structural formulas of all three species are considered there seems to be no way of getting a cyclic ion from *o*-benzoylbenzoic acid except through the open-chain ion as an intermediate step.

However, whichever choice of mechanism is made, the interpretation of the experimental data by means of the electronic theory of acids and bases is still applicable. Both mechanisms involve a cyclic ion and both can be catalyzed by SO_3 as well as by H_2SO_4 or H_3O^{+1}. Both agree that the immediate percursor of anthraquinone is the open-chain ion.

Gleason and Dougherty[4] showed that the condensation is actually first order and not merely an apparent first order reaction because of an excess of sulfuric acid. No explanation of this has been offered nor of the rapid and large evolution of heat observed when oleum is added to the *o*-benzoylbenzoic acid. We have observed that this rapid evolution of heat on mixing is many times greater at high sulfur trioxide concentrations, corresponding roughly to the much greater velocity constant. A logical explanation of these two facts in keeping with the other aspects of the Lewis interpretation is that the carbonium ion is formed rapidly according to equation (1) upon mixing. The rate-determining step would then be equation (2), which is obviously first order. The difference in rate with increasing amounts of SO_3 is due to the shifting of the equilibrium in equation (1) so that the initial concentration of carbonium ion is greater as the acidity of the solution is increased.

Summary

An explanation of some effects in the catalyzed condensation of *o*-benzoylbenzoic acid to anthra-

quinone is given according to the electronic theory of acids and bases.

An alternative mechanism is proposed, but it is shown that the application of the Lewis theory is equally valid for both mechanisms considered.

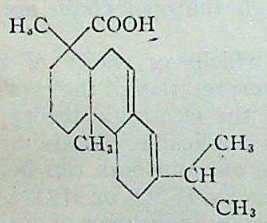
The Hydrogenolysis of Abietic Acid[1]

BY H. B. CHARMBURY AND C. C. WRIGHT

Although many investigations on the hydrogenolysis of coal are reported in the literature, interpretation of the results has been hindered because of the lack of information concerning the mechanism of the reaction. One method of attack upon this problem has been through hydrogenolysis of pure organic compounds, several of which, such as benzene, indene, naphthalene, naphthols, phenol, cresols and carboxylic acids[2] have already been studied. The complexity of the compounds has been gradually increased with the ultimate goal of hydrogenating polynuclear structures as closely related to the so-called "coal molecule" as possible. The present work is concerned with the hydrogenolysis of abietic acid, I,



I

the structure of which is such that information may be secured concerning oxygen removal from the carboxyl group, alkyl severance of the two different alkyl groups, alicyclic decomposition due to the breakdown of the hydrophenanthrene structure and hydrogen consumption due to saturation of the double bonds and to hydrogenation cracking reactions.

Hydrogenolyses were conducted for two hours at temperatures ranging from 325 to 450°, with initial hydrogen pressures of 1900 to 1975 P. s. i. (133.6–138.9 kg./sq. cm.). Because the results of these experiments indicated that 400° is the critical temperature for oxygen removal, alkyl severance and hydrogen consumption, experiments were also conducted at this temperature, using the same initial hydrogen pressure, for 1, 2 and 3 one-hour periods. The reaction gases were removed and the retort charged with fresh hydrogen at the end of each one-hour period.

(1) From the thesis of H. B. Charmbury presented to the faculty of The Pennsylvania State College in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

(2) The hydrogenolysis of these compounds has been studied by the British Fuel Research Board and their results will be found in the Board reports from 1931 to 1938 inclusive.

Oxygen Removal.—Using temperatures and pressures in the range of 300–500° and 1000–3000 P. s. i. several investigators[3,4,5,6] have shown that much of the oxygen present in coal is removed rapidly and in the early stages of hydrogenation and that the remaining oxygen is removed at a slow but rather constant rate. Boomer[7] has suggested a theory that coals contain at least two types of oxygen: oxygen as carboxyl which is removed rapidly, and oxygen as hydroxyl which is more resistant. Fisher[8] also supports this theory and shows that using a Pittsburgh coal 60% of the oxygen is eliminated much more rapidly than the remaining 40% and that most of the oxygen which is removed in the early stages appears in the products as water. Storch[9] has studied the oxygen removal of the anthraxylon fraction of various coals and found that the oxygen is removed as carbon dioxide and water in the early stages and that the oxygen removal increases with decreasing rank of the coal. An extended study by Storch[10] revealed that upon hydrogenation the low rank coals high in oxygen lose 10–20% of their oxygen as carbon dioxide whereas the higher rank coals lose only 3 to 6% in this form.

Cawley[11] has studied the removal of oxygen from the carboxyl linkage by hydrogenating benzoic acid (or ferrous benzoate) at 450° and 100 atmospheres pressure and reported 24% benzene and 41% toluene in the reaction products along with a relatively large amount of water. The presence of toluene and water indicates a removal of oxygen by a reduction of the carboxyl group.

The data of Fig. 1 show, however, that the removal of oxygen from abietic acid takes place for the most part as a straight decarboxylation with the formation of carbon dioxide, and that the total percentage of oxygen removed is directly proportional to the temperature of hydrogenolysis. At 450° the elimination of oxygen is virtually complete.

The data of Table I for intermittent operation substantiate the results obtained for two hour hydrogenolyses with respect to the formation of carbon dioxide and indicate relatively rapid oxygen removal as carbon dioxide. This supports Boomer's[7] interpretation of coal hydrogenation data.

TABLE I

REMOVAL OF OXYGEN AS CARBON DIOXIDE, CARBON MONOXIDE AND WATER FOR INTERMITTENT HYDROGENOLYSES

	% Oxygen removed as				
During	CO_2	CO	$CO_2 + CO$	H_2O	$CO_2 + CO + H_2O$
1st hr.	61.1	12.0	73.1	5.8	78.9
2nd hr.	0.0	3.0	3.0	4.9	7.9
3rd hr.	.0	0.0[a]	0.0[a]	0.3[a]	0.3[a]

[a] These values are corrected for the amount of CO and H_2O formed as a result of the decomposition of 0.22 g. of CO_2 present as impurities in the original hydrogen gas, assuming the decomposition takes place as $CO_2 + H_2 \rightarrow CO + H_2O$.

The carbon monoxide obtained in both the continuous and intermittent hydrogenolyses may result from the partial reduction of the carboxyl group to form the aldehyde followed by its decomposition, or from the reduction of carbon dioxide. Since the presence of aldehydes and alcohols was not detected in the reaction products and since the amount of carbon dioxide decreases above 400° with an increase in the amount of carbon monoxide, it appears that the carbon monoxide results from the reduction of the carbon dioxide. This is further substantiated by the fact that during the third hour of intermittent operation not all of the carbon dioxide present as an impurity in the original hydrogen gas could be accounted for, but small amounts of carbon monoxide and water were found. This can only be explained by a reduction of the carbon dioxide at this temperature and pressure to form the other gases. Such a reduction has been suggested by Storch[12] to take place in the gaseous products resulting from coal hydrogenation.

The water formation may result from the reduction of the oxides of carbon, from the reduction of the carboxyl group, or as LaLande[13] suggests from the pyrolysis of abietic acid by the formation of the anhydride.

It is believed that the same type of reduction of the carboxyl linkage does not occur with abietic acid as Cawley[11] observed with benzoic acid because of the presence of the stable methyl group attached to the same carbon as the carboxyl and/or because of the fact that the carboxyl group is attached to a tertiary alicylic carbon atom and not an aromatic structure. The present work as well as that of Cawley[11] substantiates Boomer's theory[7] in regard to carboxyl oxygen removal and both may be used to explain Storch's[10] results, since it

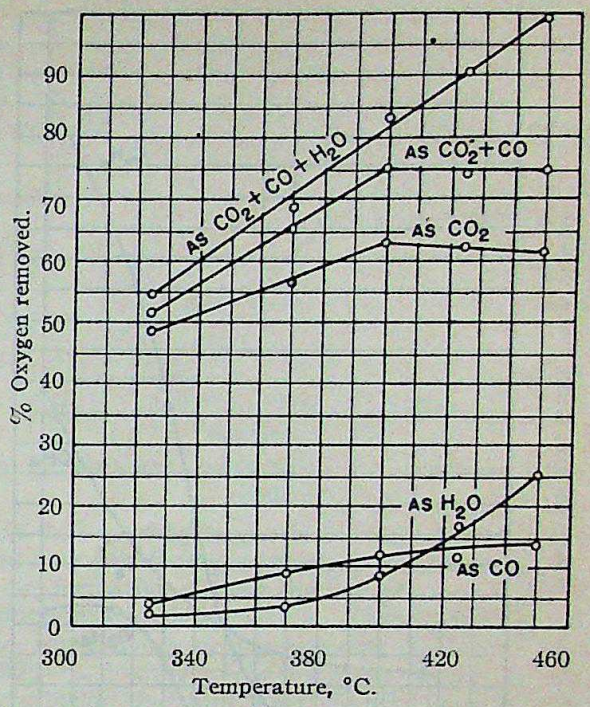

Fig. 1.—Oxygen removal for two-hour hydrogenolyses.

is generally known[14] that the aromaticity of coals increases with increasing rank.

Alkyl Severance.—The British Fuel Research Board[15] has carried out the destructive hydrogenation of such compounds as 1- and 2-methyl- and 2,6-dimethylnaphthalene and found that the methyl groups are stable up to rather high temperatures. For example, at 450° these compounds are only demethylated to the extent of about 3%, but at 500° almost complete demethylation takes place. The 2,6-dimethyl compound is demethylated in stages yielding methylnaphthalene as an intermediate product.

At the present time, the authors do not know of any literature concerning the higher hydrocarbon gases which are obtained as a result of coal hydrogenation because all the data presented in the technical literature are in terms of Orsat analyses and thus the saturated gases are reported only as methane and ethane.

Some idea concerning the amount of alkyl severance which occurs during the hydrogenolysis of abietic acid may be obtained by examining Fig. 2. This figure shows the grams of methane, ethane and propane formed from 100 g. of the acid as a function of the hydrogenolysis temperature. From the amount of propane formed it may be seen that depropylation does not occur to any appreciable extent up to a temperature of about 380°, but that above this temperature it increases rather rapidly. The theoretical yield of propane from 100 g. of abietic acid by the removal of the isopropyl group alone is 14.6 g. and if the ethane

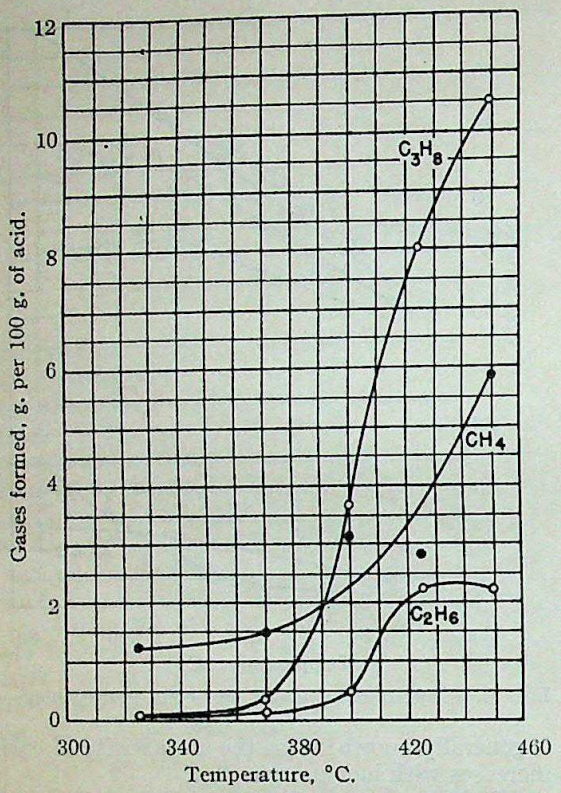

Fig. 2.—Alkyl severance for two-hour hydrogenolyses.

present is considered as resulting from the cracking of propane the total amount formed at 450° is 13.6 g.

The amount of propane formed on one hour of hydrogenolysis was only 0.98 g. as compared with 3.12 g. for two hours of continuous operation. During the second and third hours of operation only 0.53 g. and 0.37 g. were formed. Thus, after three hours of intermittent operation the total amount of propane was only 1.88 g. These data indicate that the amount of depropylation is a function of hydrogen concentration or partial pressure. Although the exact partial pressure of hydrogen cannot be calculated because of the unknown vapor pressure of the various liquid products at reaction conditions, it is, nevertheless, possible to obtain a general idea of the relative values by considering the concentration of hydrogen in the non-condensable gases at the completion of the reaction. These values are respectively 90.39% after two hours continuous operation and 92.59, 97.25 and 97.53% after the first, second and third hour of intermittent operation.

Further evidence of depropylation may be found in the liquid products resulting from the second and third hours of hydrogenolyses. Although these products were not definitely identified, the ultimate analyses definitely indicate a removal of the isopropyl group. Table IV lists the ultimate analyses of these compounds and the possibilities are 1,12-dimethyl- and 1-methyldodecahydrophenanthrene.

Because no ethane was detected in the gaseous products from the intermittent operations as compared to 0.47 g. from the two hour continuous hydrogenolysis, the experiments establish definitely that the ethane results from the cracking of propane during the second hour of continuous treatment. This again can be attributed to the lower partial pressure of hydrogen.

The mechanism of methane formation is more complex for it may result from demethylation, from the reduction of carbon monoxide, from the cracking of higher hydrocarbon gases and from alicyclic decomposition. The relatively large amount of methane at the low temperatures appears to be due to demethylation, probably of the methyl group in the number 12 position since all of the dehydrogenation experiments[16,17,18] show this group to be far less stable than the group in the number 1 position. This may occur as a straight dealkylation or as the severance of the methyl group with an adjacent hydrogen. At the higher temperatures methane is believed to result from all four possible methods.

The hydrogenolysis of the abietic acid for one, two and three hours resulted in the formation of approximately 2 g. of methane during the first hour, 1 g. during the second and 1 g. during the third. This compares with 3.69 g. for two hours of continuous operation and indicates that the methane formation is a function of time as well as hydrogen concentration. It is believed that at 400° for different lengths of time practically all the methane formation results from demethylation since there is very little evidence of alicyclic decomposition and only a small amount of carbon monoxide available for reduction.

Alicyclic Decomposition.—The present data concerning alicyclic decomposition are rather limited due to the fact that none of the hydronaphthalenes or the two-ring intermediate compounds have been definitely identified even though data are available on the three-ring structures, as well as on the final single-ring products of this type of decomposition. At 370° there is evidence of hydrogen addition either as a saturation of one of the two double bonds or as a 1,4 addition to the conjugated system. At the higher temperatures, however, dehydrogenation takes place as indicated by the presence of two and three double bonds in the liquid products. Since this type of dehydrogenation occurs, there is less tendency for alicyclic decomposition.

From the two hour hydrogenolyses the amounts of the two-ring intermediate products have been estimated in terms of the total products from the distillation curves to be about 3, 17, 20 and 25% at temperatures of 370, 400, 425 and 450°, respectively, and 10, 2 and 1% during the first, second

and third hour of intermittent hydrogenolysis. Thus, even after three hours, the amount was appreciably less than that obtained for two hours of continuous operation. These data indicate that at 400° the extent of alicyclic decomposition is a function of the hydrogen concentration and emphasizes the fact that very misleading conclusions may be obtained from coal hydrogenolysis experiments when the hydrogen concentration is not considered in interpreting the results.

The specific dispersion, refractive index and boiling point data show that these intermediate compounds are related to the alkyl hydronaphthalenes although no particular compound has been definitely identified. This would indicate splitting of one of the three rings with the formation of a hydronaphthalene ring structure and an alkyl side chain. Biggs[19] has shown that the oils resulting from the hydrogenation of Pittsburgh coal are chiefly polyhydroaromatic hydrocarbons and LeClaire[20] has found the same results for other coals. LeClaire's data indicate that the distillation fractions of such oils have refractive indices ranging from 1.4823 to 1.5710, densities ranging from 0.888 to 1.038, and specific dispersions ranging from 97.9 to 174.4.

The final products of alicyclic decomposition did not amount to more than approximately 10% of the total products even at the highest temperature of hydrogenolysis. However, the physical properties of some of the fractions of the products indicated that the following compounds were present: *trans*-1,2-dimethylcyclohexane, methylcyclohexane, 1,3-dimethylcyclopentane, ethylcyclohexane and 3,5-dimethylcyclohexene-1. Since there were no five-numbered rings in the original material, the presence of 1,3-dimethylcyclopentane indicates that isomerization must have taken place. Such an isomerization was described by independent workers[21,22] who hydrogenated benzene and cyclohexane under similar conditions and identified methylcyclopentane in the products. The presence of methyl and ethyl cyclohexane indicate agreement with the theory of Hall[23] concerning the alicyclic decomposition of hydronaphthalene.

Hydrogen Consumption.—Figure 3 shows the grams of hydrogen consumed as a function of hydrogenolysis temperature. The rather low hydrogen consumption at the lower temperatures is due principally to the saturation of one of the double bonds, to demethylation and to depropylation. The higher consumption of hydrogen at the higher temperatures is due to the alkyl and alicyclic decomposition and also to the reduction of the oxides of carbon.

The intermittent hydrogenolyses show that

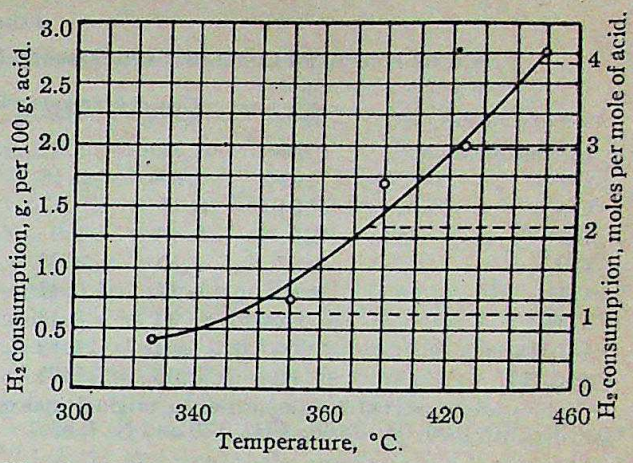

Fig. 3.—Hydrogen consumption for two-hour hydrogenolyses.

only 0.48 g. of hydrogen is consumed during the first hour and 0.44 g. of this can be accounted for in the formation of methane and propane and the reduction of carbon dioxide. During the second and third hours of intermittent operation virtually no hydrogen consumption occurred. In fact, during the third hour, slightly more hydrogen was recovered than was available at the beginning of the third hour of treatment. These data compare with a hydrogen consumption of 1.67 g. during the two-hour continuous hydrogenolysis at the same temperature. Despite the relatively low consumption of hydrogen the carbon and hydrogen analyses of the products isolated indicate that one of the two possible ethylenic linkages had been saturated and thus show the probable dehydrogenation of some of the unidentified products.

The foregoing data may be interpreted as evidence that hydrogen consumption under the conditions investigated is primarily due to cracking reactions and that little, if any, hydrogen is consumed in the saturation of ethylenic linkages. Storch,[9,10,24,25] on the other hand, has shown that after the first hour the hydrogen consumption upon hydrogenolysis of a Pittsburgh seam coal at 1000 p. s. i. and 400° is a straight line function of the reaction time up to fifteen hours of treatment, and that the straight line relationship is likewise true, irrespective of the rank or oxygen content of the coals studied. From 20 to 25% of the hydrogen consumed in this manner may have been utilized in the removal of non-carboxyl oxygen according to data for oxygen removal, but the marked difference between the results for coal and abietic acid requires further explanation. In part, the difference may be due to the more aromatic structure and greater ease of saturation of ethylenic linkages in coal, because of the presence of the hydrogen carrier, tetralin, and the 1% stannous sulfide, or as has been shown in previous sections

of the paper due to cracking reactions which appear to be favored at lower partial pressure of hydrogen.

Experimental

Procedure and Apparatus.—The acid used in the experiments was obtained by recrystallization of commercial abietic acid using LaLande's[13] modification of Steele's[26] method. At least three recrystallizations were used for each batch of crystals after which they were dried at reduced pressure over anhydrous calcium chloride at 65° for a period of three hours, weighed and placed immediately into the hydrogenation retort under an atmosphere of hydrogen. The melting point of the acid was 158° and did not vary more than ±1° for the various batches. The analyses of the various batches of acid varied within 0.1% of the theoretical values for C and H.

The hydrogenations were conducted in an alloy steel rotary type retort previously described.[27] One hundred grams of the recrystallized acid was placed in the retort together with the alloy steel stirrer, the retort flushed several times with hydrogen, and hydrogen introduced to a pressure of 1900 to 1975 p. s. i. (133.6–138.9 kg./sq. cm.). After checking the retort for leaks, it was placed in the hot furnace and heated to the reaction temperature in eighty to one hundred and thirty minutes, depending upon the temperature desired. Hydrogenolyses were conducted for one hundred and twenty minutes at 325, 370, 400, 425 and 450° and also at 400° for one, two and three sixty-minute periods with the reaction gases being removed and the retort charged with fresh hydrogen after each hour. After each of the reaction periods the retort was cooled rapidly to 150° and the gaseous products removed at this temperature.

The reaction gases were passed through a series of traps to separate and isolate the various components. The first trap was immersed in ice water, the second in a dry ice–acetone mixture, the third trap was a tube packed with ascarite and anhydrone, and the fourth trap was immersed in liquid air. The non-condensable gases then passed through a sampling bottle and a Sargent wet test meter.

The non-condensable gases were analyzed using the U. S. Steel Chemist Procedure with a Burrell Delux Model H apparatus. The gaseous products trapped in liquid air were identified by their boiling points as determined on a low temperature Podbielniak fractional distillation apparatus, Standard Precision Model J. The higher boiling gases collected in the first two traps as well as the Podbielniak residue were separated using a Penn State semi-micro distillation column and where a sufficient quantity of any one component was available it was identified by its physical constants.

After removal of the gaseous products the retort was cooled to room temperature and the remaining products removed by solution in ether and separated into basic, acidic and neutral fractions by extraction with 5% hydrochloric acid and 5% sodium hydroxide. The neutral fractions were separated by distillation at reduced pressure, and where a sufficient quantity of any one fraction was available it was purified by semi-micro distillation at reduced pressure and the probable structure determined by interpretation of the physical constants according to Thorpe and Larson,[28] and the quantitative elementary analysis.

Experimental Results.—The results for the hydrogen consumed and the gaseous products formed are listed in Table II.

The residues from the Podbielniak distillations of products resulting from the two-hour hydrogenolyses at 400, 425 and 450° were of sufficient amounts to warrant further investigation. Each individual residue was separated by semi-micro distillation. The refractive index, $n^{20}D$, of the various fractions from the 400° hydrogenolysis varied from 1.3980 to 1.4492. From this distillation there was about 0.5 g. which had a n of 1.4275, a boiling point of 119° at 732 mm., and a density of 0.773 at 20°/4°. These values agree with those for *trans*-1,2-dimethylcyclohexane.[29] The residue from the hydrogenolysis at 425° had a n ranging from 1.3691 to 1.4155 and a boiling point ranging from 40 to 92° but did not yield enough of any one fraction to be identified. The n range of the distilled residue from the hydrogenolysis at 450° varied from 1.3690 to 1.4426, the main portion of which had a n of 1.4240, a boiling point at 732 mm. of 97°, and a density at 20°/4° of 0.768. These values agree with those of Egloff[30] for methylcyclohexane.

The weight of condensable material obtained in traps 1 and 2 from the two-hour hydrogenolyses at 325, 370 and 400° was not sufficient to warrant further investigation. However, in each case there was obtained two immiscible layers in trap 1, the bottom layer of which was identified as

TABLE III

LIQUID PRODUCTS OF HYDROGENOLYSIS G./100 G. ABIETIC ACID

	Time of hydrogenolysis 2 hours					Temperature of hydrogenolysis, 400°		
	325°	370°	400°	425°	450°	During 1st hr.	During 2nd hr.	During 3rd hr.
Ether insoluble	5.1	None	None	None	None	None	None	None
Extract by acid	3.2	1.1	0.1	0.4	Trace	0.3	Trace	Trace
by alkali	17.5	14.1	2.7	1.6	0.8	3.4	0.8	0.8
Neutral material	62.8	67.6	68.9	59.4	47.7	80.4	76.6	75.3

water. The top layer, as well as the material in trap 2, could be identified only as a hydrocarbon. There was also obtained in trap 1 in each case a very small amount of red brown solid material which was identified as iron oxide. This resulted from the decomposition of an iron salt of abietic acid which will be described later.

After removal of the water layer the combined condensable material obtained in traps 1 and 2 from the two hour hydrogenolyses at 425 and 450° was dried and fractionated by semi-micro distillation. The n of the various fractions from the hydrogenolysis at 425° ranged from 1.4113 to 1.4520. Of these fractions it was possible to identify two different constituents. The first had a n of 1.4113, a boiling point of 90 to 91° at 729 mm. and a density at 20°/4° of 0.743. These values agree with those presented by Evans[31] for 1,3-dimethylcyclopentane. The second constituent had a n of 1.4356, a boiling point of 128° at 731 mm. and a density of 20°/4° of 0.783. These values agree with those of Levina[32] for ethylcyclohexane. The n of the fractions from hydrogenolysis at 450° ranged from 1.4110 to 1.4630. The main portion had a boiling point of 128° at 732 mm., a density at 20°/4° of 0.792 and a n of 1.4430. These values agree with those presented by Knoevenagel[33] for 3,5-dimethylcyclohexene-1.

The products obtained in traps 1 and 2 minus the water, from any one run of the intermittent hydrogenolyses were insufficient for further investigation. They were all combined, however, and distilled using the semi-micro column. The refractive indices and distillation temperatures of the various fractions ranged from 1.3781 to 1.4490 and from 38 to 124°, but there was not enough of any one fraction to be definitely identified.

The results of separating the products remaining in the retort into acid soluble, alkali soluble and neutral fractions are shown in Table III.

Examination of the products of hydrogenolysis at 325° which remained in the retort after the gaseous products had been removed, showed one which appeared to be ether insoluble but which upon closer examination was found to be very slightly soluble in ether. It was a light gray amorphous solid with a characteristic odor and a decomposition range of 230 to 232°. On ignition it decomposed into a black solid which burst into a bright flame and left a dark red residue. The amorphous solid was identified as an iron salt of abietic acid by tests with KCNS and $K_4Fe(CN)_6$ and by mixed melting point determinations on the recrystallized alkali soluble portion of the compound with freshly prepared abietic acid.

When the acid extracted material shown in Table III was made alkaline with 5% sodium hydroxide, ferric hydroxide precipitated. This indicated the presence of an iron salt of abietic acid in the ether soluble fraction.

The alkali extracts were acidified with 5% hydrochloric acid and extracted with ether. The ether solutions were dried over anhydrous sodium sulfate and stripped of ether over a steam-bath. On standing overnight a white crystalline material separated from the liquid fractions obtained from the hydrogenolyses at the three lowest temperatures. These crystals, representing approximately 90% of the total amount present, were identified by mixed melting points as unreacted abietic acid. The identity of the remaining liquid acidic material was not definitely established but it had a n of 1.524 and an ultimate analysis of 80.65 to 80.76% C, 10.53 to 10.80% H, and 8.55 to 8.71% O. These liquid acids also gave a negative test for unsaturation which indicated that they may be the tetrahydroabietic acid about which the existing literature is rather confusing.

Distillation of the neutral products from the hydrogenolysis at 325° under reduced pressure yielded water as a distillate and left a wax-like residue. A portion of this residue was soluble in hot acetone and crystallized from the acetone upon cooling. The crystals were separated by filtration but upon exposure to air they turned into a wet amorphous mass. Filtration of the crystals in a desiccator over phosphoric anhydride was successful, but in attempting to determine the melting point the same type of transformation again occurred. The residue from the acetone extraction was identified as a sodium salt of abietic acid.

The neutral products from each hydrogenolysis were distilled under reduced pressure and in each case, small fractions collected and their refractive indices measured at 15°. Where various fractions showed the same refractive index they were combined and redistilled using the semi-micro column. On redistillation only the middle 60% of the fraction was used for obtaining the physical constants. Table IV shows the probable products from the hydrogenolyses based on their elementary analyses, and specific dispersions. Since, to

the authors' knowledge, the physical constants of these products are not presented in the technical literature no comparison could be made.

Summary

The hydrogenolysis of abietic acid for two hours at temperatures ranging from 325 to 450° and initial hydrogen pressure of 1900 to 1975 P. s. i. and also at 400° for one, two and three hours at the same pressure has shown that:

1. The amount of unconverted acidic material is quite appreciable at 325° but decreases to practically zero as the temperature is increased to 450°.
2. The removal of oxygen takes place, for the most part, as a straight decarboxylation with the formation of carbon dioxide in the early stages of hydrogenolysis.
3. The total percentage of oxygen removed is directly proportional to the temperature of hydrogenolysis and is virtually complete at 450°.
4. The formation of carbon monoxide results at least in part from the reduction of the carbon dioxide.
5. Depropylation does not occur to any appreciable extent up to a temperature of about 380°, but increases rapidly above this temperature.
6. Depropylation is also a function of hydrogen concentration or partial pressure of hydrogen.
7. Part of the ethane results from the cracking of propane.
8. Severance of one of the methyl groups occurs to an appreciable extent even at the lower temperatures of hydrogenolysis and is also a function of time and hydrogen concentration.
9. Alicyclic decomposition does not occur to any appreciable extent up to a temperature of 425°, but increases rapidly above this temperature and is a function of hydrogen concentration.
10. The hydrogen consumption at the lower temperatures is due principally to the partial saturation of the ethylenic linkages and at the higher temperatures to the alkyl and alicyclic decomposition as well as to the reduction of the oxides of carbon.

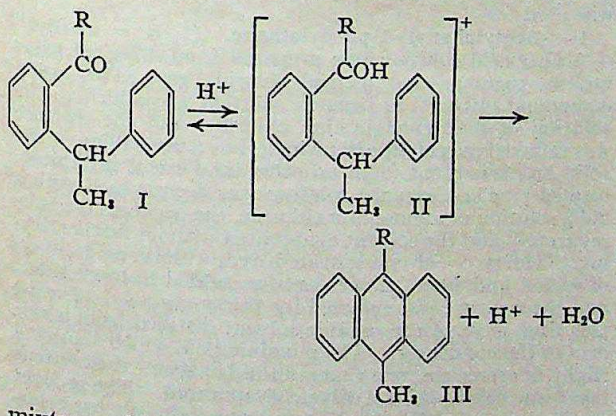
The Influence of *n*-Alkyl Groups on the Rate of a Cyclization Reaction

BY ERNST BERLINER

A general inductive effect, which is described as manifesting itself in a feeble electron-release character, is attributed to alkyl groups.[1] This effect is considered to increase with the amount of branching in the order: methyl, ethyl, *i*-propyl, *t*-butyl, and with increasing length of a normal alkyl chain from methyl to about *n*-propyl or *n*-butyl, where a maximum is reached beyond which the effect is usually not transmitted. The nature and order of the effect are not very well defined or understood as yet, but it seems increasingly probable that in some cases (where the order appears reversed) no-bond resonance or hyperconjugation[2] (the Baker–Nathan effect[3]) may play an important, if not decisive, part. In addition, steric considerations cannot be neglected.[4]

Even though still imperfectly defined, the concept of an inductive effect has been used frequently and successfully to account for certain regularities in changes of physical constants (dipole moments, acid dissociation constants) and reaction rates, and considerable kinetic data derived from measurements in homologous series have been interpreted on this basis.[5]

In the present investigation measurements have been made of the rate of cyclization of ketones of the type I to the 9,10-disubstituted anthracenes (III), a reaction first described by Bradsher.[6] The reaction was carried out in a



mixture of boiling acetic and hydrobromic acid, and the group R was varied from methyl to *n*-hexyl. The first step in the cyclization reaction involves the addition of a proton to the carbonyl group with the rapid establishment of a mobile equilibrium between the ketone and the conjugate acid II.[7] The latter exists as a resonance hybrid that attacks the *ortho* position of the opposite benzene ring in a normal aromatic substitution reaction.[8,9] As expected, the rate was found to be first order with respect to the ketone and is determined presumably by the attack of the carbonium ion on the benzene ring. The first order rate constants for the reactions of the different ketones as well as the half-life time of the cyclization reactions are listed in Table I.

TABLE I

Ketone R	K (min.$^{-1}$) $\times 10^{-2}$	$t_{1/2}$, min.
Methyl	4.6	15
Ethyl	1.8	38.4
n-Propyl	0.99	70
n-Butyl	.35	198
n-Pentyl	.36	192
n-Hexyl	.36	192
Phenyl	.16	433[a]
Benzyl	.91	76[a]

[a] The results obtained with the phenyl and benzyl ketones are not strictly comparable to those of the other ketones since some of the material remained undissolved when the reaction started. The values may, however, be taken as fair approximation.

The rate was found to decrease steadily from methyl to *n*-butyl and then to remain constant within the limits of the experimental error. The rate is also dependent upon the acid concentration; when the concentration of acid was lowered to three-fourths of the original, the observed rate constant for the methyl ketone was 0.76×10^{-2}.[10]

The decrease in rate with increasing length of the alkyl chain can be explained in terms of the inductive effect: an increase of electron density on the positive central carbon atom, caused by the electron release of the alkyl groups, results in a decrease of the effective positive character. Due to an increase in the energy of activation of the substitution reaction, the attack on the benzene ring becomes more difficult, and a decrease in rate results. This decrease reaches a limit with the limit of the inductive effect.

Although the electronic interpretation seems more attractive at the present time and fits well into the general picture of reaction mechanisms,

(10) The lack of exact relationship between the rate and acid concentration may be due to the possibility that the actual concentration of acid in the refluxing mixture of acetic acid, hydrobromic acid, and water was not exactly three-fourths of the original. Because of this fact and a possible loss of solvent the rate constants presumably do not constitute absolute values. The stress is laid on the difference in rate of the different ketones.

it should be emphasized that equally plausible explanations possibly might be obtained from purely stereochemical considerations. The slow reaction of the phenyl ketone can be ascribed to steric effects as well as to additional resonance of the conjugate acid with the benzene ring, which distributes the charge over two nuclei and makes it less available for the attack. This additional effect is not present with the benzyl group, which has a rate comparable to that of the *n*-propyl group, but on the other hand has steric requirements quite different from those of the phenyl group.

The results obtained do not confirm the statement of Bradsher and Smith[9] that the rate of cyclization is roughly independent of the nature of the group R.

Acknowledgment.—I wish to express my sincere thanks to Professor L. F. Fieser, Harvard University, for his help and kind interest in the work.

Experimental

Rate Measurements.—All determinations were carried out under the same conditions: approximately 0.002 mole of the ketone (about 500 mg.) was dissolved in 10 cc. of glacial acetic acid in a 50-cc. round-bottomed flask equipped with a ground glass reflux condenser. Four cc. of hydrobromic acid (48%) and one cc. of water were added, and the flask was immersed in a Wood's metal-bath which was preheated to 133–134° and maintained at this temperature. The first three ketones were soluble in the cold mixture, while the other three dissolved in the boiling mixture. The hydrocarbons resulting from the cyclization separated from the boiling solution. After a given time the flask was removed from the bath and cooled in an ice-bath. A crystal of the pure hydrocarbon was added if crystallization was slow. The solid material was filtered and washed with two 25-cc. portions of distilled water. It was dried in a vacuum oven overnight and weighed. The amount of hydrocarbon left in the mother liquor was negligible and never exceeded a few mg. In a typical case the following results were obtained

R = methyl

Preparation of Materials.[11]—The preparation of the intermediate ketones was similar to the procedure used by Bradsher.[6]

***o*-Chlorobenzophenone.**—This compound has been prepared previously but no exact procedure is given.[12] The acid chloride was prepared from *o*-chlorobenzoic acid (147 g.) and phosphorus pentachloride (100 g.). The phosphorus oxychloride was removed *in vacuo* and the acid chloride dissolved in 300 cc. of dry benzene. This solution was dropped on a suspension of 170 g. of aluminum chloride and 400 cc. of benzene in a three-necked flask equipped with a reflux condenser, a dropping funnel, and a hydrogen chloride trap. The addition took two hours, after which time the mixture was allowed to stand at room temperature for five hours. The reaction was completed by refluxing the mixture gently for thirty minutes. Hydrochloric acid and small pieces of ice were added carefully; the layers were separated, and the aqueous layer extracted with some fresh benzene. The combined layers were dried, the solvent evaporated, and the product distilled. It distilled at 181° at 18–19 mm. (redistilled at 178–180° (14–15 mm.)) and solidified to small crystals melting at 43–44°.[13] The yield was 175 g. (85.7%).

1-(*o*-Chlorophenyl)-1-phenylethylene was prepared according to Bergmann and Bondi[14] from magnesium (8 g.), methyl chloride gas, and *o*-chlorobenzophenone (39 g.). The mixture was refluxed overnight and decomposed with ice-cold 30% sulfuric acid. The yield was 29.7 g. (77%) of a colorless oil that distilled at 164–166° (17 mm.). Bergmann and Bondi report the value of 162–163° (18 mm.). The same compound could also be prepared from *o*-chloroacetophenone and phenylmagnesium bromide, but the yield was not higher than 50%.

1-(*o*-Chlorophenyl)-1-phenylethane.—Twelve grams of the above olefin was dissolved in 20 cc. of absolute alcohol and hydrogenated in the presence of Raney nickel catalyst at atmospheric pressure. The product distilled at 156–157° (12 mm.) as a colorless oil with a pleasant, fruit-like odor. The yield was almost quantitative. A sample redistilled at 158° (12 mm.) had the following composition:

Anal.[15] Calcd. for $C_{14}H_{13}Cl$: C, 77.59; H, 6.05. Found: C, 77.10; H, 6.03.

1-(*o*-Cyanophenyl)-1-phenylethane.—A mixture of the above chloro compound (27.5 g.), 14 g. of cuprous cyanide (dried at 100° for ten hours before use), and 12.5 cc. of dry pyridine was refluxed for thirty-six hours in a Wood's metal-bath maintained at 250–260°. The product after isolation in the usual way distilled at 183–188° (16 mm.) as an amber colored oil.[16] The yield was 20 g. (75.7%). Material redistilled at 190–191° (17–18 mm.) showed the composition:

Anal. Calcd. for $C_{15}H_{13}N$: C, 86.92; H, 6.32. Found: C, 86.76; H, 6.11.

All the ketones and hydrocarbons were prepared in the same way. In a typical procedure the following method was used:

1-(*o*-Acetylphenyl)-1-phenylethane. (I, R = methyl).—A Grignard solution was prepared from 2.7 g. of magnesium turnings and methyl chloride gas. The cyano compound (10.3 g.) in benzene solution was added to the solution of methylmagnesium chloride, and the mixture was refluxed overnight after which time a crystalline, white solid had separated. (In no other case was a precipitate formed.) The Grignard solution was decomposed with a 20% solution of ammonium chloride, the organic layer was separated, and the solvent evaporated without further drying. Thirty cc. of concentrated hydrochloric acid, 40 cc. of water, and 40 cc. of acetone were added to the residue, and the mixture was refluxed for thirty minutes. During this time most of the organic solvent distilled from a side arm of the condenser. The remaining oil, which showed a slight fluorescence, was taken up in benzene; the benzene layer was dried, and the solvent evaporated. The product distilled at 184–186° (16–17 mm.) as a light, almost colorless oil. The yield was 8.4 g. (75.5%).

Anal. Calcd. for $C_{16}H_{16}O$: C, 85.67; H, 7.19. Found: C, 85.52; H, 6.81.

9,10-Dimethylanthracene.—A mixture of 1.2 g. of the above ketone, 15 cc. of glacial acetic acid, 10 cc. of hydrobromic acid, and 2 cc. of water was refluxed in an all-glass apparatus. After fifteen minutes a crystalline product

separated from the boiling solution.[17] The flask was cooled after a total refluxing time of three hours and the hydrocarbon was filtered. Recrystallized from alcohol and little benzene, it forms yellow crystals, often described in the literature.[18] The melting point was 182.8–183.8°. The picrate forms dark brown needles of the melting point 179–180°. The physical constants of the other ketones and hydrocarbons are listed in Table II.

Summary

The rate of the cyclization of different ketones to 9,10-disubstituted anthracenes has been measured and found to decrease as the number of carbon atoms on the alkyl groups increases. The decrease in rate can best be explained in terms of the inductive effect of alkyl groups. A number of 9-alkyl-10-methylanthracenes has been prepared and the physical constants are described.

(19) Barnett and Matthews, *Ber.*, **59**, 1437 (1926), report a melting point of 112°.

(20) All picrates form dark brown crystals and decompose when recrystallized from alcohol, benzene or ligroin. They are best recrystallized from methyl alcohol in the presence of some excess picric acid.

(21) 9-Hexyl-10-methylanthracene forms a picrate which contains two molecules of hydrocarbon. The same is reported for 9-butylanthracene (Stieglitz and Marx, *Ber.*, **56**, 1619 (1923)).

(22) This hydrocarbon did not form a picrate.

(23) This ketone solidified after long standing and had a crude melting point of 47–48°.

CAMBRIDGE, MASS. RECEIVED DECEMBER 18, 1943

[CONTRIBUTION FROM THE CENTRAL EXPERIMENT STATION, BUREAU OF MINES]

Hydrogenation of Anthracene by Tetralin[1]

BY MILTON ORCHIN[2]

Examination of some of the high-boiling liquid products obtained by hydrogenation of coal at the Bureau of Mines Central Experiment Station involved attempts at dehydrogenation. The physical properties of these oils indicated a large percentage of hydroaromatic compounds, yet catalytic liquid-phase dehydrogenation gave only small quantities of evolved hydrogen. To understand better the reactions that may occur when mixtures of aromatics and hydroaromatics such as are found in the products from the hydrogenation of coal are heated in the liquid phase in the presence of a catalyst, a study of the mixture anthracene and tetralin was undertaken.

The literature reveals that under the conditions necessary for liquid-phase dehydrogenation, the hydrogen is often utilized in what may be regarded as a sort of internal oxidation–reduction process. This transfer of hydrogen can be either intramolecular or intermolecular. Examples of the former are the conversion of methyl 2-(5,6,7,8-tetrahydro)-naphthyl ketone to 2-ethylnaphthalene[3]; and 1-hydroxy-1-allyl-1,2,3,4-tetrahydrophenanthrene to 1-*n*-propylphenanthrene.[4,5] Examples of the intermolecular transfer of hydrogen are the conversion of 2,3-naphthalic anhydride to 2,3-dimethylnaphthalene in small yield by means of *p*-cyclohexylphenol[6]; the disproportionation reactions in the terpene series[7]; the incomplete dehydrogenation of tetralin due to the equilibrium tetralin $\leftrightarrows$ naphthalene + $2H_2$[8]; and the work of Adkins and coworkers, who dehydrogenated many compounds by heating in a steel bomb with benzene as a hydrogen acceptor.[9]

When tetralin and anthracene were heated together at one atmosphere pressure in the presence of a palladium catalyst, some of the hydrogen was transferred from the tetralin to the anthracene with the formation of naphthalene and hydroanthracenes. The extent of the reaction was influenced by the temperature, as indicated by the table in the experimental part. When the temperature was such that about 24% of the theoretical quantity of hydrogen was evolved, a 30% yield of 1,2,3,4-tetrahydroanthracene was obtained.

When tetralin and anthracene were heated in a sealed tube, a 60% yield of 1,2,3,4-tetrahydroanthracene was obtained. In addition, small quantities of 9,10-dihydroanthracene and 1,2,3,-4,5,6,7,8-octahydroanthracene were formed. The reaction apparently resembles the catalytic hydrogenation of anthracene.[10]

In an extension of this method of hydrogenation, 2-cyclohexenone was used as a hydrogen donor in place of tetralin. 2-Cyclohexenone in its enolic form is a dihydrobenzene derivative, and its preparation by vapor-phase dehydration of 2-hydroxycyclohexanone gives considerable phenol.[11] The reaction between cyclohexenone and anthracene resulted in a 30% yield of 1,2,3,4-tetrahydroanthracene.

The reaction between tetralin and anthracene to give naphthalene, dihydroanthracene and tetrahydroanthracene may be represented stoichiometrically by the equations

$$(1)\quad C_{10}H_{12} + 2C_{14}H_{10} \rightleftharpoons C_{10}H_8 + 2C_{14}H_{12}$$

$$(2)\quad 2C_{14}H_{12} \rightleftharpoons C_{14}H_{10} + C_{14}H_{14}$$

Reaction (1) can proceed to a limited extent in the absence of a catalyst, as indicated by experiments 8 and 9. The disproportionation reaction (2) apparently requires a catalyst, as no 1,2,3,4-tetrahydroanthracene could be found in the same reactions. The isolation of some tetrahydroanthracene when dihydroanthracene was dehydrogenated is evidence for reaction (2).[12]

In one attempt to elucidate the steps of the reaction, 9,10-dihydroanthracene was refluxed in ethanol solution with Raney nickel. The reaction mixture gave a good yield of 1,2,3,4-tetrahydroanthracene. Anthracene was found to behave similarly. Apparently, the hydrogen adsorbed on the surface of Raney nickel can be utilized for the hydrogenation reactions, and this constitutes a novel method for the preparation of small quantities of tetrahydroanthracene.

When the tetralin–anthracene reaction is accompanied by the evolution of hydrogen, the origin of the hydrogen, of course, is tetralin. As the temperature is increased, the hydrogen may also result from dehydrogenation of the hydroanthracenes. Undoubtedly other equilibria are present in the system at different times, but the mechanism of the reaction remains speculative.

The results support the theory that one of the steps in the hydrogenation of coal is the transfer of hydrogen from a reactive hydrogen donor to a molecule that can act as a hydrogen acceptor.[13] The ease of transfer of hydrogen also suggests that considerable discretion must be exercised in determining "primary" products of the hydrogenation of coal.

Experimental[14]

The apparatus used in the open-tube experiments consisted simply of a test-tube containing the reactants connected to a reflux condenser by either a rubber stopper or a ground-glass joint. A piece of rubber tubing led from the top of the condenser to an inverted cylinder of water standing in a water-bath. The catalyst used in each experiment (except 8 and 9) was a mixture of palladium and charcoal containing approximately 30% palladium.[15]

Materials

Tetralin.—A good grade of commercial tetralin, obtained by the hydrogenation of naphthalene, was distilled twice from sodium and the middle cut of the second distillation used.

Anthracene.—Commercial anthracene was purified by two distillations with ethylene glycol[16] and twice recrystallized from benzene, melting point 215.2–217.2°. For purposes of comparison, samples of 9,10-dihydroanthracene, 1,2,3,4-tetrahydroanthracene and 1,2,3,4,5,6,7,8-octahydroanthracene were prepared.

9,10-Dihydroanthracene.[17]—Sodium reduction of an amyl alcohol solution of anthracene gave 84% of 9,10-dihydroanthracene, m. p. 108.0–109.8°.

1,2,3,4-Tetrahydroanthracene prepared from the reaction between anthracene and tetralin was purified through the picrate,[18] and after two recrystallizations from alcohol, the hydrocarbon was obtained as colorless plates, m. p. 100.5–101.5°. The trinitrobenzene complex also was prepared, yellow needles, m. p. 133.2–133.8°, from alcohol. *Anal.*[19] Calcd. for $C_{20}H_{17}N_3O_6$: N, 10.63. Found: N, 10.43.

Subsequently, tetrahydroanthracene was prepared from 9,10-dihydroanthracene and from anthracene. To 0.5449 g. of 9,10-dihydroanthracene in 25 ml. of ethanol there was added about 8 g. of Raney nickel.[20] After the mixture was refluxed for two and one-half hours in a nitrogen atmosphere, it was filtered, and the filtrate was concentrated. On cooling, 0.3326 g. of 1,2,3,4-tetrahydroanthracene, m. p. 98.0–100.2°, was obtained. The mother liquor was treated with 0.3 g. of *s*-trinitrobenzene and 0.245 g. of the 1,2,3,4-tetrahydroanthracene trinitrobenzene complex, m. p. 132.8–133.4°, was obtained, making a total yield of 81%. When 0.3377 g. of anthracene in 50 ml. of ethanol was treated with about 10 g. of Raney nickel, a 71% yield of 1,2,3,4-tetrahydroanthracene was obtained.

1,2,3,4,5,6,7,8-Octahydroanthracene.—β-2-(5,6,7,8-Tetrahydronaphthoyl)-propionic acid was prepared in 70% yield by the Friedel–Crafts reaction between tetralin and succinic anhydride in nitrobenzene at 0°. Benzene also

can be used as the solvent.[3,21a] Clemmensen reduction of the keto acid gave γ-2-(5,6,7,8-tetrahydronaphthyl)-butyric acid in 94% yield.[3] The acid was converted to the acid chloride at room temperature with thionyl chloride. In the hope of minimizing the formation of 4-keto-1,2,3,4,-5,6,7,8-octahydrophenanthrene, the acid chloride was cyclized in carbon disulfide at 0° with stannic chloride. However, cyclization took place in both directions.[21b] The mixture of ketones (11.7 g. from 15.0 g. of the tetralylbutyric acid) was reduced by the Clemmensen procedure[16] and gave 4.72 g. of 1,2,3,4,5,6,7,8-octahydroanthracene, m. p. 71–72°, recrystallized from alcohol, melting point 72.0–73.0°.

2-Cyclohexenone.—After several unsuccessful attempts to prepare this ketone by selenium dioxide oxidation of cyclohexene (mole for mole in ethanol solution), it was prepared in poor yield (10%) by the chromic oxide oxidation of cyclohexene,[22] $n^{24}D$ 1.483; compound with 2,4-dinitrophenylhydrazine, m. p. 171.5°, after sintering at 163°.[22a] *Anal.*[19] Calcd. for $C_{12}H_{12}N_4O_4$: N, 20.28. Found: N, 20.02.

Reactions between Tetralin and Anthracene.—The conditions and results of the various experiments are summarized in the table. In working up the mixtures resulting from the reactions between anthracene and tetralin the problem in the most extreme case was one of separating and identifying tetralin, naphthalene, anthracene, 9,10-dihydroanthracene, 1,2,3,4-tetrahydroanthracene, and 1,2,3,4,5,6,7,8-octahydroanthracene. The reaction mixtures were not worked up in the same fashion each time, but characteristic differences in properties of these six substances were utilized to advantage. These differences may be summarized briefly. Tetralin and naphthalene sublime and steam-distil more readily than the other substances and, of these, only naphthalene forms a picrate. Anthracene alone of all these substances forms an adduct with maleic anhydride.[23] The adsorption of the anthracenes on a column of activated alumina in increasing strength of adsorption is octahydroanthracene, 1,2,3,4-tetrahydroanthracene, 9,10-dihydroanthracene, and anthracene (see below). 1,2,3,4-Tetrahydroanthracene forms a picrate, whereas 9,10-dihydroanthracene does not. The former also readily forms a complex with *s*-trinitrobenzene.[24]

Experiment 7 will be described in detail, as it illustrates all the techniques used in separating and identifying products.

Experiment 7.—A mixture of 6.2 g. of powdered anthracene, 0.5 g. of palladium-charcoal, and 5.5 cc. of tetralin was heated in a sealed tube in a nitrogen atmosphere at 340° for seven hours. The tube was cooled and opened (no pressure), the contents were dissolved in benzene, filtered, and distilled at the vacuum of the water pump. A high-boiling fraction of 4.6 g. was collected at a bath temperature of 170° and a residue (A) was retained in the flask.

The distillate consisted of naphthalene and tetralin, separated by precipitation of naphthalene as the picrate and estimation of the tetralin content of the oily hydrocarbon residue by comparison of its refractive index with that of a synthetic mixture of known composition.

Residue A yielded anthracene in the form of its maleic anhydride adduct. The filtrate from that afforded 1,2,3,4-tetrahydroanthracene, crystallizing from alcohol. Trinitrobenzene was now added to the solution, precipitating a mixture of the complexes of naphthalene and tetrahydroanthracene. The hydrocarbons were regenerated by passage of the complexes through alumina and separated by steam-distillation.

The material in the mother liquor from the complex precipitation was recovered, dissolved in benzene–petroleum ether and separated into 9,10-dihydro- and 1,2,3,4,-5,6,7,8-octahydro-anthracene by chromatographic adsorption on a column of alumina.

The isolated products were identified by their melting points and mixed melting points. The yields of purified products obtained are recorded in the table.

Chromatographic Separation of 9,10-Dihydroanthracene and 1,2,3,4-Tetrahydroanthracene.—A solution of 100 mg. of 9,10-dihydroanthracene and 100 mg. of 1,2,3,4-tetrahydroanthracene in 100 ml. of petroleum ether (b. p. 60–68°) was passed through a 9-inch column containing 65 g. of activated alumina. Following the 100 ml. of solution, an additional 125 ml. of petroleum ether, then 100 ml. of 20% benzene in petroleum ether, were passed through the column by gravity. The receivers were changed after

(21)(a) Krollpfeiffer and Schafer, *Ber.*, **56**, 620 (1923).

(21)(b) These authors cyclized γ-2-tetralylbutyric acid by heating it with concentrated sulfuric acid and obtained a 75% yield of the ketoanthracene. No keto phenanthrene was isolated.

(22) Whitmore and Pedlow, THIS JOURNAL, **63**, 758 (1941).

(22)(a) Whitmore and Pedlow give the melting point of cyclohexenone 2,4-dinitrophenylhydrazone as 117°, while Bartlett and Woods (ref. 11) give the melting point as 163°. Although these discrepancies are not readily explained, it should be noted that the hydrazone can theoretically exist in stereoisomeric forms, and there is the additional possibility that the cyclohexene portion may undergo spontaneous aromatization.

(23) Bachmann and Kloetzel, *ibid.*, **60**, 481 (1938).

(24) Although 9,10-dihydroanthracene can also form a complex with trinitrobenzene (Sudborough, *J. Chem. Soc.*, 1339 (1916)), the complex dissociates readily and is difficult to obtain.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

about every 50 ml. of solution had been collected. Six fractions were thus collected. Evaporation of fractions 1, 2, 3 and 6 gave no residue. The fourth fraction gave a mixture with m. p. 75–88°. The fifth fraction gave crystals, m. p. 104.5–108.5°, and after recrystallization there was obtained 25 mg., m. p. 108.0–109.8°, identical with 9,10-dihydroanthracene.

Dehydrogenation of 9,10-Dihydroanthracene.—In a test-tube connected to a reflux condenser were placed 1.00 g. of 9,10-dihydroanthracene and 100 mg. of palladium–charcoal catalyst. The tube was placed in a bath at 200° for a few minutes, during which time 6 ml. of gas was collected (blank). The temperature was raised to 300° and kept at 300–340° for three hours, during which time an additional 118 ml. of gas was collected (83%). The reaction mixture was cooled, dissolved in benzene, filtered, and the anthracene removed by means of maleic anhydride. There was obtained 1.24 g. of adduct equivalent to 0.8 g. of anthracene (80%). After the excess maleic anhydride had been removed, the remaining material was treated with trinitrobenzene; whereupon 70 mg. of the 1,2,3,4-tetrahydroanthracene complex, m. p. 128–131°, was obtained, mixed melting point, no depression.

Reaction between 2-Cyclohexenone and Anthracene.—In a preliminary experiment, cyclohexenone was refluxed with palladium–charcoal, but no hydrogen was evolved.[25] A mixture of 2.95 g. anthracene, 3.84 g. cyclohexenone, and 300 mg. of palladium–charcoal was heated in a sealed tube for seven and one-half hours at 295–325°. The tube was cooled in dry-ice, opened (pressure), and the contents dissolved in benzene and filtered. The benzene solution was extracted with 5% sodium hydroxide solution and the alkaline extract made to 500 ml. A 20-ml. aliquot was titrated with potassium bromate–potassium bromide solution.[26] The titration indicated 1.74 g. of phenol present in the total reaction mixture. The tribromophenol formed in the titration was filtered and recrystallized from ethanol, m. p. 91–92° (literature reports 95°). The benzene solution remaining after the alkaline extraction was treated with maleic anhydride and 1.64 g. endoanthracene maleic anhydride was precipitated and filtered. The excess maleic anhydride was extracted from the filtrate, the benzene was evaporated, and the residue was distilled. The distillate (2.45 g.) was dissolved in 20 ml. of ethanol and treated with 2 g. of picric acid. There was obtained 1.52 g. of orange-yellow crystals, m. p. 110–113°, identical with the picrate of 1,2,3,4-tetrahydroanthracene. The mother liquor was passed through a column of activated alumina. The first fraction gave 50 mg. of 1,2,3,4-tetrahydroanthracene. The second fraction contained some tetrahydroanthracene, some dihydroanthracene, and some other material that may have resulted from the polymerization of cyclohexenone. After removal of about 135 mg. of 9,10-dihydroanthracene, m. p. 107–109°, mixed melting point, no depression, the remaining material was treated with trinitrobenzene. There separated 0.386 g. of 1,2,3,4-tetrahydroanthracene trinitrobenzene complex, m. p. 128–130.5°, mixed melting point, no depression. The mother liquor was not investigated further.

(25) Compare Ruzicka, ref. 5a, who by heating 3-methylcyclohexene-2-one for two days with selenium at 260° obtained only a 15% yield of *m*-cresol.

Acknowledgment.—The author wishes to express his appreciation to Dr. H. H. Storch for his interest and suggestions throughout this work and to Dr. M. S. Newman for suggestions regarding the manuscript.

Summary

When anthracene and tetralin are heated together at 1 atmosphere pressure in the presence of a palladium catalyst, a 30% yield of 1,2,3,4-tetrahydroanthracene can be obtained.

When anthracene and tetralin are heated together in a sealed tube in the presence of a palladium catalyst, the reaction resembles a catalytic hydrogenation of anthracene and a 61% yield of 1,2,3,4-tetrahydroanthracene along with small amounts of 9,10-dihydroanthracene, and 1,2,3,4,5,6,7,8-octahydroanthracene are obtained. This type of hydrogenation of anthracene can also be achieved with 2-cyclohexenone.

The dehydrogenation of 9,10-dihydroanthracene in the liquid phase results in expulsion of less than the theoretical quantity of hydrogen and formation of some 1,2,3,4-tetrahydroanthracene.

1,2,3,4-Tetrahydroanthracene can be conveniently prepared in good yield by refluxing an ethanol solution of anthracene or 9,10-dihydroanthracene with Raney nickel.

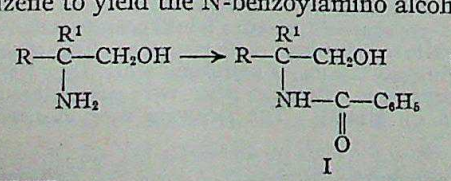
Amino Acids. III. α-Amino-*n*-butyric Acid and α-Amino-isobutyric Acid

BY JOHN H. BILLMAN AND EARL E. PARKER

The method used for the synthesis of alanine[1] from 2-amino-*n*-propanol has now been extended to the preparation of α-amino-*n*-butyric acid and α-amino-isobutyric acid from 2-amino-*n*-butanol and 2-amino-2-methyl-*n*-propanol.

The amino alcohols were benzoylated with benzoyl chloride and anhydrous sodium carbonate in benzene to yield the N-benzoylamino alcohol I.



(1)

I

The yield of crude 2-benzoylamino-*n*-butanol was 89–91% while the yield of pure 2-benzoylamino-2-methyl-*n*-propanol was 78–79%.

A number of oxidizing agents were tried in order to ascertain whether any of them possessed advantages over alkaline permanganate for the oxidation of the benzoylated amino alcohols to the corresponding amino acids II. Among those examined and found to react were lead dioxide,

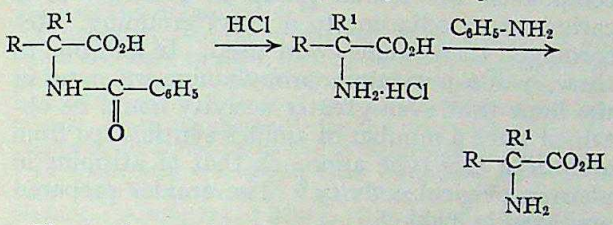
Digitized by Arya Samaj Foundation Chennai and eGangotri

sodium dichromate and sulfuric acid, chromic acid, ammonium persulfate, and nitric acid. None of them were as good as alkaline permanganate.

The yields of α-benzoylamino-*n*-butyric acid and α-benzoylamino-isobutyric acid, containing very small amounts of benzoic acid as impurity, were 67–72% and 91–93%, respectively.

The benzoylated amino acids were hydrolyzed to yield approximately the theoretical amounts of the amino acid hydrochlorides. The yields of pure α-amino-*n*-butyric acid and α-aminoisobutyric acid obtained upon liberation from their hydrochlorides were 72 and 86%, respectively.



The authors wish to thank Eli Lilly and Company for assistance in this work.

Experimental

2-Benzoylamino-*n*-butanol.—In a liter 3-necked flask equipped with a dropping funnel, a thermometer, and an efficient stirrer were placed 500 cc. of benzene, 25 g. of anhydrous sodium carbonate and 18.3 g. of pure 2-amino-*n*-butanol. The mixture was vigorously stirred and cooled to 10°. A solution containing 28.1 g. of benzoyl chloride and 100 cc. of benzene was then added drop by drop at such a rate that the temperature did not exceed 10°. After forty-five minutes, a second 25 g. of sodium carbonate was added. The mixture was stirred for four hours, then the bath was removed and stirring continued for four additional hours.

The dropping funnel was then replaced by a condenser and the reaction refluxed until no odor of benzoyl chloride could be detected. The hot mixture was filtered to remove the inorganic material. This residue was extracted with two 100-cc. portions of hot benzene. The combined filtrates were reduced to 400 cc. and chilled in the refrigerator. The crystals of 2-benzoylamino-*n*-butanol were filtered off and washed with cold benzene. A small second crop was obtained by evaporating the filtrate to 150 cc. The product weighed 34–35 g. (89–91%) and melted at 97–98°.

Recrystallization from toluene yielded a product melting at 98–99°. Calcd.: N, 7.25. Found: N, 6.98.

α-Benzoylamino-*n*-butyric Acid.—In 400 cc. of water containing 2 g. of sodium hydroxide was suspended 32.5 g. of crude 2-benzoylamino-*n*-butanol. To this vigorously stirred mixture was added 36 g. of potassium permanganate at such a rate that the temperature did not exceed 40°. Stirring was continued until most of the permanganate had been consumed and the temperature had fallen to room temperature. The manganese dioxide was filtered off and the excess of permanganate reduced with saturated sodium bisulfite solution. The mixture was again filtered, acidified with concentrated hydrochloric acid, and chilled in the refrigerator. The benzoylamino-*n*-butyric acid weighed 23.7–25.1 g. and melted at 139–40°. This was a 67–72% yield of crude material.

α-Amino-*n*-butyric Acid Hydrochloride.—In a typical experiment 25.1 g. of crude α-benzoylamino-*n*-butyric acid was suspended in 200 cc. of 18% hydrochloric acid and refluxed eight hours. The mixture was cooled to room temperature and the benzoic acid filtered off. The filtrate was then evaporated to dryness under reduced pressure. A small portion of water was added and the process repeated. The operation was repeated again with water and three more times with absolute alcohol. A theoretical yield of 17 g. of α-amino-*n*-butyric acid hydrochloride was obtained. Calcd.: N, 10.05. Found: N, 10.04.

α-Amino-*n*-butyric Acid.—The α-amino-*n*-butyric acid hydrochloride (17 g.) was dissolved by warming it with 100 cc. of 95% alcohol. The mixture was filtered and treated with 20 cc. of pure aniline. It was then chilled in the refrigerator for several hours. The product was filtered off and washed with absolute alcohol to free it of aniline. The yield of halogen free α-amino-*n*-butyric acid was 9 g. or 72% of the theoretical. *Anal.* Calcd.: N, 13.6. Found: (Van Slyke) N, 13.8.

2-Benzoylamino-2-methyl-*n*-propanol.—In a liter 3-necked flask equipped with a dropping funnel, a thermometer, and an efficient stirrer were placed 400 cc. of benzene, 50 g. of anhydrous sodium carbonate and 18.3 g. of pure 2-amino-2-methyl-*n*-propanol. The mixture was vigorously stirred and cooled to 10° with an ice-bath. A solution containing 28.1 g. of benzoyl chloride and 100 cc. of benzene was then added at such a rate that the temperature did not exceed 10°. After the mixture had been stirred for four hours, the bath was removed and stirring continued for two more hours.

The dropping funnel was then replaced by a condenser and the mixture refluxed until all of the benzoyl chloride had reacted. The hot mixture was then filtered to remove the inorganic material. This residue was extracted with two 100-cc. portions of hot benzene. The combined filtrates were reduced to 400 cc. and the solution chilled. The crystals of 2-benzoylamino-2-methyl-*n*-propanol were filtered off and washed with two small portions of cold benzene. This filtrate was reduced to 100 cc. and 200 cc. of petroleum ether added. The gummy solid that was obtained was recrystallized from benzene and yielded a small amount of crystals of the same purity as the original batch. The total yield was 30.2–30.5 g. (78–79%) of material melting 88–89°. *Anal.* 7.10% nitrogen. A sample that was recrystallized three times from benzene melted 89–90°. *Anal.* Calcd.: N, 7.25. Found: N, 7.24.

α-Benzoylamino-isobutyric Acid.—In 400 cc. of water containing 4 g. of sodium hydroxide was suspended 38.6 g. of 2-benzoylamino-2-methyl-*n*-propanol. To this vigorously stirred mixture was added 42.1 g. of potassium permanganate at such a rate that the temperature did not exceed 40°. Stirring was continued until most of the permanganate had been consumed and the temperature had fallen to that of the room. The manganese dioxide was filtered off and the excess of permanganate reduced with methyl alcohol. The mixture was again filtered and acidified with concentrated hydrochloric acid and chilled. The α-benzoylamino-isobutyric acid was filtered off and the filtrate neutralized with bicarbonate and evaporated to 150 cc. under reduced pressure. The solution was acidified and yielded from 1 to 4 g. of product. The total yield was 37.6–38.6 g. (91–93%) of material melting over a one or two degree range between 193 and 198°.

α-Amino-isobutyric Acid Hydrochloride.—In a typical experiment 37.8 g. of α-benzoylamino-isobutyric acid was suspended in 300 cc. of 18% hydrochloric acid and refluxed for eight hours. The mixture was worked up by the same procedure as for isolating α-amino-*n*-butyric acid hydrochloride; yield 25.4 g. (99%).

α-Aminoisobutyric Acid.—The aminoisobutyric acid hydrochloride (24.8 g.) was dissolved in 150 cc. of hot 95% alcohol, treated with 24 cc. of pure aniline, and chilled in the refrigerator. The product was filtered off and washed with absolute alcohol to free it of aniline. The yield of α-aminoisobutyric acid was 15.7 g. or 86% of the theoretical. *Anal.* Calcd.: N, 13.59. Found: (Van Slyke) N, 13.48.

Summary

A new method has been developed for the synthesis of α-amino-*n*-butyric acid and α-amino-isobutyric acid from the corresponding amino alcohols.

Amides of Nicotinic Acid and Related Acids. II

BY JOHN H. BILLMAN AND JOHN L. RENDALL[1,2,3]

In the first[4] of a series of articles on the preparation of compounds possessing antispasmodic and anticonvulsant activity, it was found that certain amides showed promise as antispasmodics and anticonvulsants. Further investigation of amides of various acids disclosed the fact that the benzyl amide of nicotinic acid possessed rather pronounced antispasmodic activity. However, the activities of other amides of nicotinic acid differ markedly. For example, nicotinamide[5] is relatively inert in regard to spasmodic or convulsant action while diethyl nicotinamide (Nikethamide)[6] possesses convulsant activity. It seemed, therefore, to be of interest to prepare other amides of nicotinic acid and related acids such as α-picolinic, γ-picolinic, quinoline-3-carboxylic, pyrazine monocarboxylic and pyrazine 2,3-dicarboxylic acids in order to compare their pharmacological activity. The amides were prepared by interaction of the appropriate amine either with the heterocyclic ester or the free acid.

It was thought that the activity of the benzyl amide might be due to the basicity and/or the solubility of the amine used in making the amide. Therefore, amines were selected which resemble benzylamine in structure or solubility. An amine which should have about the same solubility as benzylamine is *n*-amylamine, since a *n*-butyl group is considered approximately equivalent to a phenyl group in estimating solubility. An amine which should possess about the same basicity as benzylamine is allylamine, for in both compounds the amino group is attached to a carbon atom adjacent to a vinyl grouping. Accordingly, these amines were used. In addition to these, γ-di-*n*-butylaminopropylamine was used in the hope that even greater activity could be obtained since a number of amides synthesized from amines of this type approach that of atropine in pharmacological activity.[7] The amides prepared are listed in Table I.

TABLE I

Amides	M. p., °C.	B. p. °C.	B. p. Mm.	Yield	% Nitrogen Calcd.	% Nitrogen Found
Benzyl nicotinamide	72–73			93.0	13.20	13.08
n-Amyl nicotinamide		170–171	1	49.4	14.58	14.67
Allyl nicotinamide[a]		158–161	1	50.0	17.29	17.20
Dibutylaminopropyl nicotinamide		226–230	2	60.1	14.42	14.12
				98.0[b]		
Benzyl γ-picolinamide	84.5–85.0			54.0[c]	13.20	12.95
n-Amyl γ-picolinamide		178–182	2	70.5	14.58	14.70
Allyl γ-picolinamide		158–159	2	51.8	17.29	17.22
Dibutylaminopropyl γ-picolinamide		236–240	2	78.2	14.42	14.13
				51.7[b]		
Benzyl α-picolinamide	87.0–87.5			73.3[c]	13.20	13.00
n-Amyl α-picolinamide		135–138	2	83.3	14.58	14.65
Allyl α-picolinamide		166–170	1	94.4	17.29	17.16
Dibutylaminopropyl α-picolinamide		209–212	1	92.1	14.42	14.22
Benzyl pyrazine monocarboxamide	116.0			31.0	19.72	19.64
N,N′-Dibenzyl pyrazine-2,3-dicarboxamide	171–171.5			78.2	16.18	16.29
N,N′-Diamyl pyrazine-2,3-dicarboxamide	145.5–146.0			20.0	18.30	18.14
Benzyl quinoline-3-carboxamide	139–139.5			47.8	10.77	10.91

[a] Pictet and Sussdorff, *Arch. Sci. phys. nat. Genève.*, [4] **5**, 122; *Chem. Zentr.*, 69, 677 (1898). [b] Prepared according to Method "A." [c] Prepared according to Method "B."

Experimental

Two procedures were used in the preparation of the amides:

Method "A."—A xylene solution of the amine and acid was refluxed and the water evolved during the reaction collected in a calibrated water trap. Since the water could be measured, it was found possible to gage the speed and extent of completion of the reaction.

Obviously method "A" could not be used conveniently in the preparation of the amyl and allyl amides because of the low boiling points of the amines. It is interesting to note, however, that even when the *n*-amylamine salt of nicotinic acid was isolated and heated in refluxing xylene, dehydration could not be effected. Heating the salt to 180° in a vacuum of 2 mm. caused decomposition to the acid and amine.

Method "B."—The various amines were treated with the ethyl esters of nicotinic, α-picolinic, γ-picolinic and quinoline-3-carboxylic acids to yield the corresponding amides.

α- and γ-Picolinic Acid Hydrochlorides.—Oxidation of the corresponding picolines yielded the acids which were then isolated as the hydrochlorides.[8]

Ethyl Esters.—The ethyl esters of nicotinic, α-picolinic and γ-picolinic acids were prepared in yields ranging from 78–85% according to a procedure described by LaForge[9] for the preparation of ethyl nicotinate.

Ethyl quinoline-3-carboxylate was prepared by a series of reactions consisting of the bromination of quinoline hydrobromide,[10] formation of the nitrile with cuprous cyanide,[11] subsequent hydrolysis with 70% sulfuric acid[10] and esterification according to the method used by LaForge.[9] A 55% yield of the ethyl ester based on 3-bromoquinoline was obtained.

Pyrazine-2,3-dicarboxylic Acid.—The acid was prepared by the oxidation of quinoxaline according to directions given by Gabriel and Sonn.[12]

Quinoxaline.—In the preparation of quinoxaline, it was found necessary to use a dilute solution of *o*-phenylenediamine and glyoxal bisulfite; otherwise, polymeric substances formed and little if any of the product was obtained. Since the method[12] for the preparation of quinoxaline is vague, we are including the procedure we used.

In a one-liter erlenmeyer flask containing 400 ml. of water at 70°, was placed 27.0 g. (0.25 mole) of *o*-phenylenediamine. A solution of 68.8 g. (0.26 mole) of glyoxal bisulfite in 300 ml. of water heated to 70° was then added with shaking. The shaking was continued for five minutes after completion of the mixing. The solution was allowed to cool to approximately 40° and 100 g. of potassium carbonate added. The quinoxaline separated and was extracted with 100 ml. and three 50-ml. portions of ether. The ether extracts were combined, dried over anhydrous sodium sulfate and distilled. Yields from 29.6 to 30.5 g. of product (90.8–93.5% of theoretical) boiling at 112–115° (17 mm.) were obtained.

Benzyl Nicotinamide.—In a 200-ml. erlenmeyer flask, connected by ground glass joints to a calibrated water trap, in turn attached to a reflux condenser, were placed 12.3 g. (0.10 mole) of nicotinic acid and 10.7 g. (0.10 mole) of benzylamine. The mixture was heated gently until it became homogeneous. Seventy-five ml. of anhydrous xylene was added and the mixture refluxed for one hundred and fifty hours in an oil-bath kept at 165–170°. At the end of this time, 1.95 ml. of water was found in the trap (1.80 ml.—theoretical amount). On cooling, the product formed pure white crystals. A yield of 19.7 g. (93.0% of theoretical) of product, m. p. 72–73°, was obtained.

***n*-Amyl-α-picolinamide.**—In a 250-ml. round-bottomed flask fitted with a reflux condenser were placed 15.1 g. (0.10 mole) of ethyl α-picolinate and 17.4 g. (0.20 mole) of *n*-amylamine. The mixture was heated in an oil-bath maintained at 125° for twenty-five hours. Distillation *in vacuo* yielded 1.8 g. (11.9% recovery) of ethyl α-picolinate, 16.0 g. (83.3%) of product boiling at 135–136° (2 mm.) and 1.0 g. of residue.

Summary

1. Benzyl nicotinamide has been prepared and found to possess antispasmodic activity.

2. A series of fifteen other amides of nicotinic acid and related acids has been prepared and submitted for pharmacological testing.

Optical Isomers of 2,3-Butanediol Produced by Fermentation

BY GEORGE E. WARD, O. GLENN PETTIJOHN, LEWIS B. LOCKWOOD AND ROBERT D. COGHILL

In connection with fermentation studies conducted at this Laboratory on the production of 2,3-butanediol, some of the properties of the isolated products have been determined. *levo*-2,3-Butanediol, previously unknown in pure form and not recognized heretofore as a fermentation product, has been identified as the chief substance formed by the action of *Bacillus polymyxa* on grain mash substrates.

Previous reports concerning fermentation butanediol have stated it to be essentially optically inactive, the slight *dextro* rotation sometimes observed being attributed to the presence of a relatively small quantity of the *dextro* isomer. The butanediol produced by Harden and Walpole,[2] the first investigators in the field, was examined by Walpole[3] and was reported to be essentially a mixture of two optically inactive glycols. This product had resulted from the action of *Bacterium lactis aerogenes* (*Aerobacter aerogenes*) on glucose. The butanediol prepared by Kluyver's process,[4] presumably using *Aerobacter aerogenes*, was investigated by Böeseken and Cohen[5] and found to have a specific rotation of +2.42° and a melting point of +25°. Attempts at resolution were unsuccessful. These data suggested that the principal constituent was *meso*-2,3-butanediol and that a small quantity of the *dextro*-rotatory isomer was also present.

During the past three years we have conducted numerous fermentations with *Aerobacter aerogenes*. The 2,3-butanediol isolated *en masse* from such liquors has consistently had a specific rotation of approximately +1.0° and has shown a tendency to crystallize at room temperatures. These observations are in essential agreement with the data presented by Böeseken and Cohen. The discrepancy in specific rotation is not especially significant, since we have observed that appreciable fractionation occurs during distillation of the glycol. Unless a quantity of glycol is distilled *in toto*, the rotation exhibited by any

given fraction may not be typical of that of the total product, the asymmetric isomers concentrating in the first fractions and the *meso* form appearing in the distillate in higher amounts toward the end of the distillation.

Besides studying the *Aerobacter* fermentation, we have investigated in some detail the fermentation of grain mashes by strains of *Bacillus polymyxa*. Although this species has long been known to produce 2,3-butanediol and acetylmethylcarbinol from starch, previous investigators have not reported differences between the butanediol of this origin and that formed by *Aerobacter* species. We have recently observed that the 2,3-butanediol produced by our preferred strain of *B. polymyxa* (N. R. R. L. No. B-510) differs markedly from the 2,3-butanediol produced by *Aerobacter aerogenes*, as shown in Table I.

TABLE I

	2,3-Butanediol isolated *en masse* from fermentation by	
	Bacillus polymyxa	*Aerobacter aerogenes*
Specific rotation (25°C.)	−13.0°	+1.0°
Melting point, °C.	+19	+25
Refractive index (25°C.)	1.4307	1.4384
Viscosity (25°C.), c. p.	41.0	118.0
Hydrate	None formed	Pentahydrate, m. p. +16.8°C.

Fractional distillation at 5 mm. pressure of butanediol possessing a specific rotation of approximately −13° has not yielded fractions of greater specific rotation than −13.19°, although such a procedure is effective in partially separating the *meso–dextro* mixture. It therefore seems probable that pure *levo*-2,3-butanediol has a specific rotation slightly in excess of −13.0°. It should be noted that we have not attempted resolution by procedures other than distillation, which would not separate the *dextro* and *levo* forms.

The highest specific rotation previously reported for optically active 2,3-butanediol was +6.9° for a sample of *dextro*-2,3-butanediol prepared from *dextro*-2,3-diaminobutane by Chappell.[6] There have been very few investigations of *levo*-2,3-butanediol. Neuberg and Nord[7] obtained small quantities of a substance possessing a specific rotation of −2.4° by the reducing action of yeast on diacetyl. Neuberg and Kobel[8] obtained an analogous preparation with a specific rotation of −5.51° by the action of yeast on acetylmethylcarbinol. In the light of our findings, it is apparent that these two products were composed principally of material other than *levo*-2,3-butanediol.

The fact that *levo*-2,3-butanediol does not form a hydrate is of importance in at least one of its possible applications, namely, as a constituent of antifreeze preparations. Freezing-point measurements of aqueous solutions show that whereas pure *meso*-butanediol with an equal weight of water forms a hydrate melting at +16.8°, the levorotatory isomer does not form such a hydrate, the freezing point depression decreasing regularly with increasing glycol concentration. *levo*-2,3-Butanediol appears to be approximately the equal of ethylene glycol in this respect.

Results are not yet at hand regarding the ability of other strains of *Bacillus polymyxa* to produce *levo*-2,3-butanediol. In view of the fact that the production of the *meso–dextro* mixture is characteristic of numerous strains of *Aerobacter*, it would not be surprising if many strains of *Bacillus polymyxa* will eventually be shown to be capable of producing the *levo* isomer.

Acknowledgment.—The authors gratefully acknowledge the determination of viscosity, freezing points of aqueous 2,3-butanediol systems, and fractional vacuum distillation observations by Drs. R. T. Milner, Duncan Macmillan, and N. C. Schieltz of the Analytical and Physical Chemical Division of this Laboratory. This work will be published in detail at a later date.

Summary

levo-2,3-Butanediol, possessing a specific rotation slightly in excess of −13.0°, has been isolated and identified as the chief substance formed by the action of *Bacillus polymyxa* (N. R. R. L. No. B-510) on grain mash substrates. This optical activity is far in excess of values previously ascribed to the asymmetric 2,3-butanediols.

In contrast to the *meso–dextro*-2,3-butanediol mixture produced in *Aerobacter aerogenes* fermentations, *levo*-2,3-butanediol possesses a relatively low viscosity and does not form a hydrate.

Allylic Rearrangements. XV. The Carbonation of Butenylmagnesium Bromide

BY JOHN F. LANE, JOHN D. ROBERTS* AND WILLIAM G. YOUNG

In the course of independent investigations in these Laboratories, studies have been made of the products resulting from the carbonation of the Grignard reagent derived from crotyl and methylvinylcarbinyl bromides.

At the University of California, Los Angeles, this work was carried out as part of an extensive program of research on the nature of the allylic Grignard reagent and its reactions with a variety of substances. The approach, therefore, was one which gave detailed attention to all of the products formed in the reaction. On the other hand, certain studies now in progress at Princeton University on the reactions of the isomeric olefinic acids R—CH=CH—CH_2CO_2H(I), R—CH(CO_2H)—CH=CH_2(II), led to an investigation of the carbonation of allylic Grignard reagents with particular attention being focused on the acidic components of the reaction mixture, since it appeared that a convenient method of the synthesis for at least one and perhaps both of the isomerides I and II would be available if the reaction proved successful.

Previous attempts to obtain unsaturated monocarboxylic acids by carbonating allylic Grignard reagents have met with only moderate success. Thus Houben[1] was able to obtain but an 11% yield of 3-butenoic acid when magnesium was allowed to act on allyl bromide in an atmosphere of carbon dioxide. Using the same technique Gilman and Harris[2] obtained a similarly low yield of 2-phenyl-3-butenoic acid from cinnamyl chloride. Subsequent experiments by Gilman and co-workers[3] in which a stream of carbon dioxide was passed into a previously prepared solution of the Grignard reagent gave only slightly better results.

In the present work the Grignard reagent was prepared by the action of magnesium on a mixture of crotyl and methylvinylcarbinyl bromides and the carbonation was carried out by two different methods. (1) A dilute ethereal solution of the butenylmagnesium bromide was poured rapidly onto a large excess of solid carbon dioxide and, after decomposition of the complexes, alkaline extraction and careful fractionation a good yield (75%, based on the Grignard reagent) of practically pure 2-methyl-3-butenoic acid was obtained. The acid, b. p. 95.5° (35 mm.), was converted to its chloride, b. p. 55–58° (110 mm.), and thence to the crystalline amide, m. p. 98°. Catalytic hydrogenation of the latter compound gave 2-methylbutanoamide, m. p. 110°.

(2) The carbonation of butenylmagnesium bromide by the procedure of Arnold[4] followed by decomposition of the complexes gave on direct fractionation of the ethereal layer (without alkaline extraction) 2-methyl-3-butenoic acid (63%), b. p. 94° (30 mm.). Other fractions consisted of lesser amounts of octadienes, b. p. 52–53° (100 mm.), a dibutenyl ketone (13%), b. p. 93–94° (100 mm.), and a high boiling residue, b. p. 100–115° (30 mm.), which may be alcoholic material. The principal fraction, as well as the intermediates containing acidic substances, gave α-phenylethylamine salts,[5] all of which melted at 118–120° without recrystallization. The structure of the acid was confirmed by isomerization with strong alkali to 2-methyl-2-butenoic acid (tiglic acid), m. p. 64°, and by hydrogenation to 2-methylbutanoic acid; anilide, m. p. 109°. The structures of the other products have not yet been elucidated.

These results using butenylmagnesium bromide show that the carbonation of an allylic Grignard reagent may give good yields of acids provided that a large excess of carbon dioxide and a low reaction temperature are used. It is also to be noted that such reactions apparently lead exclusively to acids of type II rather than I. Not only in the present studies, but also in the experiments of Gilman and Harris,[2,3a] no appreciable amounts of the latter type of acid were formed.

Experimental Part

Materials.—The mixture of butenyl bromides used in these experiments was prepared by the method of Claisen and Tietze[6] from a mixture of crotyl alcohol and methylvinylcarbinol purchased from the Shell Chemical Company. The butenyl bromide mixture boiled at 90–105° (39–51° (100 mm.)) and had $n^{20}D$ 1.4781 corresponding to the composition 80% crotyl bromide, 20% methylvinylcarbinyl bromide.[7] Magnesium turnings were prepared as needed from bars of the pure metal.

A. Action of Carbon Dioxide on Butenylmagnesium Bromide (J. F. L.).—A dilute ethereal solution of the Grignard reagent was prepared from the butenyl bromide (67.5 g., 0.5 mole) according to the procedure of Young, Prater and Winstein.[8] The yield of Grignard reagent was 82% (estimated by titration of an aliquot portion with standard hydrochloric acid). This solution (555 cc.) was poured rapidly onto 400 g. of solid carbon dioxide broken into small lumps. After the excess of solid carbon dioxide had evaporated, the mixture was treated with ice and concentrated hydrochloric acid (75 cc.) to decompose the

Digitized by Arya Samaj Foundation Chennai and eGangotri

magnesium complex. The ethereal layer was then removed and the aqueous residue saturated with salt and extracted three times with ether, these extracts being united with the original ethereal solution of the product. The resulting solution was extracted three times with 100-cc. portions of 10% sodium carbonate solution. The united carbonate extracts were washed with ether, acidified with concentrated hydrochloric acid, saturated with salt, and extracted four times with ether. The united ethereal extracts were dried over anhydrous sodium sulfate. Removal of the ether by distillation gave 33 g. of the crude organic acid.

The crude product (65 g.) obtained from two such runs was freed from a small amount of residual water by mixing it with 100 cc. of benzene and removing the benzene by distillation at 100 mm. The residue from this treatment was subjected to fractionation at 35 mm. through a 1-m. column packed with Fenske spirals. Fractions were collected as follows

1	94.5°	1.5 g.	$n^{25}D$	1.4213
2	95.5°	52.0 g.	$n^{25}D$	1.4210
Holdup		9.0 g.		

The holdup was distilled from a small Claisen flask at 17 mm. The bulk of the material (6.2 g.) distilled at 80.5° and had $n^{25}D$ 1.4210. The remainder distilled at 80.5–90° and had $n^{25}D$ 1.4230. If the impurity in this fraction was 3-pentenoic acid, b. p. 93° (14 mm.), $n^{25}D$ 1.4346,[9] the amount present could not be more than 0.34 g. (13% of this fraction) or 0.5% of the total amount of the product obtained. Titration of the acid in aqueous solution gave the values 100.3, 100.5 for the equivalent weight (calcd. for $C_4H_8O_2$, 100.1).

The acid (8 g.) was warmed on the water-bath for twenty minutes with 10 g. of phosphorus trichloride. At the end of this time the upper layer of crude acid chloride was decanted into a small Claisen flask and distilled under reduced pressure. The bulk of the material (7 g.) distilled at 55-58° (110 mm.).

The acid chloride so prepared was taken up in 100 cc. of absolute ether, and ammonia gas was passed into the solution for one-half hour. The precipitated ammonium chloride was removed by filtration and the solution evaporated to dryness. The amide so obtained was purified by recrystallization from a mixture of benzene and petroleum ether, 5.0 g., m. p. 98°.

Anal. Calcd. for C_5H_9ON: N, 14.13. Found: N, 13.8.

The amide (1.0 g.) was dissolved in 25 cc. of alcohol and hydrogenated over 0.05 g. of Adams catalyst. The uptake of hydrogen was rapid and ceased after twenty minutes (98%). The catalyst was removed by filtration and the solution evaporated to dryness under diminished pressure. The crystalline residue melted at 110°, and the melting point was not depressed on admixture with an authentic specimen of 2-methylbutanoamide, m. p. 110°.

B. Action of Carbon Dioxide on Butenylmagnesium Bromide (J. D. R.).—The Grignard reagent (0.91 mole) was prepared as previously reported[8] in 84% yield[10] from butenyl bromide, magnesium turnings and dry ether in the relative mole quantities 1, 3 and 12, respectively. Of this 0.32 mole was carbonated smoothly by the procedure of Arnold[4] over a period of two hours.

The magnesium complexes were decomposed by ice and saturated ammonium chloride, the mixture acidified with dilute hydrochloric acid and the resulting ethereal layer of the products dried over magnesium sulfate. After evaporating the bulk of the ether, fractionation through a 70-cm. column[11] packed with small glass helices gave the following cuts:

Fraction	B. p., °C.	Press., mm.	Wt., g.	$n^{20}D$
1	34– 35	753	5.2	....
2	46– 52	100	0.8	1.4232
3	52– 53	100	2.1	1.4239
4–6	53– 85	100	2.2	1.4253–1.4351
7	93– 94	100	1.8	1.4371
8–11	94–118	100	2.7	1.4388–1.4352
12–13	118–119	100	7.54	1.4251–1.4235
14	94	30	8.1	1.4226
15–16	94–115	30	4.69	1.4390–1.4625

Residue 1.5 g.

Fraction 1 is diethyl ether and Fractions 2–6 consist mainly of octadienes formed by the coupling of the butenylmagnesium bromide with butenyl bromide. Except for carbon–hydrogen analysis on Fraction 3, these were not further investigated.

Anal. Calcd. for C_8H_{14}: C, 87.19; H, 12.80. Found: C, 85.69; H, 12.85.

Fraction 7 gave a positive test with 2,4-dinitrophenylhydrazine reagent and the analysis indicated that the material was a dibutenyl ketone.

Anal. Calcd. for $C_9H_{14}O$: C, 78.21; H, 10.21. Found: C, 77.23; H, 10.10.

Fractions 11, 14 and 16, but not Fraction 7, gave nicely crystalline α-phenylethylamine salts[5] which without recrystallization melted from 118–120°. A sample crystallized from ethyl acetate for analysis showed m. p. 119.5–120.5°.

Anal. Calcd. for $C_{13}H_{19}O_2N$: C, 70.55; H, 9.11. Found: C, 70.22; H, 8.78.

The structure of the acid (Fraction 14) was confirmed in the following ways.

(1) Hydrogenation of a 2.13-g. sample over platinum oxide in ethyl acetate gave 2-methylbutanoic acid, b. p. 90–95° (35 mm.), $n^{20}D$ 1.4069; yield 1.9 g. (90%). Somewhat less than the theoretical amount of hydrogen was absorbed (83%). The saturated acid was identified by conversion to the anilide m. p. 109° (lit., 105.5–106.5°,[12a] 108°,[12b] 110–111°[12c]).

(2) A small sample of the acid was refluxed with 60% potassium hydroxide solution for ten minutes.[13] After dilution, acidification and purification of the product there was obtained tiglic acid, m. p. 64° (lit.,[14] 64°).

Anal. Calcd. for $C_5H_8O_2$ (2-methyl-3-butenoic acid): C, 59.98; H, 8.05; neut. eq., 100.1. Found: C, 59.35; H, 8.24; neut. eq., 104.2.

Investigation of the higher boiling material which is probably an alcoholic substance is in progress.

Summary

1. From the reaction of carbon dioxide with butenylmagnesium bromide 2-methyl-3-butenoic acid was obtained in excellent yield. No detectable amounts of the isomeric 3-pentenoic acid were isolated. Other non-acidic substances were formed in the reaction.

2. It is indicated that good yields of acids from carbonation of allylic Grignard reagents may be obtained by using a low reaction temperature and a large excess of carbon dioxide.

(9) Constants determined for a sample of pure 3-pentenoic acid prepared by the method of Linstead, Noble and Boorman, *J. Chem. Soc.*, 557 (1933).

(10) If very vigorous stirring is used, such as that afforded by a Model L "Lightning" mixer driving a large Hershberg stirrer, the time of addition may be cut to three hours or less without apparent diminution in the yield of Grignard reagent.

Allylic Rearrangement in the Reaction of Cuprous Cyanide with Butenyl Halides[1]

BY JOHN F. LANE, JAMES FENTRESS AND L. T. SHERWOOD, JR.

That cuprous cyanide reacts smoothly with allyl halides to give good yields of 3-butenonitrile is well known.[2] Until the present time, however, the reaction has not been extended to α- and γ-substituted allyl halides; *i. e.*

$$R{-}CHX{-}CH{=}CH_2\ (I),\quad R{-}CH{=}CH{-}CH_2X\ (II)\qquad (X = Cl, Br)$$

In connection with studies being carried out in this Laboratory on the preparation and reactions of isomeric olefinic acids of the type

$$R{-}CH(CO_2H){-}CH{=}CH_2\ (III)$$
$$R{-}CH{=}CH{-}CH_2CO_2H\ (IV)$$

it seemed desirable to investigate the action of cuprous cyanide on a pair of allylic isomerides such as I and II in the hope of producing the nitriles

$$R{-}CH(CN){-}CH{=}CH_2\ (V)$$
$$R{-}CH{=}CH{-}CH_2CN\ (VI)$$

corresponding to the acids III and IV.

Replacement of halogen by cyanide in such a system might proceed either by normal (bimolecular) substitution to give the expected nitrile from each isomeride

$$(1)\quad R{-}CH{=}CH{-}CH_2X + CuCN \longrightarrow R{-}CH{=}CH{-}CH_2CN + CuX$$

or by an "ionic" mechanism

$$(2)\quad R{-}CH{=}CH{-}CH_2X \longrightarrow X^- + [R{-}CH{=}CH{=}CH_2]^+ \xrightarrow{CN^-} \begin{cases} R{-}CH{=}CH{-}CH_2CN \\ R{-}CH(CN){-}CH{=}CH_2 \end{cases}$$
(VII)

to give a mixture of the isomeric nitriles V and VI.[3] In the latter event the composition of the mixture obtained should be independent first of the isomeric halide (I or II) used, and second of the nature of X. There remains also the possibility that the replacement might proceed by an "inverse" (bimolecular) substitution process[3c] to give from each isomeric halide the nitrile corresponding to the other form

$$(3)\quad R{-}CH{=}CH{-}CH_2X + CuCN \longrightarrow R{-}CH(CN){-}CH{=}CH_2 + CuX$$

Of these three types of substitution process, all of which are known in reactions involving allylic systems, the process 2 is most frequently encountered, since the high resonance energy of ions such as VII greatly facilitates reaction by this path.

We have investigated the action of cuprous cyanide on the butenyl halides (R = CH_3, X = Cl, Br) and have found that at 60–70°, regardless of the nature of the halide used, the same mixture of isomeric nitriles is always produced

$$\left.\begin{matrix} CH_3{-}CH{=}CH{-}CH_2X + CuCN \\ CH_3{-}CHX{-}CH{=}CH_2 + CuCN \end{matrix}\right\rangle \begin{cases} CH_3{-}CH{=}CH{-}CH_2CN \\ CH_3{-}CH(CN){-}CH{=}CH_2 \end{cases} + CuX$$

After the two pure isomers had been isolated, it was possible to estimate the composition of this mixture by measurement of the refractive index. By this means we have determined that the mixture produced in each instance consisted of 91.5 ± 0.5% 3-pentenonitrile and 8.5 ± 0.5% 2-methyl-3-butenonitrile.

The simplest interpretation of these results is that the action of cuprous cyanide on halides such as I and II belongs to that class of allylic replacement reactions which are completely "ionic" in nature (mechanism 2 above). It has been pointed out,[3a] however, that assignment of such a mechanism may be most satisfactorily made only when the allylic reactants and products are not susceptible to thermal rearrangement under the conditions employed. While in the present investigation this requirement was fulfilled with respect to the products of the reaction, it could not be fulfilled with respect to the reacting halides. Even the butenyl chlorides, normally rather stable substances, are, under the conditions of the reaction (*i. e.*, at 60° in the presence of cuprous chloride), isomerized fairly rapidly to an equilibrium mixture containing 74.0 ± 0.5% 1-chloro-2-butene and 26.0 ± 0.5% 3-chloro-1-butene. The butenyl bromides, of course, are extremely labile substances which rearrange almost instantaneously at elevated temperatures to an equilibrium mixture containing 87% 1-bromo-2-butene and 13% 3-bromo-1-butene.[4]

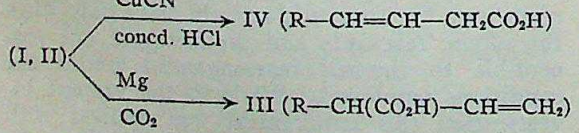
We feel, however, that an alternative mechanism presuming initial rearrangement of the butenyl halides followed by reaction of each isomer in normal fashion (mechanism 1 above) is improbable. It is scarcely possible that such normal reactions of the two isomeric halides present at equilibrium in each case could proceed at precisely those rates necessary to give the same mixture of nitriles regardless of whether the reactants were butenyl bromides or butenyl chlorides. We prefer to assume, therefore, that the composition of the nitrile mixture is governed entirely by the relative rates of coördination of the entering cyanide ion at positions 1 and 3 in the mesomeric carbonium ion

$$[CH_3—CH{=}{=}CH{=}{=}CH_2]^+ \quad (VII, R = CH_3)$$

We have also investigated the reaction of each of the two isomeric nitriles with concentrated hydrochloric acid according to the technique of Falaise and Frognier[5] for the preparation of 3-butenoic acid from 3-butenonitrile. It was found that while 3-pentenonitrile was readily converted to 3-pentenoic acid by this method, 2-methyl-3-butenonitrile was scarcely affected under the same conditions. Refluxing concentrated hydrochloric acid slowly attacked the latter nitrile to produce extensive charring but did not produce any appreciable amounts of the expected 2-methyl-3-butenoic acid.

From the results of this study it would appear that to derive an acid of type IV from either of the corresponding pair of halides (I, II) the proper procedure consists in treating the halides with cuprous cyanide and hydrolyzing the resulting nitrile with concentrated hydrochloric acid. On the other hand, the results previously reported[6] on the carbonation of butenylmagnesium bromide indicate that acids of type III will be exclusively produced when the corresponding halides (I, II) are converted to the Grignard reagent and the latter is treated with carbon dioxide. This may be summarized as follows



The general applicability of such methods to systems involving different alkyl and aryl groups R is being investigated.

Experimental Part

Materials.—1-Chloro-2-butene ($n^{20}D$ 1.4350), 2-chloro-1-butene ($n^{20}D$ 1.4150) and mixtures of these two butenyl chlorides were prepared by fractionation of a mixture containing approximately equal quantities of the two isomers which was purchased from the Shell Chemical Company. The composition of mixtures was determined before use in each instance by measurement of the refractive index. The mixture of butenyl bromides used in these experiments was prepared by the method of Claisen and Tietze[7] from a mixture of crotyl alcohol and methylvinylcarbinol purchased from the Shell Chemical Company. The cuprous cyanide employed in the preparation of nitriles was the Merck technical grade, dried for two hours at 110° before use. Cuprous chloride was prepared by the method of Marvel and McElvain,[8] washed successively with glacial acetic acid, alcohol, and ether, and dried in a vacuum desiccator over sulfuric acid before use.

Preparation of 3-Pentenonitrile and 2-Methyl-3-butenonitrile.—The method used was similar to that described by Bruylants, Breckpot and others[2] for the preparation of allyl cyanide from allyl halides. One hundred grams of a mixture of butenyl chlorides ($n^{20}D$ 1.4238: 56% 3-chloro-1-butene, 48% 1-chloro-2-butene) was mixed with dry cuprous cyanide (110 g.) in a flask equipped with a mechanical stirrer and an efficient reflux condenser protected by a calcium chloride tube. The mixture was heated on the water-bath with continuous stirring for one and one-half hours at 60–70°. The temperature of the bath was then increased to 95–100° for an additional half-hour in order to ensure complete reaction of the halide. The stirrer having been removed, the water-bath was replaced by an oil-bath, and at a bath temperature of 150–160° the volatile products were distilled under diminished pressure (200–100 mm.) into a trap immersed in an ice-salt bath. The crude product (70 g.) was dried over phosphorus pentoxide.

Fractionation of the product so obtained (200 g.) through a one meter column packed with glass helices, gave pure 3-pentenonitrile (133 g.); b. p. 146° (cor.); $n^{20}D$ 1.4228; d^{20}_4 0.8369[9]; M_D, calcd. 24.59, obs. 24.60, together with a low-boiling material, b. p. 120–143°. Systematic refractionation of this material gave pure 2-methyl-3-butenonitrile (22 g.); b. p. 126° (cor.); $n^{20}D$ 1.4063; d^{20}_4 0.8131; M_D, calcd. 24.59, obs. 24.57.

Anal. Calcd. for C_5H_7N: N, 17.26. Found: 3-pentenonitrile, N, 17.2, 2-methyl-3-butenonitrile, N, 17.5.

The identity of the low-boiling nitrile was further confirmed by preparation of an identical substance from 2-methyl-3-butenoamide[6] by dehydration with phosphorus pentoxide according to the technique of v. Auwers[9] for the preparation of 3-pentenonitrile from 3-pentenoamide. The nitrile so prepared boiled at 126° cor. and had $n^{20}D$ 1.4065; d^{20}_4 0.8131.

The refractive index of a mixture of the two nitriles was found to vary linearly with the composition. Mixtures of the two isomers could therefore be conveniently determined by measurement of this property.

TABLE I

REFRACTIVE INDICES OF MIXTURES OF 3-PENTENONITRILE AND 2-METHYL-3-BUTENONITRILE

Mixture	1	2	3
3-Pentenonitrile, %	30.0	50.0	74.0
2-Methyl-3-butenonitrile, %	70.0	50.0	26.0
$n^{20}D$ (calcd.)	1.4113	1.4146	1.4185
$n^{20}D$ (obs.)	1.4113	1.4146	1.4184

Action of Cuprous Cyanide on Different Butenyl Halides.—The procedure described above was repeated using (1) a mixture of butenyl chlorides (1 mole; $n^{20}D$ 1.4170) containing 90% 3-chloro-1-butene, 10% 1-chloro-2-butene; (2) pure 1-chloro-2-butene (1 mole, $n^{20}D$ 1.4350); (3) a mixture of butenyl bromides (⅔ mole, $n^{20}D$ 1.4781) containing 80% 1-bromo-2-butene, 20% 3-bromo-1-butene. These gave the following mixtures of nitriles: (1) 60 g., $n^{20}D$ 1.4215; (2) 58 g., $n^{20}D$ 1.4214; (3) 47 g., $n^{20}D$ 1.4212. The composition of the product in each instance was estimated first from the refractive index of the crude

mixture (method A) and then from the refractive indices and weights of the fractions obtained when the crude mixture was submitted to fractionation (method B). Thus, for mixture (1) the composition estimated by method A was 92.1% 3-pentenonitrile, 7.9% 2-methyl-3-butenonitrile, while fractionation gave the following results:

Fraction	Wt., g.	B. p. (755 mm.), °C.	$n^{20}D$	3-Pentenonitrile (g.)	2-Methyl-3-butenonitrile (g.)
(a)[10]	10.7	119–140	1.4154	5.91	4.79
(b)	1.8	140–141.5	1.4220	1.71	0.09
(c)	45.8	141.5	1.4228	45.8	.00
Total				53.4	4.88

from which the estimated percentage composition (method B) was 91.7% 3-pentenonitrile, 8.3% 2-methyl-3-butenonitrile. The residue (2 g.) was a viscous tarry material. The compositions of the three mixtures as estimated by both methods are given in Table II. Regardless of the

TABLE II

COMPOSITION OF THE NITRILE MIXTURE PRODUCED BY THE ACTION OF CUPROUS CYANIDE ON BUTENYL HALIDES

Mixture	$n^{20}D$ (crude)	Composition, % 3-Pentenonitrile A	3-Pentenonitrile B	2-Methyl-3-butenonitrile A	2-Methyl-3-butenonitrile B
(1)	1.4215	92.1	91.7	7.9	8.3
(2)	1.4214	91.5	91.2	8.5	8.8
(3)	1.4212	90.3	91.6	9.7	8.4
Av.	1.4214	91.3±0.6	91.5±0.2	8.7±0.6	8.5±0.2

butenyl halide used, the reaction leads to a mixture of nitriles having the composition 91.5 ± 0.5% 3-pentenonitrile, 8.5 ± 0.5% 2-methyl-3-butenonitrile.

Action of Cuprous Cyanide on the Isomeric Nitriles.—To 8 g. of a mixture of 3-pentenonitrile (44.3%) and 2-methylbutenonitrile (55.7%), $n^{20}D$ 1.4136, was added an equal weight of cuprous cyanide. The mixture was heated for three hours with frequent agitation on the boiling water-bath. At the end of this time the water-bath was replaced by an oil-bath, and at a temperature of 140–150° the nitriles were distilled completely into a trap cooled by an alcohol–dry-ice mixture. The last traces of volatile material were removed from the cuprous cyanide at a pressure of 20 mm. The refractive index of the nitrile mixture so obtained was $n^{20}D$ 1.4137, corresponding, within the experimental error of the measurement, to the same composition as that of the starting material. It may therefore be concluded that under conditions such as those employed in their synthesis and purification these nitriles are quite stable and show no tendency toward interconversion.

Action of Cuprous Chloride on the Butenyl Chlorides.—The butenyl chloride (30 g.) was stirred mechanically under reflux at 60° with an equal weight of cuprous chloride. Five-ml. samples were removed at intervals and transferred to a small distilling flask. The chloride was then distilled completely from the copper salt at a temperature of 30–35° and a pressure of 15 mm. into a trap cooled in an alcohol–dry-ice mixture. The composition of the purified sample was determined by measurement of the refractive index. The results are summarized in Table III. It is evident that an equilibrium mixture of the two chlorides having the composition crotyl chloride 74.0 ± 0.5%, methylvinylcarbinyl chloride 26.0 ± 0.5% is rapidly produced over cuprous chloride at this temperature.

Preparation of 3-Pentenoic Acid from 3-Pentenonitrile.—3-Pentenonitrile (81 g.) was treated

(10) Direct estimation of halogen by a slightly modified Volhard procedure, standardized against the pure butenyl halides, indicated that this fraction and the corresponding first fractions for mixtures (2) and (3) contained in each instance less than 0.2% unreacted butenyl chloride.

TABLE III

ISOMERIZATION OF BUTENYL CHLORIDES OVER CUPROUS CHLORIDE AT 60°

Expt.	Time, hr.	$n^{20}D$ of butenyl chloride mixture	Composition, % Crotyl chloride	Composition, % Methylvinylcarbinyl chloride
	0	1.4168	9.0	91.0
I	1.5	1.4298	74.0	26.0
	3.0	1.4299	74.5	25.5
	0	1.4331	90.5	9.5
II	1.0	1.4301	75.5	24.5
	2.0	1.4299	74.5	25.5
	3.0	1.4297	73.5	26.5

with concentrated hydrochloric acid (100 ml.) in the manner described by Falaise and Frognier[5] for the conversion of 3-butenonitrile to 3-butenoic acid. After twenty-five minutes the reaction mixture was diluted with water, saturated with salt and extracted four times with ether. The acid was obtained from the ethereal extract by alkaline extraction as previously described[6] for the isolation and purification of 2-methyl-3-butenoic acid. It distilled completely at 93° (14 mm.): m. p. −0.5°; $n^{20}D$ 1.4362; d^{20}_4 0.9876; M_D calcd. 26.36, obs., 26.50; eq. wt., calcd. 100.1, obs., 101. The melting point of the product was not depressed by admixture with 3-pentenoic acid prepared by the method of Linstead, Noble and Boorman.[11] When the acid was treated with bromine in carbon disulfide solution, the crystalline dibromide,[12] m. p. 64°, was obtained. The yield of pure acid was 70 g., 70% of the theoretical amount. This yield may be somewhat bettered when large quantities of the acid are to be prepared, since unreacted 3-pentenonitrile may then be profitably recovered from the neutral ethereal extracts of several runs and subjected again to hydrolysis in the manner described.

Attempted Hydrolysis of 2-Methyl-3-butenonitrile.—The experiment described above was repeated using 2-methyl-3-butenonitrile (10 g.) and 15 cc. of concentrated hydrochloric acid. On treatment of the reaction mixture by the purification methods described almost all of the nitrile was recovered in the neutral fraction (9 g.). The sodium carbonate extract was acidified and extracted with ether as before, but no appreciable amount of product was obtained on evaporation of this ethereal extract. When the nitrile (4 g.) was refluxed for one-half hour with concentrated hydrochloric acid, extensive charring took place. On working up the reaction mixture a neutral fraction of 3 g. was obtained. Less than 0.1 g. of acidic material was obtained by ether extraction of the acidified carbonate extract.

Summary

Cuprous cyanide acts on crotyl and methylvinylcarbinyl halides to produce a mixture of isomeric nitriles containing 91.5 ± 0.5% 3-pentenonitrile and 8.5 ± 0.5% 2-methyl-3-butenonitrile. It is suggested that this reaction belongs to that type of allylic replacement reaction which proceeds through a mesomeric carbonium ion.

It has been further shown that of the two isomeric nitriles produced by this reaction only 3-pentenonitrile is susceptible to acid hydrolysis.

These results and those of a previous study[6] on the carbonation of butenylmagnesium bromide indicate that either an α or γ-substituted butenoic acid may be prepared from either of a given pair of α- and γ-substituted allyl halides by an appropriate choice of method, as shown.

PRINCETON, NEW JERSEY RECEIVED OCTOBER 30, 1943

Fish Poisons from *Ichthyomethia Piscipula*. I

BY ALFRED RUSSELL AND E. A. KACZKA[1]

Since the occurrence of toxic principles in various species in many genera of the family *Fabaceae* is well established and covered in several review articles,[2] it is unnecessary to give here a general survey of the field.

In connection with another study[3] there was collected on Key Largo, Florida, several hundred pounds of the roots, and wood, including bark, of the Jamaica dogwood. The powdered bark of the roots has been used extensively throughout tropical and subtropical America to narcotize fish but no exact information is available as to the nature of the toxic materials present.

The Jamaica dogwood has now been identified as *Ichthyomethia piscipula* (L) A. Hitchc. and it appears to be the same species as *Piscidia erythrina* L. Although six species in genus *Ichthyomethia* are stated[4] to occur in tropical and subtropical America, *I. piscipula* is the only member native to the United States.

E. Hart[5] separated, from a commercial liquid extract of *Piscidia erythrina*, a substance of m. p. 192° which he claimed was the toxic principle and named it piscidia. Freer and Clover[6] denied this, stating that Hart's product was not toxic and was not a chemical individual but a mixture of two distinct compounds, one melting at 201° and the other at 216°. They obtained a number of products from *Piscidia erythrina* "bark" by extraction with water and with petroleum ether. None of these was positively identified and apparently no toxicity tests were made since none was claimed to be toxic.

A drug known as "Cortex Piscidiae erythrinae," claimed to be an extract of the bark of *Piscidia erythrina*, was examined by Dankwortt and Schütte.[7] Ten assorted products were isolated by these workers and they came to the conclusion that the toxic principle was an amorphous saponin. Finally, Hauschild[8] made an examination of the bark of *Piscidia erythrina* and concluded that the toxic substance was a crystalline material m. p. 72° and not the saponin of Dankwortt and Schütte.

Obviously there is no way of correlating this earlier work since it appears that four different initial materials were used—root bark, tree bark, a commercial liquid extract and "Cortex Piscidiae erythrinae."

The physiological properties associated with *Piscidia erythrina* may be summarized: Ott[9] states that it is a direct sedative, producing narcotic effects that are refreshing and not followed, like those produced by opium, by hyperaemia of the brain, nausea and general nervous disturbance. It is claimed, also by Ott,[10] to be of value in treatment of bronchitis, asthma, nervous cough, writer's cramp, muscular spasms, chorea, tetanus and toothache. According to Reko[11] some quantity of *Piscidia erythrina* is included in "Sinicuichi"—a Mexican drink which causes rapid stupefaction. Drake and Spies[12] and Hauschild[8] report that an extract of the bark is toxic to goldfish.

In the present work, a few preliminary tests showed that the powdered root bark and root wood were very toxic to goldfish, two grams of either sprinkled into four liters of water producing death in a few minutes. Neither the powdered wood nor the powdered bark of the tree were noticeably toxic. Accordingly the work has been confined to a study of the extractives of the root bark and root wood.

Extraction of the ground bark with cold water followed by evaporation at low temperatures gave a large quantity (30% of the weight of the bark) of a dark colored resinous vitreous material. This extract was toxic to goldfish, the extracted bark was not. No satisfactory analytical separation of the components of aqueous extract could be achieved and the procedure was abandoned. Extractions with methanol, acetone and ethyl

acetate were similarly unsatisfactory. Finally it was found that prolonged extraction (Soxhlet) of the dried bark with petroleum ether (30–60°) removed all the toxic material with a small quantity of wax. The latter was easily removed from the dried petroleum ether extract by washing with ether. The ether washed residue formed a white crystalline mass. After this preliminary trial, the extraction was carried out on a much larger scale using a continuous type extractor handling about two kilos of bark at one time. The crystalline material was most easily separated by interrupting the extraction when much of the more soluble part had been removed (continued extraction gave the less soluble portion). Final purification was accomplished by repeated crystallizations from ethanol. Two pure compounds A and B were isolated.

The same two compounds occur to the same extent and in about the same proportion in the root wood. Extraction of the root wood by the same process as applied to the bark was, comparatively, very easy and the wood was used as the source of most of the toxic material examined.

Extraction of the root bark or root wood (Soxhlet) with chloroform gave some low-melting, wax-like material that had toxic properties. This product has not been further examined.

Both A and B are very toxic to goldfish, causing death in less than two hours at a dilution of about one part in a million. The compound A is identical with rotenone; the compound B is new and is, very likely, closely related to rotenone, its molecular formula is $C_{23}H_{20}O_7$ and it has been named "ichthynone."

Experimental

Qualitative Extractions of Root Bark and Root Wood of *I. piscipula* with Petroleum Ether.—I. Root bark: 50 g. of air dry bark (milled to the consistency of tea) was extracted in a large Soxhlet apparatus. The apparatus functioned about twenty times an hour and the bark was exhausted of toxic materials after twenty-four hours. The solvent was distilled and the residue collected—this was a pale yellow crystalline mass containing a little wax. The wax was removed by washing three times with 10-cc. portions of ether. The wax-free residue formed a white crystalline mass that was very toxic. The yield was 0.04 g.

II. Root wood: 50 g. of air-dry wood (chipped to about the size of rice) was extracted and treated as described for the bark. The yield of mixed crystalline, wax-free, toxic material was 0.039 g.

The large-scale extraction process was run fifteen times and a total of 18 g. of wax-free crystalline toxic material was obtained.

Separation of Rotenone.—The more soluble fraction, obtained when the extraction process was interrupted, was freed from traces of wax by washing with ether—the ether washed residue melted at 150–155°. After eight crystallizations from ethanol, a pure compound of m. p. 164° resulted. Its solubility in various solvents were in agreement with those recorded for rotenone and it gave a positive Durham test identical with that given by rotenone. *Anal.* Calcd. for $C_{23}H_{22}O_6$: C, 70.05; H, 5.58. Found: C, 70.08; H, 5.72. Mixed m. p. (with sample of authentic rotenone) was 163°.

Isolation of Icthynone.—The less soluble fraction obtained during the second extraction period was collected, freed from traces of wax by washing twice with 10-cc. portions of ether and crystallized four times from ethanol. A pure compound crystallizing in stout hexagonal rodlets was obtained m. p. 203–204°. *Anal.* Calcd. for $C_{23}H_{20}O_7$: C, 67.65; H, 4.92; mol. wt., 408. Found: C, 67.50; H, 5.07; C, 67.61; H, 5.14; C, 67.49; H, 5.09; mol. wt. 398, 416, 384, 390, av. 397. (The low solubility of ichthynone in all suitable solvents made it difficult to get consistent values for molecular weight. The above values were obtained by the boiling point method using chloroform as a solvent.)

Ichthynone is insoluble in water, acids or alkalies, very slightly soluble in petroleum ether, diethyl ether and acetone, and rather more soluble in ethanol, chloroform, and carbon tetrachloride. Ichthynone is optically inactive and is an unsaturated ketone containing two methoxyl groups. There is no evidence indicating the presence of either an alcoholic or a phenolic hydroxyl group. This distinguishes ichthynone from toxicarol, sumatrol and tephrosin since toxicarol and sumatrol are phenolic in character while tephrosin contains an alcoholic hydroxyl group that is easily removed by dehydration. However, all attempts to dehydrate ichthynone were unsuccessful. *Estimation of methoxyl:* Calcd. for $C_{21}H_{14}O_5(OCH_3)_2$: OCH_3, 15.2. Found: OCH_3, 15.1, 15.2, 15.8.

Estimation of Unsaturation: I. Ichthynone Dibromide.—0.25 g. ichthynone was dissolved in 26 cc. of carbon tetrachloride containing 0.12 g. of bromine and the solution refluxed for three hours. The carbon tetrachloride was evaporated, the white crystalline residue washed with a little ether and dried, m. p. 234–235°. *Anal.* Calcd. for $C_{23}H_{20}O_7Br_2$: Br, 28.2. Found: Br, 27.2. 26.0.

II. Tetrahydroichthynone.—1.00 g. of ichthynone, dissolved in 150 cc. ethyl acetate containing 0.1 g. of platinum black, was reduced (room temperature) in a low pressure (semi-micro) bomb (30 cm. pressure). After three hours no more hydrogen was taken up and the reduced product, which had precipitated, was collected, separated from the catalyst by dissolving in sufficient hot alcohol and filtering. On cooling tetrahydroichthynone separated in slender white needles, m. p. 233–234° after one recrystallization. *Anal.* Calcd. for $C_{23}H_{24}O_7$: C, 66.99; H, 5.82. Found: C, 67.30; H, 5.83.

Carbonyl Derivatives. I. Ichthynone Hydrazone.—0.20 g. of ichthynone and 0.20 g. of hydrazine hydrate were dissolved in 50 cc. of ethanol and 2 cc. of 0.1 *N* KOH added. The solution was refluxed for four hours, cooled and neutralized, whereupon the hydrazone crystallized. It was collected, washed with a little ethanol and crystallized twice from ethanol as pale yellow needles, m. p. 215–217°. *Anal.* Calcd. for $C_{23}H_{22}O_6N_2$: N, 6.63. Found: N, 6.70, 6.77.

II. Ichthynone Phenylhydrazone.—0.50 g. of ichthynone was dissolved in 100 cc. of ethanol and 5 cc. of phenylhydrazine, followed by 2.5 cc. of 0.2 *N* KOH, added. After refluxing for four hours the reaction mixture was cooled and neutralized. After standing for twelve hours the phenylhydrazone separated. Recrystallized twice from ethanol it formed brilliant yellow needles m. p. 195–200° (d.). *Anal.* Calcd. for $C_{29}H_{26}O_6N_2$: N, 5.62. Found: N, 5.76, 5.77.

Toxicity Tests on Goldfish.—0.001 g. of ichthynone dispersed (by dissolving in 1 cc. of acetone and then adding the solution to water) in 1000 cc. of water was fatal to goldfish in less than two hours. Ichthynone is, then, toxic to goldfish at a concentration of approximately one part in a million.

Summary

Extraction of the root bark or root wood of *Ichthyomethia piscipula* with petroleum ether gives a mixture of crystalline materials very toxic to goldfish.

Two pure compounds have been isolated, rotenone and a new compound "ichthynone." Ichthynone crystallizes difficultly from ethanol in sturdy hexagonal rodlets m. p. 203–204°. It

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

has the molecular formula $C_{23}H_{20}O_7$ and is an unsaturated ketone containing two methoxyl groups.

Ichthynone kills goldfish at a concentration of, approximately, one part in a million.

The Nitrogen Compounds in Petroleum Distillates. XXV. Isolation and Identification of 3- and 4-Cyclopentylpyridines from California Petroleum

BY H. L. LOCHTE, E. D. THOMAS[1,2] AND PRICE TRUITT[3]

In a recent communication from this Laboratory[4] the chloroform extraction method of Bailey and co-workers[5] was extended to the hydrochlorides of petroleum bases boiling below the quinolines in the hope that, just as in the higher boiling range where the quinolines are found in the water layer and those of the substituted pyridines in the chloroform layer, so in the lower range the water layer might selectively dissolve the hydrochlorides of pyridines carrying cyclic substituents while the chloroform layer might hold the alkyl substituted pyridines. The chloroform layer was indeed found to contain alkyl substituted pyridines of which *dl*-2-(*s*-butyl)-4,5-dimethylpyridine was identified and several others isolated and analyzed.[4]

The water layer from the chloroform extraction of hydrochlorides of bases boiling at 210–213° reported in the previous communication[4] has been studied to determine what type of bases predominate.

Using a combination of fractionation by distillation and by fractional neutralization two isomeric cyclopentylpyridines were isolated. Since 2-cyclopentylpyridine is easily prepared by the interesting reaction of Emmert,[6] this compound was synthesized but it was found that neither of the petroleum compounds was identical with it.

Since one of the petroleum pyridines must then be the 3- and the other the 4-cyclopentylpyridine and since there was not enough pure base available to warrant a study of conditions required to obtain nicotinic or isonicotinic acids by oxidation, the synthesis of 3- and 4-substituted pyridines was studied. The new method of Crouch and Lochte[7] was finally used to prepare both 3- and 4-cyclopentylpyridines and thus show that the base yielding a picrate melting at 117.5° is 3-cyclopentylpyridine and the other one is the 4-cyclopentyl isomer.

Experimental

Fractional Distillation of Bases from Water Layer of Chloroform Extraction of 210–213° California Petroleum Bases.—Approximately three liters of bases were obtained from the water layer of the extraction reported in the previous paper.[4] These bases were distilled through a 12-foot Berl saddle-packed steel column at 20 mm. pressure using a 10:1 reflux ratio to yield 13 fractions of 240 cc. boiling at 207–219° with 9 fractions boiling between 212.5 and 214.0°. The index of refraction ranged from 1.502 to 1.516, that of the 9 fractions lay between 1.510 and 1.511, thus indicating that unsaturated or cyclic substituents might be expected.

Fractional Acid Extraction.—Fraction 6 (b. p. 213°; $n^{20}D$ 1.5102) was dissolved in 500 cc. of petroleum ether and extracted in the counter-current apparatus described in the previous paper,[4] Fig. 1, to yield 21 fractions with an average volume of 8 cc. and index of refraction, $n^{20}D$, ranging from 1.505 to 1.515.

Isolation of 3-Cyclopentylpyridine.—Since the index of refraction of the acid extraction fractions indicated that the alkyl substituted pyridines preceded those with cyclic side chain, fraction 19, with a volume of 25 cc. and $n^{20}D$ 1.5152, was selected to determine what type of substituents are present in the fractions with the high index of refraction. The base was dissolved in sulfurous acid and treated with picric acid. A crystalline picrate formed on standing in the ice-box. It melted at 117.5° after repeated recrystallizations from dilute ethanol and from 50% acetic acid. Additional amounts of the same picrate were obtained from fractions 17 and 18 of the same series.

Anal. Calcd. for $C_{16}H_{16}O_7N_4$: C, 51.06; H, 4.26; N, 14.89. Found: C, 50.97; H, 4.16; N, 15.03.

One gram of the picrate was heated with concentrated ammonium hydroxide to liberate the base which was extracted in benzene, dried and distilled in a semi-micro distillation apparatus. A middle fraction gave the following constants: b. p. 215.5° (747 mm.); $n^{20}D$ 1.5173.

Anal. Calcd. for $C_{10}H_{13}N$: N, 9.52. Found: N, 9.55.

Isolation of 4-Cyclopentylpyridine.—Fraction 21, volume 30 cc., $n^{20}D$ 1.5116, yielded a new crystalline picrate which after repeated recrystallizations from dilute ethanol and from 50% acetic acid melted at 145–146° but only a few grams of the pure crystalline picrate were obtained. Since this new base was isolated from the higher boiling fraction of fraction 6 of the distillation series it seemed probable that greater amounts could be isolated from a higher boiling fraction and fraction 11 was fractionally neutralized in the counter current column to yield 21 neutralization fractions. Fractions 10 through 12 yielded only oily picrates but 13 through 21 yielded larger amounts of a picrate melting at 145–146° and showing no depression when mixed with the previous picrate.

Anal. Calcd. for $C_{16}H_{16}O_7N_4$: C, 51.06; H, 4.26; N, 14.89. Found: C, 51.20; H, 4.45; N, 14.96.

One gram of the picrate was decomposed as before and fractionated, b. p. 218° (744 mm.); $n^{20}D$ 1.5167. Both of the cyclopentylpyridines were difficult to analyze, probably because of their tendency to take up moisture.

Anal. Calcd. for $C_{10}H_{13}N$: N, 9.52. Found: N, 9.30.

The chloroplatinate of this base crystallizes readily, forming orange needles decomposing at 225–227°.

Anal. Calcd. for $(C_{10}H_{13}N)_2H_2PtCl_6$: Pt, 27.71. Found: Pt, 27.50.

Synthesis of 2-Cyclopentylpyridine

1-(2-Pyridyl)-cyclopentanol.—This compound was prepared by the method of Emmert and Pirot.[6] Into a three-necked flask fitted with stirrer, condenser, and dropping funnel was placed 155 g. of pyridine, 30 g. of aluminum turnings, and a crystal of iodine. Twenty-three grams of mercuric chloride dissolved in 154 g. of cyclopentanone was placed in the dropping funnel. A reaction started after about 10 cc. of this solution had been added to the flask and the remainder of the solution was now added, a few drops at a time, at such a rate as to keep the reaction mixture refluxing slowly. Finally the mixture was stirred for five hours on a steam-bath before the mixture was poured into cold dilute sodium hydroxide. The base was extracted with ether, dried over potassium hydroxide, and distilled at 5 mm. pressure. The material boiling at 130–140° was collected. It solidified on cooling and was recrystallized from petroleum ether; yield 30.5 g. of white solid melting at 83°.

Anal. Calcd. for $C_{10}H_{13}ON$: C, 73.63; H, 8.03. Found: C, 73.63; H, 8.26.

Dehydration of 1-(2-Pyridyl)-cyclopentanol.—Six cubic centimeters of concentrated sulfuric acid was added drop by drop to 2 g. of the cyclopentanol. This solution was heated for one hour on a steam-bath, poured on ice, neutralized with sodium hydroxide, and extracted with ether. The yield was practically quantitative; however, when this operation was repeated with 14 times these quantities, a viscous tar formed from which only 8 cc. of 1-(2-pyridyl)-cyclopentene-1 could be isolated. The cyclopentene readily decolorized 2% potassium permanganate. It boiled at 238–239° (748 mm.).

Hydrogenation of 1-(2-Pyridyl)-cyclopentene-1.—An acetic acid solution of the cyclopentene was hydrogenated at atmospheric pressure in six hours over Adams catalyst. The resulting base was dried over potassium hydroxide and fractionated, b. p. 217–218° (750 mm.), $n^{20}D$ 1.5205.

The picrate after recrystallization from dilute ethanol and from 50% acetic acid melted at 106.5°. A mixture of this picrate with the picrates of the two petroleum base cyclopentylpyridines melted below 100° thus showing that neither of these was 2-cyclopentylpyridine.

Anal. Calcd. for $C_{16}H_{16}O_7N_4$: C, 51.06; H, 4.26; N, 14.89. Found: C, 51.17; H, 4.36; N, 15.03.

Synthesis of 3-Cyclopentylpyridine

Diethyl 2-Cyclopentyl-2-(2-cyanoethyl)-malonate.—Following the general procedure of Bruson and Riener,[8] 19 g. of acrylonitrile was added to a stirred solution of 40 g. of cyclopentylmalonic ester,[9] 40 g. of dioxane, and 1.2 g. of sodium ethylate at 35–40°. The solution was stirred for one hour, the temperature raised to 50° for several hours or overnight with continued stirring. The reaction mixture was neutralized with 10% hydrochloric acid, and extracted with 100 cc. of benzene. The benzene layer was washed twice with 50-cc. portions of distilled water, and the benzene removed on a steam-bath. The residual oil was fractionated at 2 mm. pressure and 30 g. of the cyanoethylation product obtained, b. p. 162° at 2 mm., $n^{20}D$ 1.4612, d^{20}_4 1.0614.

Anal. Calcd. for $C_{15}H_{23}O_4N$: C, 64.03; H, 8.24; N, 4.98. Found: C, 64.02; H, 8.26; N, 4.94.

2-Cyclopentylglutaric Acid[10] (low melting form).—One hundred grams of the cyanoethylation product obtained as above was hydrolyzed by refluxing with 300 cc. of concentrated hydrochloric acid for twenty hours. The solution was evaporated on a steam-bath and the residue extracted with ether. The ether was evaporated off and the residue heated to 200° *in vacuo* until carbon dioxide ceased to be liberated. The sirupy material remaining was distilled at reduced pressure yielding 44 g. of the very viscous acid, b. p. 176–177° at 1.5 mm. pressure. The acid solidified on standing and was recrystallized from petroleum ether (b. p. 60–75°) to a constant melting point of 69°.

Anal. Calcd. for $C_{10}H_{16}O_4$: C, 59.98; H, 8.06. Found: C, 60.03; H, 8.03.

Diethyl 2-Cyclopentyl-2-(ethyl-3-propionate)-malonate.—To a stirred solution of 90 g. (0.395 mole) of cyclopentylmalonic ester and 500 cc. of anhydrous xylene was added 8.5 g. (0.37 mole) of clean sodium and the mixture refluxed for three hours. A solution of 75 g. of ethyl 3-bromopropionate and 30 cc. of xylene was added slowly to the refluxing solution and the heating continued for fifteen hours. At the end of this time the solution was allowed to cool, 75 cc. of water added to dissolve the sodium bromide, and the aqueous layer removed. The xylene solution was washed twice with water and the xylene distilled under 40–50 mm. pressure. The residual liquid was fractionated at 2–3 mm. pressure. Sixty-seven grams of the tricarboxylic ester (72% conversion, with 25 g. of cyclopentylmalonic ester recovered) was obtained, b. p. 168–170° at 2.4 mm. pressure; $n^{20}D$ 1.4589; d^{20}_4 1.068.

Anal. Calcd. for $C_{17}H_{28}O_6$: C, 62.17; H, 8.59. Found: C, 62.13; H, 8.57.

2-Cyclopentylglutaric Acid (high melting form).—Sixty-seven grams of the tricarboxylic ester was hydrolyzed by refluxing with 500 cc. of 10% aqueous potassium hydroxide for forty-eight hours. Concentrated hydrochloric acid was added to neutralize the solution which was then evaporated to dryness on a steam-bath in a stream of air. The sodium chloride–organic acid residue was extracted twice with an ether–alcohol solution, the two extracts combined, and the solvents evaporated on a steam-bath. The sirupy product which remained evolved carbon dioxide on continued heating at 100°. When carbon dioxide ceased to be evolved the residue was dissolved in boiling benzene–petroleum ether and the acid allowed to crystallize out of the solution. After two recrystallizations from petroleum ether 30 g. of 2-cyclopentylglutaric acid, m. p. 152.5°, was obtained.

Anal. Calcd. for $C_{10}H_{16}O_4$: C, 59.98; H, 8.06. Found: C, 59.84; H, 8.09.

2-Cyclopentylglutaryl Dichloride.—By a modification of Scheiber's[11] procedure 17 g. of the low melting cyclopentylglutaric acid was dissolved in 27.4 g. of thionyl chloride. The solution was warmed to 60° for three hours and finally refluxed for two hours. The excess thionyl chloride was removed under vacuum and the residual oil fractionated at 4–5 mm. pressure. Twenty grams (90%) of the dichloride was obtained, b. p. 140–142° at 4.5 mm. pressure.

Anal. Calcd. for $C_{10}H_{14}O_2Cl_2$: Cl, 30.10. Found: Cl, 29.93.

2-Cyclopentylglutaryl Diamide.—Eight grams of the acid chloride was poured slowly into 50 cc. of concentrated ammonia and the crystals, which formed after standing in the ice-box overnight, were filtered off. Recrystallization from concentrated ammonia gave 2 g. of white crystals which melted at 174° with the evolution of ammonia.

Anal. Calcd. for $C_{10}H_{18}O_2N_2$: C, 60.60; H, 9.13; N, 14.13. Found: C, 60.48; H, 9.18; N, 14.19.

3-Cyclopentylglutarimide.—Two grams of the diamide was heated to 200° at 5 mm. pressure in a 10-cc. flask equipped with an internal condenser until the evolution of ammonia ceased. A charred mass remained in the flask but a white solid, m. p. 131°, collected on the condenser. Recrystallization from petroleum ether gave 0.5 g. of white flakes melting at 131°.

Anal. Calcd. for $C_{10}H_{15}O_2N$: N, 7.73. Found: N, 7.84.

Eight grams of the cyclopentylglutaric acid (high melting form) was converted to the anhydride by refluxing one

hour with 12 g. of acetyl chloride, after which the excess acetyl chloride and acetic acid were distilled *in vacuo*. Dry ammonia was passed into the residue at 130–140° for one hour and the product heated to 210° to form the imide which was then purified by recrystallization from benzene and petroleum ether. Four grams of the fine white flakes, m. p. 131°, was obtained. A mixture of this imide and that obtained from the diamide of the low melting cyclopentylglutaric acid showed no depression of melting point, thus showing the two imides to be identical.

Anal. Calcd. for $C_{10}H_{15}O_2N$: N, 7.73. Found: N, 7.85, 7.81.

2,5,6-Trichloro-3-cyclopentylpyridine.—By a modification of the procedure of Crouch and Lochte[7] an intimate mixture of 1.8 g. of 3-cyclopentylglutarimide and 6.4 g. of phosphorus pentachloride was warmed slowly in a water-bath to 43° at which temperature a vigorous reaction began. When this initial reaction had subsided the mixture was heated to 100° for fifteen minutes and the viscous liquid poured into shallow dishes and allowed to evaporate in a hood. The crystals, which soon formed, were washed into a beaker with ice-water, filtered off, and recrystallized from dilute ethanol and dilute acetic acid. Three grams of the trichloride was obtained, m. p. 141°.

Anal. Calcd. for $C_{10}H_{10}NCl_3$: N, 5.59; Cl, 42.46. Found: N, 5.62; Cl, 42.31.

3-Cyclopentylpyridine.—A methanol solution of 1.3 g. of the trichlorocyclopentylpyridine was reduced using hydrogen at 20 pounds pressure over palladium–charcoal[12] catalyst. Ninety-five per cent. of the calculated quantity of hydrogen was absorbed in four hours. The solution was now filtered, concentrated, and 15 cc. of 20% sodium hydroxide solution added. The oil, which immediately separated, was extracted with ether, separated from the aqueous layer, and the ether evaporated. The free pyridine base was dissolved in sulfurous acid solution and 1.5 g. of picric acid in a saturated aqueous solution was added. The picrate separated as an oil which crystallized on standing in the ice-box. After alternate recrystallizations from dilute acetic acid and dilute ethanol it melted at 118.7°.

Anal. Calcd. for $C_{10}H_{13}N \cdot C_6H_3O_7N_3$: C, 51.06; H, 4.26; N, 14.89. Found: C, 50.98, 51.03; H, 4.32, 4.24; N, 15.00, 14.97.

The picrate showed no depression in melting point when mixed with the petroleum base picrate melting at 117.5°, but did show a depression when mixed with the picrate of the isomeric petroleum base.

Synthesis of 4-Cyclopentylpyridine

Cyclopentyl Aldehyde.—Cyclopentyl aldehyde was prepared by the action of magnesium bromide etherate on cyclohexene oxide according to the procedure of Clemo and Ormston.[13] One hundred and twenty grams of cyclohexene oxide gave 9 g. of cyclopentyl aldehyde, b. p. 136°, $n^{20}D$ 1.4432. Clemo and Ormston give the boiling point as 135°.

3-Cyclopentyl-2,4-dicyanoglutaryl Diamide.—Following the general procedure of Day and Thorpe,[14] 15.4 g. of recrystallized cyanoacetamide was dissolved in 75 cc. of water, 9 g. of cyclopentyl aldehyde added, the solution clarified by adding 35 cc. of alcohol, then 0.2 cc. of 50% potassium hydroxide added. The solution was shaken vigorously for a few minutes and allowed to stand for two days at room temperature. The white solid which separated was removed by filtration. After two recrystallizations from 95% alcohol 4 g. of a white powdery substance was obtained, m. p. 213° (effervescence).

Anal. Calcd. for $C_{12}H_{16}O_2N_4$: C, 58.22; H, 6.51; N, 22.62. Found: C, 58.00; H, 6.55; N, 22.62, 22.55.

3-Cyclopentylglutaric Acid.—To 3.3 g. of 3-cyclopentyl-2,4-dicyanoglutaryl diamide was added 8 cc. of concentrated hydrochloric acid and the mixture heated until the solid dissolved. Eight cubic centimeters of water was added and the solution refluxed for five hours. The mixture was allowed to cool and the acid extracted with 50 cc. of ether. After evaporating off the ether, the acid was recrystallized twice from petroleum ether to give 1.7 g. of 3-cyclopentylglutaric acid, m. p. 111.5°.

Anal. Calcd. for $C_{10}H_{16}O_4$: C, 59.98; H, 8.06. Found: C, 59.82; H, 8.09.

4-Cyclopentylpyridine.—One and one-half grams of 3-cyclopentylglutaric acid was refluxed with 5 g. of acetyl chloride for one hour, the acetic acid and excess acetyl chloride were distilled under vacuum, and dry ammonia passed into the anhydride at 130° for one hour. The product was heated to 210–230° for fifteen minutes to form the imide which was extracted with benzene. This extract gave 1 g. (damp weight) of the imide which was subsequently treated with phosphorus pentachloride to give the corresponding trichloropyridine as before.

The trichloro compound was hydrogenated in methanol–hydrogen chloride solution over palladium chloride–charcoal catalyst.[12] The resulting cyclopentylpyridine was removed as before and the picrate prepared. After several recrystallizations from water the melting point was constant at 146°. The picrate showed no depression in the melting point when mixed with the petroleum base picrate melting at 145°, but did show a depression when mixed with the picrate of the isomeric petroleum base.

Summary

1. In an extension of a study of California petroleum bases boiling in the 210–213° range, 3-cyclopentyl- and 4-cyclopentylpyridine have been isolated and identified.

2. 2-, 3- and 4-cyclopentylpyridine have been synthesized and characterized.

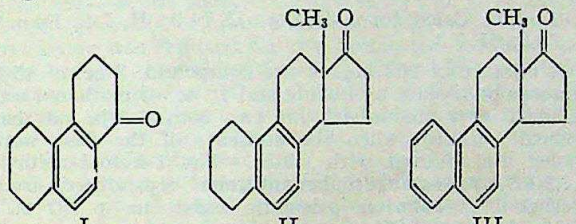
The Synthesis of Compounds Related to the Sex Hormones

BY W. E. BACHMANN AND R. D. MORIN[1]

From 1-keto-*sym*-octahydrophenanthrene (I), the *cis* and *trans* forms of 1,2,3,4-tetrahydro-17-equilenone[2] (II), an isomer of desoxyestrone, were prepared by the method employed for the synthesis of equilenin[3] and related compounds. Since the configurations of the two forms of II (m. p. 72–73° and 114–115°) are not known, they are designated by the prefixes α and β. The structures of the two forms were established by dehydrogenation. When heated with sulfur the α-form

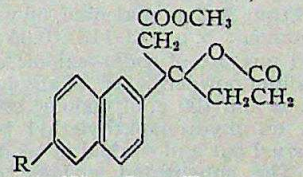


I II III

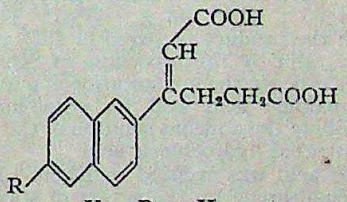
of II gave the α-form of 17-equilenone[2] (III) and the β-form yielded the β-form of 17-equilenone. These reactions relate the configurations of the compounds in the two series. The new compounds should prove useful in studies of the sex hormones and compounds derivable from neoergosterol. Marker and Rohrmann[3a] prepared one of the optically active forms (m. p. 107–109°) of II from equilenin.

A number of 3-arylcyclopentenones and 3-arylcyclopentanones were synthesized from the β-3-aroylpropionic acids. In the synthesis of VIc, the methyl ester of β-6-methoxy-2-naphthoylpropionic acid was treated with zinc and methyl bromoacetate to yield the lactone (IVb) of the Reformatsky ester. When the lactone was hydrolyzed by methanolic sodium hydroxide and a solution of the resulting sodium salt was acidified, the unsaturated dicarboxylic acid (Vb) was formed. The double bond is probably in the position indicated, for the acid is reduced readily by means of sodium amalgam and water. By cyclization of the dimethyl ester of this acid by means of sodium methoxide, followed by treatment of the product with a boiling mixture of acetic acid and hydrochloric acid, a mixture of 3-(6′-hydroxy-2′-naphthyl)-cyclopenten-2-one-1 (VIc) and its methyl ether (VIb) was obtained. 3-(6′-Hydroxy-2′-naphthyl)-cyclopentanone-1 was obtained by catalytic reduction of VIc and also by cyclization of the ester of the saturated dicarboxylic acid, obtained by reduction of Vb by means of sodium amalgam and water. Banerjee[4] prepared 3-(*p*-hydroxyphenyl)-cyclohexanone by a similar procedure.

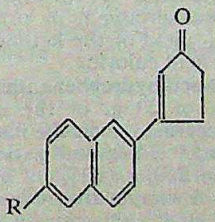
By a similar series of reactions 3-(2′-naphthyl)-cyclopenten-2-one-1 (VIa), 3-(2′-naphthyl)-cyclopentanone, 3-(5′,6′,7′,8′-tetrahydro-2′-naphthyl)-cyclopenten-2-one-1 (VII) and the corresponding cyclopentanone were prepared. By catalytic dehydrogenation, the tetralylcyclopentenone (VII) was converted to the naphthylcyclopentenone (VIa). VIa and the corresponding cyclopentanone had been prepared previously by Weidlich and Daniels by another method.[5] The 2-methyl derivatives, of VIa,[5] of VIc[6] and of the corresponding cyclopentanones have been prepared by other methods.



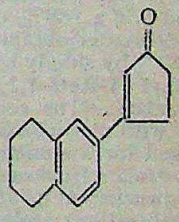
IVa R = H
IVb R = OCH_3



Va R = H
Vb R = OCH_3



VIa R = H
VIb R = OCH_3
VIc R = OH



VII

The ring structures of these compounds were confirmed completely by Wolf–Kishner reduction of VIa to 1-β-naphthylcyclopentene and of VIb to 1-(6′-methoxy-2′-naphthyl)-cyclopentene. Both of these reference compounds have been prepared previously by another method.[7]

Experimental

1-Keto-1,2,3,4,5,6,7,8-octahydrophenanthrene (I).—α-Naphthylamine (20 g.) was reduced by sodium and fusel oil by the procedure described for the β-isomer.[8] After all

the sodium had reacted, the hot mixture was poured into water and after separation of the layers, the organic layer was acidified with hydrochloric acid. Six such runs were combined and concentrated by distillation until the *ar*-tetrahydro-α-naphthylamine hydrochloride began to crystallize from the hot solution. The cooled solution was filtered and the crystalline hydrochloride was washed several times with ether to remove colored impurities; the product obtained was sufficiently pure for the next step; yield, 131 g. (84%).

Diazotization and conversion to 1-iodo-5,6,7,8-tetrahydronaphthalene was carried out according to the directions for 1-iodo-6-methoxynaphthalene.[9] From 110 g. of *ar*-tetrahydro-α-naphthylamine, 102 g. (66%) of 1-iodo-5,6,7,8-tetrahydronaphthalene, b. p. 153–158° (20 mm.), was obtained.

The Grignard reagent of the iodotetralin was prepared and allowed to react with ethylene oxide according to the procedure described for *m*-iodoanisole.[10] From 51.6 g. of the 1-iodotetralin, 20 g. (57%) of β-(5,6,7,8)-tetrahydro-1-naphthylethyl alcohol was obtained as a viscous yellow oil; b. p. 125–135° (0.4 mm.).

Conversion of the alcohol to β-5,6,7,8-tetrahydro-1-naphthylethyl bromide by means of phosphorus tribromide was carried out in the same manner as described for a similar case.[3] From 35.2 g. of alcohol, 30 g. (62%) of the bromide was obtained; b. p. 113–118° (0.05 mm.).

To the cooled mixture of sodio-malonic ester obtained from 10 g. of sodium powder, 30 cc. of absolute alcohol, 25 cc. of dry benzene and 100 g. of malonic ester was added 71.7 g. of the tetrahydronaphthylethyl bromide. The reaction was carried out and worked up as described for a similar case.[3] The substituted malonic acid was decarboxylated at 180° to γ-5,6,7,8-tetrahydro-1-naphthylbutyric acid. After recrystallization from ligroin, the acid melted at 94–95°; yield, 42 g. (65%). The acid was identical with the product prepared in 45% yield from 1-chloroacetyltetralin by the procedure of Schroeter.[11] In one step of his process, the precipitation of a mixture of the substituted malonic acid and its potassium salt was avoided by adding the aqueous solution of the dipotassium salt to concentrated hydrochloric acid.

The butyric acid was cyclized to 1-keto-1,2,3,4,5,6,7,8-octahydrophenanthrene by the action of stannic chloride on the acid chloride according to the procedure described by Wilds[10] for γ-1-naphthylbutyric acid. From 21.8 g. of the acid 17.6 g. (88%) of ketone was obtained; m. p. 80.5–82°. Schroeter obtained an 80% yield of the ketone (m. p. 81–82°) by simply heating the acid chloride.

Methyl 1-Keto-1,2,3,4,5,6,7,8-octahydrophenanthrene-2-glyoxalate.—The condensation of 20 g. of the cyclic ketone with methyl oxalate was carried out in the manner described for a similar compound.[3] Recrystallization of the glyoxalate from methanol gave 25.5 g. (89%) of bright yellow prisms; m. p. 101–102°. A sample after two more recrystallizations melted at 103–104°. It gave a dark purple-brown color with alcoholic ferric chloride.

Anal.[12] Calcd. for $C_{17}H_{18}O_4$: C, 71.3; H, 6.3. Found: C, 71.4; H, 6.3.

1-Keto-2-carbomethoxy-1,2,3,4,5,6,7,8-octahydrophenanthrene.—Following the procedure described,[3] 10 g. of the glyoxalate and 5 g. of powdered soft glass were heated at 180° for exactly one-half hour. The product was separated from the glass with hot benzene and the benzene solution was washed with 2% aqueous sodium hydroxide to remove any unreacted glyoxalate. The product after recrystallization from methanol was suitable for the next step; yield, 7.95 g. (88%); m. p. 81–84°. A sample after three more recrystallizations formed stout colorless prisms which melted at 83–85°. It gave an immediate dark blue-green color with alcoholic ferric chloride.

Anal.[12] Calcd. for $C_{16}H_{18}O_3$: C, 74.4; H, 7.0. Found: C, 74.3; H, 7.1.

1-Keto-2-methyl-2-carbomethoxy-1,2,3,4,5,6,7,8-octahydrophenanthrene.—A solution of 10.32 g. (0.04 mole) of the aforementioned keto ester in 50 cc. of dry benzene was added to a solution of sodium methoxide prepared from 4.6 g. of sodium and 90 cc. of absolute methanol. After being warmed for one-half hour and then cooled, the mixture was treated with 14 cc. of methyl iodide and kept at room temperature until nearly all of the sodio derivative had disappeared. An additional 14 cc. of methyl iodide was added and within thirty minutes all of the solid had reacted. The product was isolated according to the procedure described[3] and recrystallized from methanol; yield, 9.42 g. (86%) of nearly colorless material sufficiently pure for the next step; m. p. 72–75°. A sample after two more recrystallizations formed colorless prisms which melted at 77–78°. It gave no color with alcoholic ferric chloride.

Anal.[12] Calcd. for $C_{17}H_{20}O_3$: C, 74.9; H, 7.4. Found: C, 74.3; H, 7.3.

A mixture of 262 mg. of the compound, 3 cc. of 45% aqueous potassium hydroxide and 10 cc. of methanol was refluxed on a steam-bath for two hours. The oil that formed solidified when the contents of the flask were cooled and diluted with water. The **1-keto-2-methyl-1,2,3,4,5,6,7,8-octahydrophenanthrene** crystallized from methanol in colorless prismatic rods; m. p. 87–88°; yield, 171 mg. (80%).

Anal.[12] Calcd. for $C_{15}H_{17}O$: C, 84.0; H, 8.5. Found: C, 83.6; H, 8.6.

Dimethyl Ester of 2-Methyl-2-carboxy-1-hydroxy-1,2,3,-4,5,6,7,8-octahydrophenanthrene-1-acetic Acid.—The Reformatsky reaction between the methyl keto ester (5.44 g.), zinc and methyl bromoacetate was carried out as described for a similar compound,[3] except that extremely vigorous stirring was employed. The product crystallized from methanol in stout colorless prisms; yield, 5.3–5.6 g. (76–81%); m. p. 100–101°. A sample after two more recrystallizations melted at 102–103°.

Anal.[12] Calcd. for $C_{20}H_{26}O_5$: C, 69.3; H, 7.6. Found: C, 69.5; H, 7.7.

When a mixture of 346 mg. of the Reformatsky ester, 3 cc. of 45% aqueous potassium hydroxide and 10 cc. of methanol was refluxed on a steam-bath for two hours, 150 mg. (after recrystallization from methanol) of 1-keto-2-methyl-1,2,3,4,5,6,7,8-octahydrophenanthrene; m. p. 87–88°, was obtained.

Conversion of the Reformatsky Ester to the Unsaturated Acids.—The hydroxy ester (1.52 g.) was converted to the chloride by means of thionyl chloride and pyridine and the product was treated with aqueous alcoholic potassium hydroxide in the manner described.[3] The **2-methyl-2-carboxy-1,2,3,4,5,6,7,8-octahydrophenanthrylidene-1-acetic acid** which precipitated on acidification of the aqueous solution of the potassium salt weighed 1.21 g. (92%); m. p. 137–140°. It crystallized from acetone–ligroin in colorless prisms; m. p. 140–141° with evolution of gas.

Anal. Calcd. for $C_{18}H_{20}O_4$: C, 72.0; H, 6.7. Found: C, 71.8; H, 6.7.

Preparation of α- and β-2-Methyl-2-carboxyl-1,2,3,4,5,-6,7,8-octahydrophenanthrene-1-acetic Acid.—Usually the Reformatsky ester (6.92 g.) was converted directly to the α- and β-reduced acids without isolation of the unsaturated acid. The aqueous solution of the potassium salts of the unsaturated acids was shaken vigorously for one-half hour with 150 g. of 2% sodium amalgam. The dried mixture of reduced acids (5.5–5.7 g.) was dissolved in a hot mixture of 20 cc. of acetic acid and 30 cc. of xylene. Without filtering, the solution was allowed to cool; 2.4–2.6 g. (40–43%) of the α acid crystallized; m. p. 208–211°. A sample crystallized from acetic acid in short stout colorless prisms; m. p. 218–219°.

By evaporation of the filtrate and recrystallization of the residue from benzene-ligroin 1.8–2.0 g. (46–50%) of the β acid

was obtained; m. p. 160–161°. A sample of the β acid crystallized from ethyl acetate–ligroin in small colorless prisms; m. p. 162–163°.

Anal. Calcd. for $C_{18}H_{22}O_4$: C, 71.5; H, 7.3. Found: (α-form) C, 71.4; H, 7.4; (β-form) C, 71.6; H, 7.4.

Dimethyl Ester of 2-Methyl-2-carboxy-1,2,3,4,5,6,7,8-octahydrophenanthrene-1-acetic Acid.—The α-form of this compound, prepared in 97% yield from the α-acid by means of diazomethane, crystallized from methanol in stout colorless prisms; m. p. 70–71.5°. A sample after one more recrystallization melted at 70.5–71°.

The **β-form**, prepared from 6.04 g. of the β-acid and diazomethane, crystallized from methanol in colorless prisms; yield, 6.07 g. (92%); m. p. 79–81°. After two more recrystallizations a sample melted at 81.5–82.5°.

Anal.[12] Calcd. for $C_{20}H_{26}O_4$: C, 72.7; H, 7.9. Found: (α-form) C, 73.0; H, 7.6; (β-form) C, 73.3; H, 7.8.

2-Methyl-2-carbomethoxy-1,2,3,4,5,6,7,8-octahydrophenanthrene-1-acetic Acid.—A mixture of 4.62 g. of the dimethyl ester, 100 cc. of methanol and 14.3 cc. of *N* sodium hydroxide was refluxed for two hours, the methanol was removed and the residue dissolved in about 25 cc. of warm water. About 3 cc. of ethyl acetate was added and the mixture was acidified. The acid ester, which gradually crystallized as the ethyl acetate evaporated, was sufficiently pure for the next step.

In this manner 4.21 g. (95%) of the α-form melting at 120–122° was obtained. A sample after two recrystallizations from acetone–ligroin formed colorless prisms; m. p. 121–122°.

The β-form was obtained in 98% yield; m. p. 136–139°. From ethyl acetate it crystallized in small colorless prisms melting at 141–142°.

Anal. Calcd. for $C_{19}H_{24}O_4$: C, 72.2; H, 7.6; neut. equiv., 316. Found: (α-form) C, 72.3; H, 7.7; neut. equiv., 317. (β-form) C, 72.0; H, 7.6; neut. equiv., 318.

Arndt–Eistert Reaction on the Acid Esters.—This was carried out on 1.58 g. of the acid esters as described for a similar compound.[3] The solution of the product obtained by the action of silver oxide on the diazoketone in methanol was filtered and evaporated, and the residue was evaporatively distilled at 180° (0.05 mm.).

The **dimethyl ester of α-2-methyl-2-carboxy-1,2,3,4,5,6,7,8-octahydrophenanthrene-1-β-propionic acid** crystallized from methanol in small colorless prisms; yield, 1.29 g. (75%); m. p. 63.5–64.5°.

Anal.[12] Calcd. for $C_{21}H_{28}O_4$: C, 73.2; H, 8.2. Found: (α-form) C, 73.0; H, 8.0.

The β-isomer, a pale yellow liquid, was used directly in the next step; yield, 1.59 g.

1,2,3,4-Tetrahydro-16-carbomethoxy-17-equilenone.—Cyclization of 1.38 g. of the aforementioned esters by sodium methoxide in benzene (ten hours of refluxing) was accomplished by the procedure described.[3]

The **α-form** crystallized from methanol in fine colorless needles; yield, 1.12 g. (90%); m. p. 124–124.5°. After two more recrystallizations a sample melted at 124–125°. The compound gave a dark green color with alcoholic ferric chloride.

By recrystallization from methanol the **β-form** was obtained as colorless prisms; yield, 1.08 g. (85%); m. p. 118–121°. After three recrystallizations a sample melted at 121–122°. The compound gave an immediate greenish-brown color with alcoholic ferric chloride.

Anal.[12] Calcd. for $C_{20}H_{24}O_3$: C, 76.9; H, 7.8. Found: (α-form) C, 76.8; H, 7.7; (β-form) C, 76.9; H, 8.1.

1,2,3,4-Tetrahydro-17-equilenone (II).—A mixture of 0.9 g. of the 16-carbomethoxy derivative, 45 cc. of acetic acid, 22 cc. of concentrated hydrochloric acid and 4 cc. of water was refluxed for two hours in an atmosphere of nitrogen. The residue remaining after removal of the solvents under reduced pressure was dissolved in benzene and washed with 2% aqueous sodium hydroxide. The benzene solution was concentrated and the residue was dissolved in hot methanol from which the product crystallized.

The α-form crystallized in stout colorless prisms; yield, 0.65 g. (88%); m. p. 72–73°. After evaporative distillation at 100° (0.05 mm.) and two recrystallizations from methanol it melted at the same temperature.

The β-form crystallized in small colorless prisms; yield, 0.60 g. (79%); m. p. 113–114°. After evaporative distillation at 110° (0.05 mm.) and two recrystallizations from methanol, it melted at 114–115° (vac.).

Anal.[12] Calcd. for $C_{18}H_{22}O$: C, 85.0; H, 8.6. Found: (α-form) C, 84.7; H, 8.3; (β-form) C, 84.4; H, 8.4.

The **semicarbazones** were prepared with semicarbazide hydrochloride in a mixture of absolute alcohol and pyridine. The **α-form** crystallized from alcohol in colorless prisms; m. p. 243–244°. The **β-form** was obtained in colorless prisms; m. p. 274–275° (vac.).

Anal. Calcd. for $C_{19}H_{25}ON_3$: N, 13.5. Found: (α-form) N, 13.3; (β-form) N, 13.4.

Dehydrogenation of 1,2,3,4-Tetrahydro-17-equilenone.—A mixture of 50 mg. of II and 15 mg. of sulfur was heated at 210° for two hours. The product was purified by sublimation at 100° (0.05 mm.) and recrystallization from methanol. The **α-form** gave 20 mg. of α-17-equilenone (41%) melting at 97–98.5°; when mixed with α-17-equilenone (III) (m. p. 100–101°)[2] it melted at 98–99°. The **β-form** gave 24 mg. (49%) of β-17-equilenone melting at 186–187.5° (vac.); when mixed with β-17-equilenone (m. p. 188.5–189.5°) it melted at 187–188.5° (vac.).

Lactone of the Monomethyl Ester of β-Hydroxy-β-(6-methoxy-2-naphthoyl)-adipic Acid (IVb).—β-Naphthyl methyl ether (158 g.) and 110 g. of succinic anhydride were brought into reaction according to the procedure of Short, Stromberg and Wiles.[13] Fractional crystallization of the mixture of isomeric acids from acetone gave 49 g. of β-(6-methoxy-2-naphthoyl)-propionic acid (m. p. 147–148°). Esterification of this acid by alcoholic hydrogen chloride yielded 52.5 g. of the ethyl ester (m. p. 107.5–108°). By esterification of the mixture of acids in the acetone mother liquor an additional 40 g. of the ethyl ester was obtained.

The Reformatsky reaction on the above keto ester (8.05 g.) was carried out in the manner previously described[3] except that vigorous stirring was employed; in working up the reaction mixture washing with ammonium hydroxide was omitted in order to avoid hydrolysis of the product. The lactone ester crystallized from methanol in yellowish prisms; yield, 8.02 g. (84%); m. p. 115–119°. This was sufficiently pure for the next step. A sample after evaporative distillation at 115° (0.05 mm.) crystallized from methanol in fine colorless prisms; m. p. 121–122°.

Anal.[12] Calcd. for $C_{18}H_{18}O_5$: C, 68.8; H, 5.8. Found: C, 69.2; H, 5.7.

3-(6′-Methoxy-2′-naphthyl)-2-hexendioic Acid (Vb).—A mixture of 12.4 g. of the above crude lactone ester, 300 cc. of methanol and 80 cc. of *N* sodium hydroxide was refluxed for three hours on a steam-bath. The methanol was removed in a current of air, some water was added to the residue, and this solution was filtered and acidified. The unsaturated acid which precipitated was filtered and dried; yield, 11.27 g. (98%); m. p. 194–195°. A sample crystallized from acetone–ligroin in small colorless prisms which melted at the same temperature.

Anal. Calcd. for $C_{17}H_{16}O_5$: C, 68.0; H, 5.3. Found: C, 68.2; H, 5.4.

3-(6′-Hydroxy-2′-naphthyl)-cyclopenten-2-one-1 (VIc).—Ethereal diazomethane was added to 4.2 g. of the above unsaturated acid to form the dimethyl ester. The product was an oil which was purified by evaporative distillation at 190° (0.05 mm.). Cyclization of 3.28 g. of the ester was accomplished by the procedure described[3] (twelve hours of refluxing). The cyclic keto ester crystallized from methanol as a light tan powder; yield, 2.36 g. (80%); m. p. 123–125°. A sample of the **3-(6′-methoxy-2′-naphthyl)-5-carbomethoxycyclopenten-2-one-1** after three more recrystallizations from methanol formed small colorless prisms; m. p. 125–126°.

Anal. Calcd. for $C_{17}H_{17}O_2N_3$: N, 14.2. Found: N, 14.0.

A mixture of 118 mg. of the semicarbazone and a solution of sodium methoxide prepared from 0.3 g. of sodium and 6 cc. of absolute alcohol was heated in a sealed tube at 180° for twenty hours. From the reaction mixture 34 mg. (37%) of 1-(6′-methoxy-2-naphthyl)-cyclopentene was obtained; m. p. 141–142°, alone and when mixed with an authentic specimen.[7]

3-(6′-Hydroxy-2′-naphthyl)-cyclopentanone.—A solution of 3.0 g. of the substituted hexendioic acid (Vb) in 1.75 cc. of 45% aqueous potassium hydroxide and 20 cc. of water was shaken with 75 g. of 2% sodium amalgam for one-half hour. The **β-(6-methoxy-2-naphthyl)-adipic acid** obtained by acidification of the filtered solution crystallized from acetone–ligroin in colorless prisms; yield, 3.01 g. (99%); m. p. 164–165°.

Anal. Calcd. for $C_{17}H_{18}O_5$: C, 67.5; H, 6.0. Found: C, 67.8; H, 6.1.

The liquid dimethyl ester of the acid, prepared by means of diazomethane, was evaporatively distilled at 180–190° (0.05 mm.). Cyclization of 1.98 g. of the ester and hydrolysis, decarboxylation and demethylation were accomplished as previously described for similar cases.[3] A solution of the phenolic product in 125 cc. of hot 2.5% potassium hydroxide was filtered and acidified. The **3-(6′-hydroxy-2′-naphthyl)-cyclopentanone** after evaporative distillation at 200° (0.05 mm.) crystallized from methanol in small colorless prisms; yield, 1.14 g. (83%); m. p. 176–176.5°. The m. p. remained unchanged after two more recrystallizations.

The same compound was obtained by shaking a solution of 100 mg. of VIc in 10 cc. of acetic acid with 25 mg. of palladium–charcoal catalyst[14] and hydrogen for four hours. The filtered solution was evaporated and the residue was crystallized from methanol; yield, 70 mg. (70%); m. p. 176–176.5°.

Anal.[12] Calcd. for $C_{15}H_{14}O_2$: C, 77.9; H, 6.2. Found: C, 77.5; H, 6.3.

The **semicarbazone** crystallized in cream-colored prisms; m. p. 212–213°.

Anal. Calcd. for $C_{16}H_{17}O_2N_3$: N, 14.8. Found: N, 15.1.

3-(2′-Naphthyl)-cyclopenten-2-one-1.—The Reformatsky reaction was carried out on 7.5 g. of methyl-β-2-naphthoylpropionate (m. p. 74–75°), which was prepared from the acid in quantitative yield by means of diazomethane. The **lactone of the monomethyl ester of β-hydroxy-β-(2-naphthyl)-adipic acid (IVa)** (5.7 g.; m. p. 106–108°) was sufficiently pure for the next step. A sample after evaporative distillation at 170° (0.05 mm.), followed by two recrystallizations from methanol formed fine colorless needles; m. p. 111–112°.

Anal.[12] Calcd. for $C_{17}H_{16}O_4$: C, 71.8; H, 5.7. Found: C, 72.0; H, 5.5.

A mixture of 8.9 g. of the crude lactone ester, 150 cc. of methanol and 63 cc. of *N* sodium hydroxide was refluxed for three hours. The **3-(2′-naphthyl)-2-hexendioic acid (Va)** was isolated as described for the methoxy compound; yield, 8.06 g. (96%); m. p. 179–180°. The crude product was pure enough for the next step. After two recrystallizations from acetone–ligroin a sample was obtained as colorless prisms with the same m. p.

Anal. Calcd. for $C_{16}H_{14}O_4$: C, 71.0; H, 5.2. Found: C, 71.3; H, 5.2.

The liquid dimethyl ester of the unsaturated dicarboxylic acid, prepared by means of diazomethane, was evaporatively distilled at 170–180° (0.05 mm.). Cyclization of 1.64 g. of the ester and hydrolysis and decarboxylation of the product was carried out as described.[3] The **3-(2′-naphthyl)-cyclopenten-2-one-1 (VIa)** was evaporatively distilled at 160–170° (0.05 mm.) and then recrystallized twice from methanol; yield, 0.93 g. (81%) of small colorless prisms; m. p. 126–127° (reported,[5] 126–127°).

Anal.[12] Calcd. for $C_{15}H_{12}O$: C, 86.6; H, 5.8. Found: C, 87.2; H, 5.9.

The **semicarbazone** melted at 240–241° (reported, 244°[5]).

Anal. Calcd. for $C_{16}H_{15}ON_3$: N, 15.8. Found: N, 16.0.

The Wolff–Kishner reduction of 115 mg. of the above semicarbazone was carried out exactly as described for the methoxy compound and yielded 40 mg. (49%) of 1-(2′-naphthyl)-cyclopentene; m. p. 84.5–86° (reported,[7] 85–86°).

3-(2′-Naphthyl)-cyclopentanone.—Reduction of 3.24 g. of the naphthylhexendioic acid by 2% sodium amalgam was carried out as described for the methoxy derivative; yield, 3.14 g. (96%) of **β-(2-naphthyl)-adipic acid** sufficiently pure for the next step; m. p. 151–153°. After two recrystallizations from acetone–ligroin a sample formed colorless prisms; m. p. 153–154°.

Anal. Calcd. for $C_{16}H_{16}O_4$: C, 70.6; H, 5.9. Found: C, 70.7; H, 5.9.

The liquid dimethyl ester of the acid prepared by means of diazomethane was evaporatively distilled at 180° (0.05 mm.). Cyclization of 2.4 g. of the diester and hydrolysis and decarboxylation of the cyclic keto ester were carried out as described. The **3-(2′-naphthyl)-cyclopentanone** after evaporative distillation at 150° (0.05 mm.) followed by two recrystallizations from methanol formed small colorless prisms; yield, 1.47 g. (87%); m. p. 65–66° (reported,[5] 61°).

The same compound was obtained in 75% yield by catalytic hydrogenation of 200 mg. of VIa in acetic acid in the presence of 50 mg. of palladium-charcoal catalyst.

Anal.[12] Calcd. for $C_{15}H_{14}O$: C, 85.7; H, 6.7. Found: C, 85.7; H, 6.7.

The **semicarbazone** crystallized in colorless prisms; m. p. 199–199.5° (reported,[5] 196–197°).

Anal. Calcd. for $C_{16}H_{17}ON_3$: N, 15.7. Found: N, 15.5.

3-(5′,6′,7′,8′-Tetrahydro-2′-naphthyl)-cyclopenten-2-one-1 (VII).—A malonic ester synthesis was carried out on 104.5 g. of 2-chloroacetyl-5,6,7,8-tetrahydronaphthalene as described[11] except that benzene was used as the solvent and one hour of refluxing was employed. By adding the aqueous solution of the potassium salt of the substituted malonic acid to concentrated hydrochloric acid, the free

acid was obtained. After decarboxylation of the substituted malonic acid at 150–170°, the β-(5,6,7,8-tetrahydro-2-naphthoyl)-propionic acid was recrystallized from benzene using Norite; yield, 94.5 g. (85%); m. p. 120.5–121.5° (reported,[11] 121–122°). The methyl ester, prepared from 23 g. of the acid by means of diazomethane, solidified after distillation (b. p. 168–173° at 0.1 mm.) to a colorless solid; yield, 22 g.; m. p. 31–32° (reported,[15] 31°).

A Reformatsky reaction was carried out on 7.38 g. of the methyl ester as described. The product was an oil which was purified by evaporative distillation at 180° (0.05 mm.) and heated with 50 cc. of *N* sodium hydroxide in 50 cc. of methanol for three hours. The **3-(5′,6′,7′,8′-tetrahydro-2′-naphthyl)-2-hexendioic acid** (4.9 g., m. p. 183–185°) was sufficiently pure for the next step. A sample twice recrystallized from acetone–ligroin formed colorless prisms which melted at 185–186°.

Anal. Calcd. for $C_{16}H_{18}O_4$: C, 70.1; H, 6.6. Found: C, 70.0; H, 6.7.

The liquid dimethyl ester, prepared by means of diazomethane was evaporatively distilled at 180° (0.05 mm.); and 2.8 g. of it was cyclized as described. The cyclic keto ester was hydrolyzed and decarboxylated by heating with hydrochloric and acetic acids,[3] and the **3-(5′,6′,7′,8′-tetrahydro-2′-naphthyl)-cyclopenten-2-one-1** (VII) was evaporatively distilled at 150° (0.05 mm.) and recrystallized twice from methanol from which it crystallized in small colorless prisms; yield, 1.64 g. (77%); m. p. 82–82.5°.

Anal. Calcd. for $C_{15}H_{16}O$: C, 84.8; H, 7.6. Found: C, 84.6; H, 7.5.

The **semicarbazone** melted at 235–236°.

Anal. Calcd. for $C_{16}H_{19}ON_3$: N, 15.6. Found: N, 15.8.

A mixture of 50 mg. of VII and 10 mg. of palladium–charcoal catalyst was heated for fifteen minutes at 320° in an atmosphere of nitrogen. The 3-(2′-naphthyl)-cyclopenten-2-one-1 was evaporatively distilled at 150° (0.05 mm.); yield, 30 mg. (61%); m. p. 125–126°, alone and when mixed with a sample of VIa.

Summary

The *cis* and *trans* forms of 1,2,3,4-tetrahydro-17-equilenone, an isomer of desoxyestrone, have been synthesized from 1-keto-*sym*-octahydrophenanthrene. The compounds were dehydrogenated by sulfur to the *cis* and *trans* forms of 17-equilenone (desoxyequilenin).

Three 3-arylcyclopentenones and the corresponding 3-arylcyclopentanones were prepared in which the aryl groups were 2′-naphthyl-, 2′-tetralyl- and 6′-methoxy-2′-naphthyl.

Relationship between Solution Viscosity and Molecular Weight in the Amylose Series[1]

BY JOSEPH F. FOSTER[2] AND R. M. HIXON

Data on the solution viscosities of a series of amyloses prepared from various starch sources have recently been given.[3] Investigations of the osmotic behavior of some of these materials have been carried out with a view to establishing a relationship between molecular weight and viscosity for this series of glucose polymers. Unfortunately, it has been necessary to discontinue these investigations, temporarily, in the present rather preliminary stage.

Attempts to relate the solution viscosities of high polymers with their molecular weights through simple equations, of which that of Staudinger is best known, have been complicated by several factors. In the first place it is essential that the polymers be either linear or, if branched, have a constant degree of branching, so that the length or axial ratio may be expressed as a simple function of molecular weight. Much confusion has been caused in attempting to apply the Staudinger equation to starch and its degradation products, due to the fact that this polymer apparently consists of two types of molecules,[3,4,5] the one highly branched and the other linear. Obviously the same equations could not be expected to apply to both types of polymer.

In the second place it is now recognized that viscosity measurements on high polymers yield not a simple number average molecular weight as in the case of osmotic studies but one which is weighted in some manner.[6] Therefore it is essen-

tial that the material used be well fractionated if a comparison of values from the two methods is to be made.

A third point of very great importance which must also be considered is the degree of flexibility (randomness of kinking) of the polymer chains. Theoretical derivations of Kuhn[7] and more recently Huggins[8] predict, for the case of rigid rods, a linear relationship between the intrinsic viscosity and the square of the molecular weight (or length). However, if the chain is kinked in a random manner the result is compatible, according to Huggins, with the Staudinger equation

$$\eta_i = KM \qquad (I)$$

Kuhn,[9] in fact, predicts for such molecules a dependence of η_i on a power of M even lower than 1.0, the lower limit being 0.5. Most actual long-chain molecules would be expected to behave in a manner intermediate between these extremes and a general form for the equation relating these quantities would be[10] where α takes on values between the limits 0.5 and 2.0 depending on the flexibility of the chains. Values for α of 0.64 for the polyisobutylene series[11a] and 0.67 for cellulose acetates[11b] have been found.

$$\eta_i = KM^{\alpha} \qquad (II)$$

The evidence is quite conclusive that the amyloses are linear polymers,[3,4,5] and there is some evidence that they are fairly homogeneous with respect to molecular size.[5] With regard to the third point mentioned above, the amyloses are of peculiar interest. Inspection of molecular models[12] emphasizes in a striking manner the difference between this polymer and a polymer such as a simple hydrocarbon or rubber, or even cellulose. The amylose molecule is remarkably rigid due to restricted rotation about the glucosidic linkages. Thus in this case it might be expected that the value of the exponent in Equation (II) would be considerably greater than unity, perhaps approaching the maximum value of 2.0. The present paper presents evidence that this is the case.

Osmotic Pressure Measurements

Apparatus.—The osmotic cell used for this investigation was of the dynamic type working on the counter-pressure principle, patterned after a cell previously described by Hepp.[13] Peters and Saslow[14] have found this type of cell satisfactory for aqueous solutions. The design was considerably simplified in the present cell through the use of all-brass construction. A flat, circular brass block was drilled vertically and then horizontally to meet the glass capillary which was platinized and set in Wood's metal to provide a tight seal. The membrane was placed on top of this block over a disk of bolting silk and clamped in place by means of a brass ring. To prevent upward motion of the membrane, it was weighted with a grooved brass block which fitted inside the brass ring. Evaporation of solvent was minimized by covering the cell with an inverted glass funnel, open to the atmosphere through a fine capillary.

Suitable pressures (positive and negative) were obtained by means of leveling bulbs containing water and were measured with a water manometer.

Membranes.—Cellophane[15] was found to be the most satisfactory membrane material for this work in spite of its low permeability to organic solvents. Three grades of cellophane were tried, numbers 300, 450 and 600. In general the thinner grades, 300 and 450, were somewhat more satisfactory. Swelling in water–alcohol as recommended by McBain and Stuewer,[16] was found to increase the permeability temporarily but this decreased again after a few hours contact with the organic solvent. Ordinary parchment was also fairly satisfactory, being much more permeable than cellophane and hence giving more rapid attainment of equilibrium (about one hour as compared to four to eight hours with cellophane). In a few cases parchment disks were found permeable to the solute molecules. This was in no case observed with cellophane.

Materials.—Inasmuch as there is no solvent for amylose suitable for osmotic pressure work it was necessary to render the material soluble in organic solvents. This was done by acetylating, using pyridine and acetic anhydride which have been shown to produce no degradation.[17] The amyloses were the same preparations used in the viscosity work.[3] Chloroform was the solvent for all measurements reported here.

Procedure.—It is necessary to correct the equilibrium pressure in the cell for head of solvent and capillarity. This zero point was ascertained experimentally prior to each run by filling the cell with solvent and permitting it to come to equilibrium. The value varied somewhat from run to run, apparently due to slight leakage around the membrane which affects the rate of flow. This variation constitutes the chief uncertainty of the measurements.

Following the determination of the zero point the solvent was withdrawn from the chamber above the membrane and the top of the membrane pressed dry with filter paper. The cell was now filled with solution and permitted to come to equilibrium. The rate of flow of the meniscus was ascertained at various pressures using a low power microscope mounted on a micrometer, and the equilibrium point obtained by interpolating to zero flow rate.

Results and Calculations

The osmotic pressure results are given in Table I, and in Fig. 1 the quantity π/C is given as a function of concentration.

Substituting the limiting values of π/C in the van't Hoff equation the molecular weights of corn and tapioca amylose are found to be 42,000 and 75,000, respectively, corresponding to 260 and 460 glucose units.

Viscosity of Amylose Acetates in Chloroform.—The viscosities of the acetates of corn, tapioca and potato amyloses (butanol method) were determined. An Ostwald viscometer (capillary dimensions 15 by 0.04 cm., capacity 10 ml., flow time with chloroform about 21 sec.) equipped with ground-glass joints to cut down solvent evaporation was used. All measurements were at 25 ± 0.01° and all the usual precautions were observed. Results are shown graphically in Fig. 2.

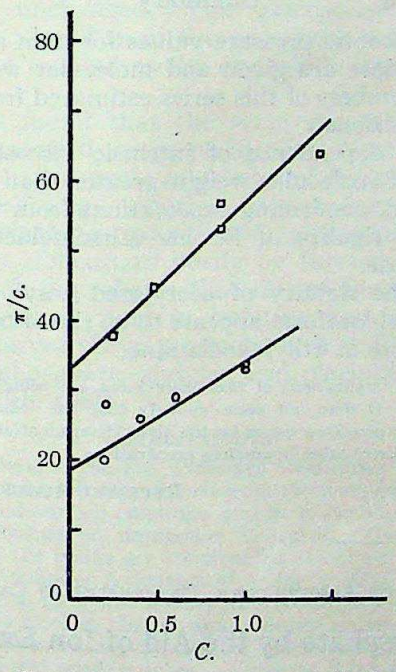

Fig. 1.—Concentration dependence of the function π/c. Concentration is given in g. per 100 ml., π in mm. of water. Squares are experimental points for corn amylose, circles for tapioca amylose.

Discussion

Unfortunately, of the materials whose viscosity behavior was studied earlier,[3] only three were available in large enough quantities for acetylation and osmometric study, namely, corn, tapioca and potato butanol precipitates. Discordant results were obtained with the latter, at least in part due to a strong tendency of even 1% solutions in chloroform to gel. Nevertheless, other evidence is available as to molecular weight of some of these preparations. Schoch[18] has recently reported "alkali numbers" for the potato and corn amyloses. The method is admittedly empirical but

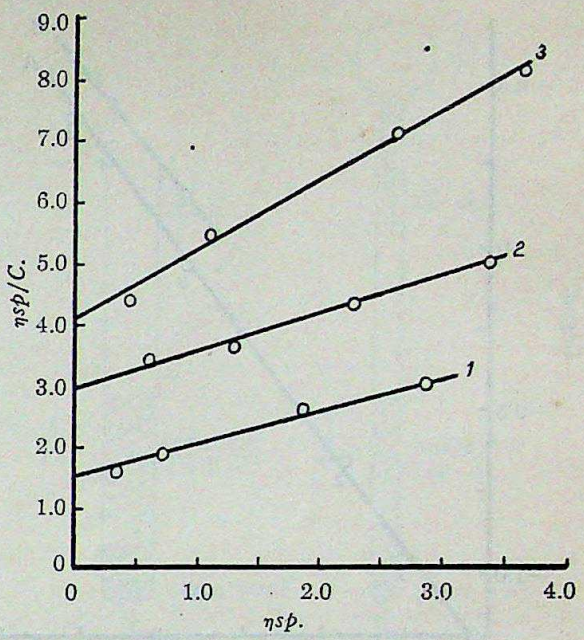

Fig. 2.—Calculation of the intrinsic viscosities of: 1, corn; 2, tapioca and 3, potato amylose acetates.

it is apparently a measure of the number of reducing groups present. It does not seem unlikely that for molecules of this size, where any inconsistencies should enter equally in the two cases, the ratio of the molecular weights would be approximately inversely proportional to the ratio of the alkali numbers which are about 25 for corn and 11 for potato amylose. This would correspond to a value of about 600 glucose units for potato amylose based on the osmometric value for corn.

Haworth, *et al.*,[19] have determined the chain length of a synthetic starch preparation, prepared in identically the same manner as the one used here, by means of analysis for end-groups (tetramethyl glucose analysis). They report a value of 80–90 glucose units.

Reducing value measurements,[20] both by hypoiodite and ferricyanide, on the amylodextrin fraction number 4 give values of the order of 50 glucose units for the molecular size.

In Fig. 3 these various values are plotted as log N *versus* log η_i where N is the number of glucose units in the molecule. The slope of this curve, 1.5, corresponds to α in Equation II.

All of the molecular weight calculations made above yield number average molecular weights. Too much emphasis cannot be placed on the value of 1.5 for α in view of uncertainty as to the homogeneity of these materials. Fraction 4 of amylodextrin was prepared by careful fractionation and should be reasonably homogeneous. The other materials have not been fractionated except in that the preparation itself probably gives fractionation, the longer amylose molecules precipitating preferentially. However, in view of the fact

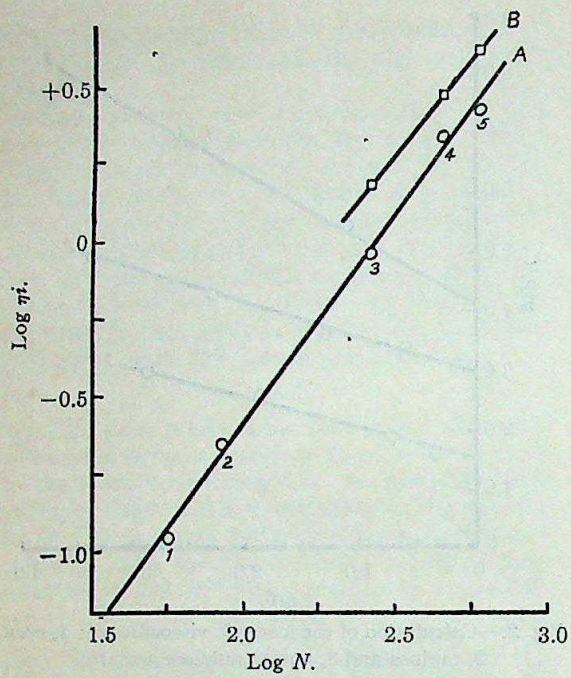

Fig. 3.—Relation between intrinsic viscosity and degree of polymerization for amyloses in ethylenediamine (A) and amylose acetates in chloroform (B): 1, amylodextrin 4; 2, synthetic starch; 3, corn; 4, tapioca and 5, potato amylose.

that most of these materials are prepared from natural sources with little if any degradation it does not seem unlikely that their homogeneity approaches that of materials prepared by fractional precipitation of originally highly polydisperse materials such as synthetic polymers (or even such natural polymers as cellulose where considerable degradation is involved in the preparation). Also the fact that these different materials can be titrated quantitatively with iodine in mixtures[5,21] would seem to indicate that the molecular weight distributions are fairly small relative to the magnitude of the differences between them. For the present, however, it is perhaps best to consider the value 1.5 as an upper limit for α in this series. There would seem to be little doubt that the value is greater than unity confirming the expectations from the rigidity of Fischer–Hirschfelder models of amylose.

The fact that α for the acetates in chloroform is the same, within the experimental error, as for the amyloses in ethylenediamine (as shown by the similar slopes in Fig. 3) is somewhat surprising. This would seem to indicate the molecules to be equally rigid in the two cases.

Summary

1. Osmotic pressure values for corn and tapioca amylose are given and molecular weights of other members of this series estimated from other considerations.

2. A dependence of intrinsic viscosity on a power of molecular weight greater than unity is indicated, confirming expectations from the comparative rigidity of Fischer–Hirschfelder models of amylose.

3. The rigidity of acetylated amylose molecules in chloroform appears to be the same as that of amylose in ethylenediamine.

(21) The implications of this observation are being further investigated. It does not seem unlikely that the iodine titration method may provide a means for the direct determination of molecular weight distribution in amylose preparations.

The Preparation and Purification of Glucose 1-Phosphate by the Aid of Ion Exchange Adsorbents

By R. M. McCready[1] and W. Z. Hassid

The establishment of glucose-1-phosphate (Cori ester) as an important intermediary product in the synthesis and breakdown of glycogen and starch[2,3] contributed much toward the stimulation of further study of the mechanism of carbohydrate formation in general. Since studies along these lines require an available supply of glucose-1-phosphate, it is important to have a satisfactory method whereby this ester can readily be prepared. Although Hanes' method[3] of preparing the ester from starch in fairly large quantities is satisfactory, the product is usually contaminated with small amounts of dextrins, which are very difficult to remove, and which are objectionable in certain types of experiments. Green and Stumpf[4] for example, in studying the influence of different carbohydrates on the synthesis of starch from glucose-1-phosphate *in vitro*, were obliged to use synthetic glucose-1-phosphate, which is laborious to prepare. Hanes' procedure can be very much shortened and improved by using ion exchange adsorbents,[5,6] whereby the following steps are eliminated: concentration of large volumes of

solution, precipitation of the ester with considerable quantities of alcohol, addition of trichloroacetic acid to precipitate the proteins, and the enzymatic hydrolysis of dextrin impurities.

In the present procedure the phosphorolysis of starch in the presence of phosphate buffer and the precipitation of the inorganic phosphate were carried out according to a modified procedure of Hanes, but the purification of the ester was accomplished by ion exchange adsorbents. The reaction mixture containing the ester was first passed through a column of cation exchange adsorbent, which removed the cations from solution, exchanging them for hydrogen ions. The effluent was then run through an acid adsorbing column. In this operation the Cori ester, being a strong acid with a high exchange capacity, was adsorbed, while the soluble impurities, including dextrins, proteins and weak organic acids, passed through unchanged. The glucose-1-phosphate was then eluted from the adsorbent with dilute alkali and isolated as the crystalline dipotassium salt.

It was found that the same general method could be applied to the purification of other hexosephosphates, such as fructose-1,6-diphosphate (Harden–Young ester), fructose-6-monophosphate (Neuberg ester), and glycerophosphate which are difficult to purify by the usual methods,[7,8,9] It is probable that this method may be advantageously used in isolating and purifying other phosphorylated products, such as dihydroxyacetone phosphate, glyceric acid phosphates, and also organic acids.

Experimental

Preparation of the Ion Exchange Columns.—The resin exchange materials as obtained from the manufacturer are in moist and swollen condition and little swelling or disintegration occurs on immersion in water. The columns containing the resins are constructed as shown in Fig. 1. The larger cylinder A consists of a 100 × 1000 mm. tube containing a 1200 ml. Amberlite IR-100 bed and some Pyrex glass wool at the bottom. Tubes cc_1 are attached to distilled water; aa_1 are outflow tubes for backwashing; bb_1 are effluent outflow tubes. Cylinder B is a 35 × 1000 mm. tube containing a 200 ml. bed of Amberlite IR-4 and a glass wool plug at the bottom. C is a 1-liter flask arranged to give a constant level of influent. After filling the columns the exchange material should be "classified" to size by washing before use in a particular process. The classification is accomplished by backwashing with water at such a rate as to produce a 50% bed volume expansion.[10] Flow resistance is thus reduced by the elimination of fines and the classification to a desirable particle size. The bed should be "broken in" by three or four exchange cycles followed by regeneration and washing to eliminate any color discharge and fines.

In the present work 4% hydrochloric acid was used to regenerate a 1200-ml. bed volume of Amberlite IR-100.

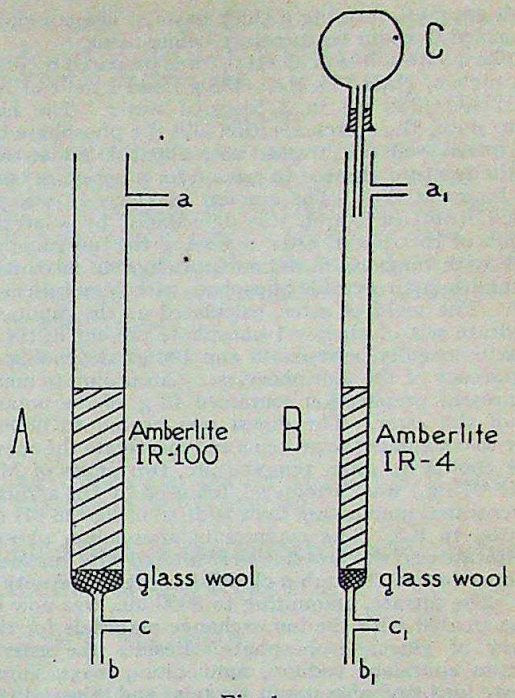

Fig. 1.

The acid was passed through the resin at the rate of seven bed volumes per hour, followed by thorough washing until the titratable acidity was negligible. Under these conditions the wash water effluent did not rise above *p*H 3. The resin in the form of the hydrogen derivative was treated with 4% sodium chloride solution to exchange the hydrogen of the resin for the cation of the sodium chloride solution. After 3000 ml. of the sodium chloride solution was allowed to pass through the resin at the rate of ten bed volumes per hour, the resin was completely saturated with sodium ions. The resin was then backwashed with distilled water and again regenerated with 3000 ml. of 4% hydrochloric acid solution by allowing it to pass through the column at the rate of 10 bed volumes per hour. The titratable acidity of the effluent then became the same as that of the influent, and the regeneration was considered complete. The column was put through three more exchange cycles as previously described, before it was ready for use.

The acid adsorbing Amberlite IR-4 was "broken in" in the same manner as the IR-100, except that ammonium hydroxide was used in the regeneration and 4% hydrochloric acid to saturate its acid binding capacity. In treating the IR-4 resin with ammonium hydroxide, its regeneration was considered complete when the reaction of the effluent became *p*H 11. When the column was subsequently treated with hydrochloric acid in the "breaking in" treatment, the *p*H value of 4.0 was used as an index of saturation of the resin with acid. Four exchange cycles were carried out on the Amberlite IR-4 before it was put into operation.

Preparation of the Digest.—Two kilograms of fresh potatoes were peeled and ground through a meat grinder fitted with a peanut butter cutter and the juice pressed through cheesecloth. Approximately 1200 ml. of the juice obtained from this weight of raw potatoes was then filtered through a canvas precoated with a thin layer of filter aid[11] on a Buchner funnel, using suction.

One hundred grams of air-dried potato starch was stirred into 600 ml. of cold water, then poured with stirring into 3500 ml. of boiling water and maintained at 100° for half an hour. This treatment completely ruptures the

starch granules, forming a thick paste. The starch paste was cooled to room temperature before using.

A phosphate solution of *p*H 6.7 was prepared by dissolving 1 mole of $NaH_2PO_4 \cdot H_2O$ (138 g.) and 1 mole of $Na_2HPO_4 \cdot 12H_2O$ (358 g.) in 3 liters of water. The filtered potato juice, the starch solution and the phosphate buffer were mixed well, and treated with about 50 ml. of toluene and the mixture allowed to remain for a period of twenty-four hours at 25°. The amount of glucose-1-phosphate formed from the starch was determined by analyzing a portion of the digest, after removing the inorganic phosphate with magnesium ammonium chloride mixture[12] for ten-minute hydrolyzable phosphate with *N* sulfuric acid at 100°. The yield of ester, calculated as the dipotassium dihydrate salt of glucose-1-phosphate present in the total digest, is usually between 40 and 100 g., depending upon the potency of the phosphorylase. According to analysis, the present preparation contained 43 g. of the potassium salt of the ester. The digest was heated to boiling in order to coagulate the proteins and inactivate the enzymes. After cooling to room temperature, two moles of $MgAc_2 \cdot 4H_2O$ (428 g.) was introduced, followed by the addition of concentrated ammonium hydroxide to bring the *p*H of the solution to 8.5. The magnesium ammonium phosphate precipitate and the proteins were filtered with suction on a Buchner funnel through a cloth filter precoated with filter aid. The filtrate, amounting to 8000 ml., was now ready to be treated with the ion exchange materials for the recovery of glucose-1-phosphate. Besides the ester, the solution contained sodium, ammonium, magnesium and acetate ions, and also starch, proteins and other impurities from the potato juice.

Treatment of the Digest with Amberlite IR-100.—The solution containing the glucose-1-phosphate and impurities was passed through a column of 1200-ml. bed volume of Amberlite IR-100 at the rate of 10 bed volumes per hour, taking the *p*H of the effluent as an index of saturation capacity of the resin. The cations in the solution were exchanged for hydrogen ions by this treatment. When the *p*H value rose to 4 the resin was considered to be near its saturation capacity and was regenerated with acid. To pass eight liters of solution through this column required four regenerations with hydrochloric acid followed by washing as previously described.

Adsorption of the Glucose-1-phosphoric Acid on Amberlite IR-4.—The solution was run through a column of Amberlite IR-4 of a 200-ml. bed volume at the rate of seven bed volumes per hour. When the reaction of the effluent from the Amberlite IR-4 falls to a value of *p*H 4 its saturation capacity has been reached and the Amberlite should be regenerated. However, in the case of glucose-1-phosphoric acid, it is still being adsorbed, although according to the *p*H value, the resin appears to be saturated. The glucose-1-phosphoric acid, having a stronger affinity for combination with this resin than acetic acid, is preferentially adsorbed, thus facilitating the removal of the glucose-1-phosphoric acid present in relatively low concentration as compared to the acetic acid. Analysis of samples of effluent for ten-minute hydrolyzable phosphate showed that practically all the glucose-1-phosphoric acid was removed from the solution. After the eight liters of the solution containing the glucose-1-phosphoric acid passed through the Amberlite IR-4, the resin was washed with three liters of water to remove soluble impurities such as starch or protein.

Recovery of Glucose-1-phosphate and Regeneration of the Amberlite IR-4.—A 4% solution of ammonium hydroxide was passed through the Amberlite IR-4 at a rate of five bed volumes per hour, and the *p*H of successive 50-ml. portions of effluent was determined. When 500 ml. of the solution had passed through the resin the reaction of the effluent became *p*H 11. An additional 200 ml. of 4% ammonium hydroxide was passed through this column to ensure complete regeneration of the resin, but it was not combined with the first 500 ml. of effluent, containing at least 99% of the glucose-1-phosphate. A concentration of 8000 ml. to 500 ml. in terms of glucose-1-phosphate had thus been effected by the use of the exchange materials.

The solution containing the glucose-1-phosphate was treated with 50 g. of potassium acetate and the reaction adjusted to *p*H 12 with 10% potassium hydroxide. One and a half volumes of methanol was then added to the solution and the potassium salt allowed to crystallize at 4°. After twenty-four hours the crystals of dipotassium glucose-1-phosphate dihydrate were removed by filtration, washed with methanol and ether, and dried *in vacuo* at 50°. A yield of 40.5 g. was obtained. This yield constitutes 94% recovery of the ester, formed from starch after treatment with potato phosphorylase, shown to be present in the digest according to analysis of acid hydrolyzable phosphorus. The product was free of inorganic phosphorus, nitrogen and dextrins. Its reducing value in terms of glucose, after hydrolysis with *N* sulfuric acid, was 48.4% (calculated reducing value, 48.38%).

Anal. Calcd. for $C_6H_{11}O_5OPO_3K_2 \cdot 2H_2O$: P, 8.33. Found: P, 8.3. Specific rotation: $[\alpha]_D$ +78° (in water, $c = 2$).

Adsorption Capacity of Amberlite IR-4 with Various Acids at their "Break through" Points.—When the resin is saturated with acid to its full capacity, the concentration of the effluent becomes equal to that of the influent. When quantitative adsorption of an acid is desired, it is of interest to determine the point at which the resin is not fully saturated, but only to the degree where some or the acid begins to appear in the effluent. This point is termed by Myers, *et al.*,[13] as the "break through" capacity of the resin.

The adsorption capacities of Amberlite IR-4 with respect to hexose phosphate esters were determined as follows: a 500-ml. solution, containing two hundred milli-equivalents of hexose phosphate, was passed through a 300-ml. bed of Amberlite IR-100 to remove cations, and then through a bed of Amberlite IR-4 to adsorb the phosphoric acid ester. The weight of the Amberlite IR-4 bed in the column was equivalent to 10 g. of resin on the dry weight basis. The results of the adsorption capacities are expressed in terms of grams of acid adsorbed per gram of dry resin. Table I shows the break through capacities of the resins when treated with various hexose phosphoric acids and also of glycerophosphoric acid.

TABLE I

ADSORPTION CAPACITY OF AMBERLITE IR-4

Acid	Influent concn., milli-moles/liter	Capacity at break through g. acid/g. dry resin	Capacity at break through millimoles acid/g. dry resin

according to Kobel and Neuberg[7] was treated with the resin exchange adsorbents and recovered as the amorphous calcium salt by precipitation with alcohol. Analysis of this hexosediphosphate before treatment with the ion exchange adsorbents showed only 70% purity, the chief contaminants being proteins and calcium phosphate. After purification by the aid of the resin exchange adsorbents the calcium salt of the fructose diphosphoric acid was obtained in pure condition. *Anal.* Calcd. for $C_6H_{10}O_6(PO_3Ca)_2$: P, 14.9; Ca, 19.2. Found: P, 15.3; Ca, 19.4.

Crude fructose-6-monophosphate (75% purity) was similarly treated with the resin exchange adsorbents and the ester recovered as the barium salt. *Anal.* Calcd. for $C_6H_{11}O_6(PO_3Ba)$: P, 7.8; fructose, 45.5. Found: P, 8.0; fructose, 45.5.

The authors wish to thank Drs. J. R. Matchett, R. R. Le Gault and J. F. Carson for their interest and valuable suggestions.

Summary

A method for preparation of dipotassium glucose-1-phosphate dihydrate is described. The glucose-1-phosphate is obtained by digesting a starch with crude potato phosphorylase in the presence of inorganic phosphate and the purification of the ester is accomplished by using ion exchange adsorbents.

The Autoxidation of β-Eleostearic Acid. The Application of the Spectrophotometer to the Study of the Course and the Kinetics of the Reaction[1,2]

BY RALPH W. BRAUER[3] AND LUVILLE T. STEADMAN

The course and mechanism of the reactions between unsaturated fatty acids and molecular oxygen have remained obscure in spite of a vast amount of careful investigation. The solution of this important problem has been held up by a dilemma which the conventional approach has been unable to evade: Either the autoxidation takes a complicated destructive course, with the formation of numerous secondary products, or there are several centers within the molecule capable of undergoing reaction. In either case the methods hitherto employed measure a number of simultaneously occurring reactions which cannot be disentangled for theoretical studies.

Of the known fatty acids, those which contain a conjugated system of unsaturation show the least breakdown and the most clearly defined oxygen uptake. Due to their conjugated double bonds, these compounds all show strong absorption of light in the middle or remote ultraviolet region. This property permits the determination, impracticable by other methods, of a particular grouping throughout the course of the autoxidation reaction. Thus, in spite of the fact that more than one center in these molecules is capable of absorbing oxygen, it becomes possible to dissociate the various reactions from one another to some degree.

The work reported in this paper has been performed upon β-eleostearic acid, an octadecatrienoic acid of structure

$$CH_3(CH_2)_3(CH{=}CH)_3(CH_2)_7COOH$$

which is readily obtained in a state of high purity from tung oil. The autoxidation of this material was followed by spectrophotometric means and by simultaneous oxygen uptake measurements.

In order to attain a satisfactory degree of accuracy and reproducibility, it was deemed desirable to carry out the reactions in liquid solutions in an inert solvent. This required the development of a special technique for the oxygen uptake measurements, which will be described below in some detail, not only as an integral part of the spectrographic studies, but also because the procedure permits the investigation of the relation between the concentration of autoxidizable substrate and the rate of autoxidation. In the opinion of the authors such studies are of vital importance to the further elucidation of the mechanism of autoxidation of ethylenic systems.

Experimental

β-Eleostearic Acid.—Sulfur isomerized tung oil[4] was saponified according to the method of Dann, *et al.*,[5] and the non-saponifiable matter was extracted with ether from the alkaline mixture diluted 1:1 with water. The aqueous layer was separated and acidified after heating to about 90°. The liberated fatty acids were washed repeatedly with hot water, and finally solidified by the addition of ice water, and were then separated by filtration. β-Eleostearic acid was isolated from the mixed fatty acids by crystallization, once from methyl alcohol and three times from petroleum ether (b. p. 40–60°) at 0°.

The β-eleostearic acid thus obtained consisted of white platelets of m. p. 71.5–71.8°. The entire isolation was performed under nitrogen. The final product was stored in the dark in nitrogen-flushed containers, kept evacuated to less than 1 mm. of mercury.

***n*-Amyl Acetate.**—The commercial product (Eastman Kodak Co., C. P. grade) was purified by two different pro-

cedures, namely, that of Likhtman[6] and that recommended by Weissberger and Proskauer.[7] The physical constants of samples prepared by either procedure were identical and indicated the presence of some lower esters in the product. Neither sample showed any oxygen uptake when shaken for twenty-four hours at 64.5° under 1 atmosphere of oxygen in the dark.

Preparation of Solutions.—In all, five solutions were employed in the experiments here reported. The concentrations are shown in Table I. These solutions were

TABLE I

Solution no.	1	2	3	4	5
Concn. in g. β-eleostearic acid per 10 cc. soln.	0.204	0.315	0.397	0.890	1.490

made up by weight under nitrogen in 5-g. lots and were freed of air by passing a stream of solvent-saturated nitrogen through the liquid for five minutes. Aliquots of 0.2–0.5 g. were weighed under nitrogen into thin-walled ampules, which were then cooled to −80°, evacuated and sealed. The finished ampules were kept in a dark vacuum desiccator, evacuated to below 1 mm.

Apparatus and Procedure.—The apparatus employed in these experiments consisted essentially of the following parts (see Fig. 1): the reaction cell A attached to the shaking eccentric E and connected to the manometer D and the gas buret C_r; the compensating cell B attached to the other side of the manometer D and to the gas buret C_c; the gas and vacuum train, consisting of the mercury trap H, the drying tower I, the solvent saturating tube J and the dry-ice trap L placed before the vacuum pump P; the stopcock manifold 1, 2, 3, 4, 5, 6, which permitted the connection of the various parts of the system with one another and the atmosphere. Cells A and B were kept in the water thermostat a-a which was maintained at 64.5 ± 0.2°. The gas burets C_r and C_c were placed in the circulating water jacket b-b thermostated at 28.0 ± 0.3°. A shaking rate of 40 cycles per minute was found to be well above the critical rate of shaking and was employed throughout.

The apparatus was operated as follows: Stopcock 6 was opened, thus putting the manometer D out of operation. The glass rod F was removed from cell A and the solution to be tested was introduced in ampule G. A was then closed by replacing F into its rubber collar, and the shaking mechanism was started. The entire apparatus was next evacuated and tested for leaks. After the system had been made completely gas-tight, dry oxygen, saturated with *n*-amyl acetate vapor, was admitted through H, I, J into all parts of the apparatus. This procedure of alternately evacuating and filling with oxygen was repeated three times and finally the oxygen pressure within the apparatus was brought to 10–15 mm. of mercury above atmospheric pressure. After fifteen minutes the apparatus had reached temperature equilibrium. The reaction was then started by crushing ampule G with the rod F. Gas pressure within the apparatus was adjusted to atmospheric pressure by momentarily opening stopcocks 3 and 4 to the outside, and finally the manometer arms were separated by closing 6. Oxygen uptake was measured directly by introducing mercury from the reservoir R into the gas buret so as to maintain a constant oxygen pressure differential between A and B. The geometry of the apparatus was such that distillation of solvent from A into C_r did not take place to any detectable amount under the conditions of the experiments. All volume changes employed in the calculations are uncorrected for the partial pressure of the solvent since suitable data are not available in the literature. When such data become available a downward correction of all oxygen values reported below will have to be made which will probably not exceed 2–3%.

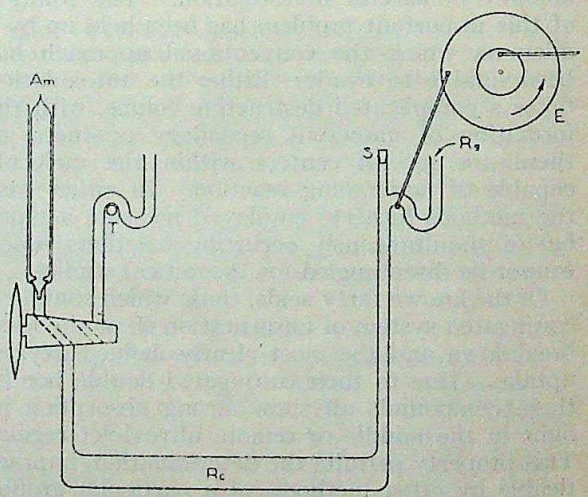

Fig. 2.—Oxidation cell for the spectrographic studies.

For the spectrographic experiments the cell shown in Fig. 2 was connected to the shaking eccentric and simultaneous oxygen uptake and spectrophotometric determinations were performed. The sample was introduced into the spectrographic cell by cracking both ends of the ampule Am. The cell R_c was next flushed with oxygen and connected to the gas reservoir R_g which was kept filled with oxygen at atmospheric pressure. From time to time samples for spectrographic analysis were withdrawn from the cell through the stud S. Such samples were weighed and diluted with a calculated amount of ether to a concentration of 1.84 mg. of β-eleostearic acid per liter of ether for the initial samples; for the later samples the concentrations were adjusted so that the density at 2685 Å. was between 1.5 and 2.0. The spectrographic examination was performed by means of a medium size Bausch and Lomb quartz spectrograph using a rotating sector spectrophotometer with an iron spark as light source.

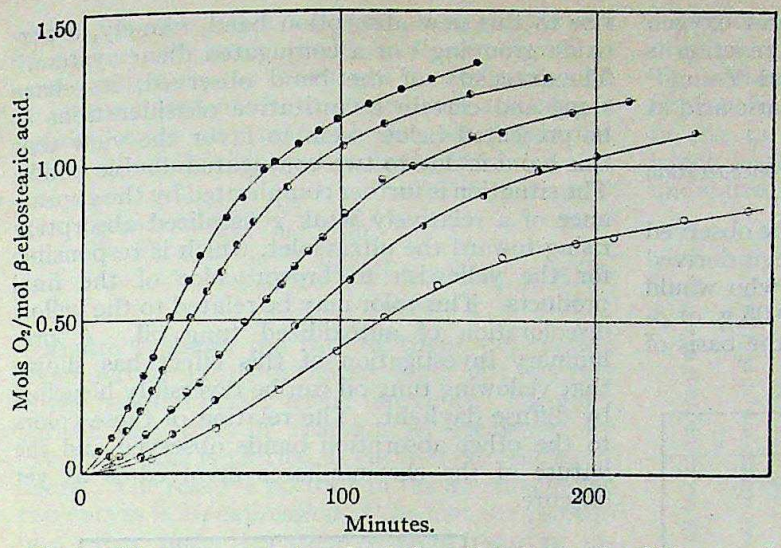

Fig. 3.—The oxygen uptake of solutions of β-eleostearic acid in *n*-amyl acetate: ○, solution no. 1; ◑, solution no. 2; ◒, solution no. 3; ◐, solution no. 4; ●, solution no. 5 (*cf.* Table I).

Results and Discussion

Figure 3 shows the oxygen uptake of different concentrations of solutions of β-eleostearic acid in *n*-amyl acetate as a function of time.

In all cases induction periods of from twenty to forty minutes were observed. These, however, were found to be irreproducible even with duplicate samples of the same solutions.[8] The variations observed in the induction periods apparently were not due to impurities present in the solvents, since no differences could be observed between the solvent purified by the two procedures.[6,7] Neither can the blame be laid upon impurities of the acid employed, since all samples were prepared from the same batch of material. The oxygen tension was substantially the same in any duplicate experiments; the extremes of the variation of total pressure of the entire series of experiments were 755.5 and 729.8 mm. of mercury, respectively; hence, this factor can hardly be responsible for the results obtained. A plausible explanation might be found in the persistence of minute traces of dissolved oxygen in the solvent in spite of the precautions taken.

But for their induction periods, duplicate oxygen uptake curves were found to be superimposable within an accuracy of ±1–2%. The induction periods shown in Fig. 3 were arbitrarily chosen to permit convenient representation.

Several samples were studied for twenty-four to thirty-six hours. In all cases it was found that the uptake of oxygen became extremely small after 2 mols of oxygen per mol of β-eleostearic acid had been absorbed. These observations agree with those of Myers, Kass and Burr,[8] who studied the autoxidation of the acid spread upon filter paper at 40° and with the results of Miller and Claxton,[9] who worked with the molten acid at 80°. The agreement of these various experiments suggests that the main reaction is terminated when 2 mols of oxygen have been taken up per mol of β-eleostearic acid, and that any further oxygen absorption represents a side reaction, possibly of a degradative type.

The final product of the autoxidation has been isolated by the dilution of the completely oxidized solutions with petroleum ether. This procedure precipitates the oxidized material, a dark brown, viscous, non-volatile oil. Analysis[10] showed a composition $C_{36}H_{58.8}O_{12.2}$, a neutral equivalent of 312.4 and a molecular weight of about 600 (ebullioscopic determination in acetone). These properties would agree closely with those expected for a dimer of β-eleostearic acid, formed with the uptake of 2 mols of oxygen per mol of acid and without the participation of the carboxyl groups: $C_{36}H_{58-60}O_{12}$, neutral equivalent 315, molecular weight 630. All attempts to crystallize this material have failed so far, and it is suggested that several isomers are present which differ in the relative orientation of the chains (head-to-head or head-to-tail), the sites of mutual attachment and possibly in geometric configuration.

The rate of oxygen uptake in each experiment increased from 0 to a maximum after the absorption of 0.3 to 0.5 mol of oxygen per mol of β-eleostearic acid, and thereafter decreased slowly, to reach 0 when the limiting amount of oxygen had been consumed (see, *e. g.*, Fig. 7). The re-

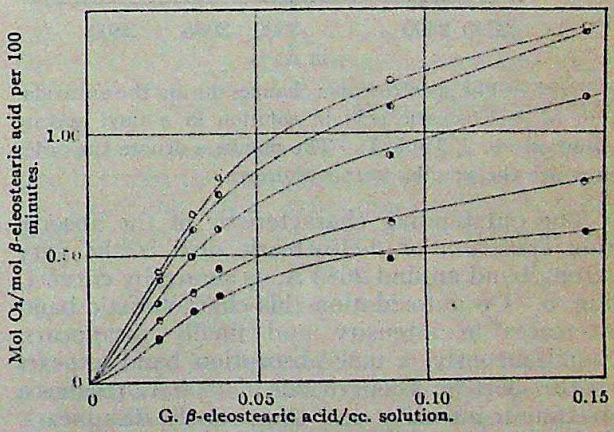

Fig. 4.—The rate of oxygen uptake of solutions of β-eleostearic acid in *n*-amyl acetate as a function of the initial concentration: ●, after the absorption of 0.025; ◒, of 0.050; ◑, of 0.100; ◐, of 0.200; and ○, of 0.300 mol of oxygen per mol of β-eleostearic acid.

lation between initial concentration and oxygen uptake rates for various stages of the reaction is represented in Fig. 4. Henderson and Young[11] working with oleic acid dissolved in stearic acid at 70° reported a relation

$$\text{Rate of oxygen uptake} = A + B \times (\text{initial concentration of oleic acid})$$

where A and B are constants. It will be observed that a similar equation might have been derived for β-eleostearic acid by an observer who would employ a concentration greater than 0.05 g. of β-eleostearic acid per cc. of solution as the basis of his considerations.

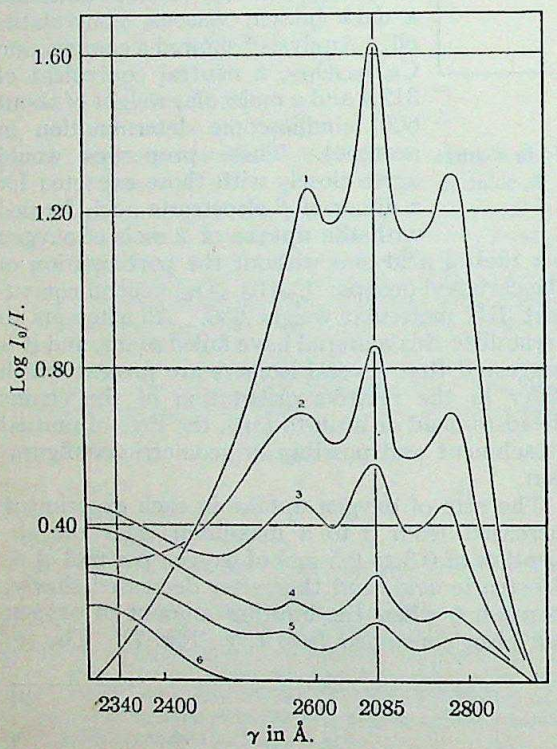

Fig. 5.—The spectroscopic changes during the autoxidation of β-eleostearic acid in solution in *n*-amyl acetate (solution no. 2, Table I). The numbers denote the order in which the samples were withdrawn.

The outstanding characteristic of the absorption spectrum of β-eleostearic acid is the very strong band around 2685 Å. as shown by curve 1, Fig. 5. On autoxidation this characteristic band decreases in intensity and finally disappears. Simultaneously, a new absorption band appears on the short wave length side of 2500 Å., reaches a maximum intensity and then slowly disappears. Unfortunately, the spectrograph employed does not permit measurements below 2330 Å., so that only one side of the new band can be observed. This restriction makes it impossible to definitely identify the new band as due to a particular chromophore. Under the conditions of these experiments, two groupings might plausibly give rise to this new absorption band, namely, a peroxide grouping[12] or a conjugated diene system.[13] The intensity of the band observed, its sharp slope and certain quantitative considerations to be presented below seem to favor the view that this band is due to two conjugated double bonds. The situation is further complicated by the appearance of a relatively weak generalized absorption rising toward the ultraviolet, which is responsible for the yellowish to brown color of the final products. This color may be related to the yellow discoloration of autoxidized tung oil. A preliminary investigation of this effect has shown that yellowing tung oil can be reversibly bleached by diffuse daylight. The relation of these colors to the other absorption bands observed and the nature of the chromophores involved is as yet obscure.

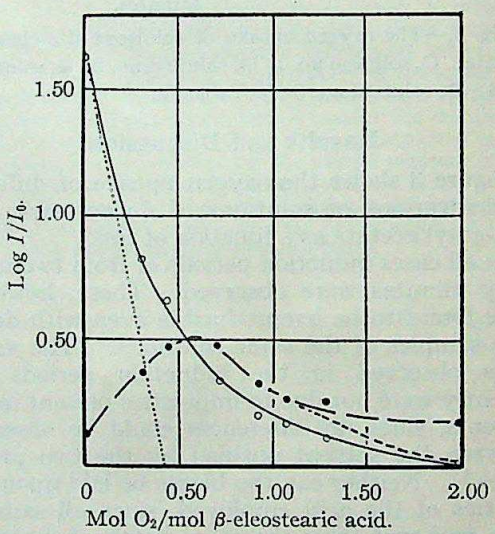

Fig. 6.—The extinction coefficients of autoxidizing β-eleostearic acid as a function of oxygen taken up: ○, log I_0/I at 2685 Å.; ●, log I_0/I at 2340 Å.; ———, calculated from equation 1; – – – –, late course of diene curve as predicted from reactions A and B.

Figure 6 shows the relation between the amount of oxygen absorbed and the extinction coefficient of the autoxidizing solution at 2685 and at 2340 Å., respectively. The relation between the extinction coefficient of the triene band and the amount of oxygen taken up is given by the empirical expression:

$$K_{3\Delta_t} = K_{3\Delta_0} \frac{O_{2\infty} - O_{2t}}{(1.265\, O_{2t} + \sqrt{O_{2\infty}})^2}$$

where $O_{2\infty}$ and O_{2t} represent the amount of oxygen taken up at infinite time and at time t, respectively, and where $K_{3\Delta_0}$ and $K_{3\Delta_t}$ represent the extinction coefficient at 2680 Å. at zero time and at time t, respectively. In view of what has been said

above, $O_{2\infty}$ is equal to 2.0 mols of oxygen per mol of β-eleostearic acid. From this expression it is possible to compute the rate of triene destruction at any moment of the reaction from the oxygen uptake curve and relatively few spectrographic data. The following relation is obtained

$$(1)\qquad \frac{d}{dt}K_{3\Delta_t} = \frac{\partial K_{3\Delta_t}}{\partial O_2}\frac{dO_2}{dt} = \frac{dO_2}{dt} \times K_{3\Delta_0} \times \frac{1.265(O_{2t} - 2O_{2\infty}) - \sqrt{O_{2\infty}}}{(1.265\,O_{2t} + \sqrt{O_{2\infty}})^3}$$

Figure 7 shows the rate of triene destruction computed by means of this equation as a function of the residual intact triene (curve a). For comparison the rate of reaction as measured by oxygen uptake is plotted as curve b into the same figure. The relative position of the maxima of the two curves is an expression of the fact that groupings other than the triene system take an increasingly important part in the absorption of oxygen as the reaction progresses.

The marked asymmetry of curve a is of theoretical interest. Either a simple autocatalytic mechanism or a mechanism involving an autocatalytic chain reaction would lead to the prediction of a symmetrical shape for this curve. The asymmetry of curve a, Fig. 7, is therefore indicative of one of two possibilities: either a catalyst which is formed in the first stages of the reaction is destroyed in later phases, or an inhibitor substance gradually accumulates during the course of the reaction. Which of these possibilities is the correct one cannot be determined on the basis of available data.

The data presented in Fig. 6 also give some indication of the fate of the absorbed oxygen. Inspection of the triene decay curve will reveal the fact that the intercept with the O_2 axis of the tangent drawn to this curve at the value $O_2 = 0$, yields directly the value of the ratio (O_2 taken up)/(triene destroyed) at the start of the reaction. Calculation shows this value to be equal to 0.44. Thus, a little less than $1/2$ mol of oxygen suffices initially to destroy 1 mol of triene system. Present evidence indicates that the uptake of oxygen by unchanged molecules does not involve the initial rupture of the strong O–O bond. The results here obtained can be explained in terms of either of two hypotheses: (A) the peroxidation is succeeded by a very rapid decompostion reaction involving the peroxidized molecule and one intact molecule; or (B) the initial peroxidation may lead either directly or in a rapid secondary reaction to the formation of dimeric products with the formation of additional C–C and C–O bonds. These products may or may not be peroxidic. The fact that low molecular weight decomposition products are not observed in the course of the autoxidation of β-eleostearic acid makes the first of these possibilities improbable, while the assumption that dimerization is an essential part of the reaction between the triene and molecular oxygen is supported by the appearance of dimers of the original acid as the major product of the reaction. The somewhat low value obtained for the initial oxygen to triene ratio (0.44 instead of 0.50) may be due to a reaction caused by the peroxide and which leads to the formation of polymers of the unoxidized acid.[14]

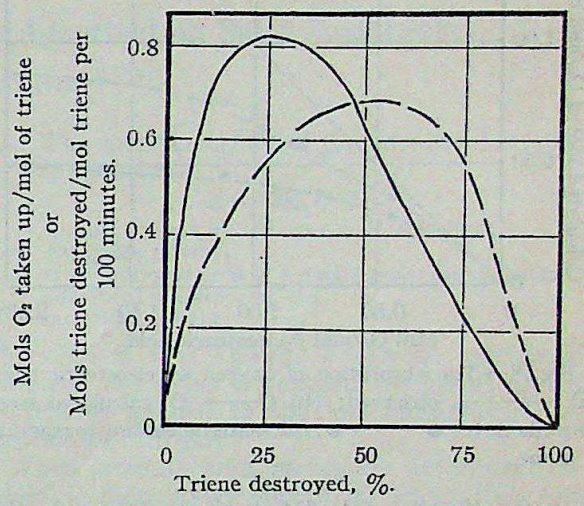

Fig. 7.—Rate of autoxidation as measured by oxygen uptake or by triene destruction: (a) ———, triene destruction; (b) – – – – –, oxygen uptake.

The oxygen–triene curve very soon deviates from the tangent which would represent the course of the reaction if only the step described above took place. A closer approach to the observed oxygen uptake can be achieved if it be assumed that the absorption at 2340 Å. is due to a conjugated diene which is formed directly from the triene and which in turn is capable of absorbing oxygen. The sequence of the reactions which would represent this hypothesis is

(A) $2(\text{—C=C—})_3 + O_2 \longrightarrow n(\text{—C=C—})_2$

(B) $(\text{—C=C—})_2 + mO_2 \longrightarrow$ spectrographically inert product capable of absorbing $(3\text{-}nm)$ mols of O_2

These formulas permit the calculation of the relation between the amount of oxygen taken up and the diene and triene extinction coefficients after various periods of reaction. The relation obtained is

$$(2)\qquad O_2 = \frac{K_{3\Delta_0} - K_{3\Delta_t}}{2K_{3\Delta_0}}(1 + mn) - m\frac{K_{2\Delta_t}}{K_{3\Delta_0}}\frac{\epsilon_{3\Delta}}{\epsilon_{2\Delta}}$$

where $\epsilon_{3\Delta}$ and $\epsilon_{2\Delta}$ designate the specific extinction coefficients of the triene and the diene, respectively. The ratio $\epsilon_{3\Delta}/\epsilon_{2\Delta}$ has been determined by extrapolation from the experimental data. If n is assumed to be $1/2$, or 1, or 2, then $\epsilon_{3\Delta}/\epsilon_{2\Delta}$ equals 2, or 1, or $1/2$, respectively. From the authors' data for β-eleostearic acid and from those of Van der Hulst[15] for 9,11-linoleic acid, this ratio can be computed and is found to be 1.5, thus eliminating

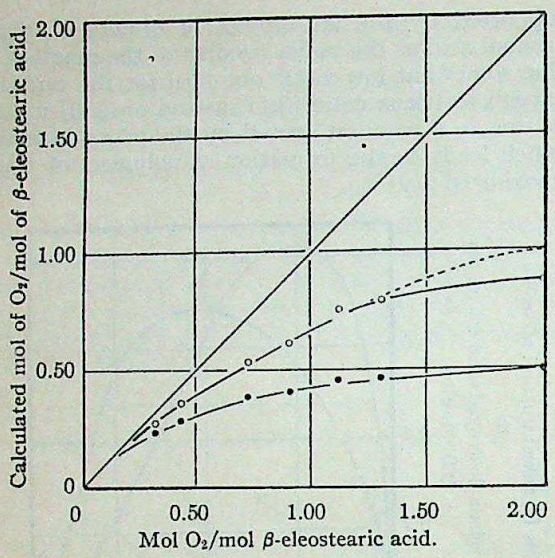

Fig. 8.—The absorption of oxygen by eleostearic acid: (a) ————, observed; (b) O————O, calculated from formula 2; (c) ●— — —●, calculated according to reaction A alone.

$n = 2$. Further calculation shows that only the case $n = 1$, $m = 1$ yields satisfactory results. The curve calculated on this basis is shown as curve b, Fig. 8. For comparison, the curve computed on the assumption that the oxygen uptake value = $^1/_2 \times$ (mols of triene destroyed) is shown in the same figure as curve c and the experimental values are indicated by the straight line a. The course of curve b deviates in its later part from that expected on the basis of the proposed scheme of reactions as indicated by the dotted line on the graph. This deviation might be due to the generalized light absorption mentioned earlier in this paper and which becomes more prominent as the reaction progresses. The difference between the value of $\epsilon_{3\Delta}/\epsilon_{2\Delta}$ as observed in these experiments and as calculated from the studies on pure compounds is hardly surprising in view of the fact that the hypothetical diene certainly must possess a structure differing widely from that of the straight chain fatty acid investigated by Van der Hulst.

The results reported in this paper permit no more than a tentative description of the autoxidation of β-eleostearic acid. Further progress will depend largely upon an elucidation of the structure of the several compounds[16] formed as intermediate and final products of the reaction. Some preliminary work has been performed in this connection and has indicated marked differences in the stability of differently combined oxygen. In the dimeric acid already described, all but $^1/_2$ mol of oxygen per mol of β-eleostearic acid is unstable and can be removed by boiling for one hour with 2% aqueous potassium hydroxide. The product obtained from such treatment is still a dibasic dimer of β-eleostearic acid of composition $C_{36}H_{58.0}O_{5.92}$[10] (formula for 2 mols β-eleostearic acid + $^1/_2$ mol O_2 = $C_{36}H_{60}O_6$). In view of the fact that $^1/_2$ mol of oxygen initially accounts for the destruction of one triene system, this observation may hold a valuable clue.

(16) It would seem inadvisable, therefore, to make use of structural formulas in this paper; such formulas at the best could only represent one of a very considerable number of possible reaction courses, and their use would thus obscure rather than clarify the results actually obtained.

Acknowledgment.—Ralph W. Brauer wishes to acknowledge gratefully the constant friendly advice and encouragement of Dr. Harold C. Hodge. He also desires to express his gratitude toward Professor W. R. Bloor for his friendly attitude which has materially aided in the completion of this research.

Summary

1. A method has been described for the study of the autoxidation of fatty acids in liquid solution by oxygen uptake measurements and by the simultaneous determination of the absorption spectra of the autoxidizing solutions.

2. Curves showing the relation between the rate of oxygen uptake of β-eleostearic acid and the initial concentration of the substrate have been presented.

3. From the spectrographic changes observed in autoxidizing solutions of β-eleostearic acid, it has been suggested that during the reaction a conjugated diene is formed which in turn undergoes autoxidation.

4. A method has been described which permits the computation of the rate of triene destruction employing (a) the oxygen uptake curves and (b) the relation between absorbed oxygen and residual intact triene groups.

5. In order to destroy 1 mol of β-eleostearic acid, slightly less than one-half mol of oxygen is required initially. Consequently, it has been assumed (a) that the initial uptake of oxygen by β-eleostearic acid results in a dimerization involving the formation of some carbon to carbon bonds and (b) that a parasitic polymerization reaction is induced by the peroxides formed in the course of the reaction. The formation of dimeric products in the reaction has been verified by molecular weight determinations.

6. The amount of oxygen taken up can be computed approximately for the early stages of the reaction from the extinction coefficients of the diene and the triene bands if the following sequence of reactions is assumed

$$2(\text{—C=C—})_3 + O_2 \longrightarrow (\text{—C=C—})_2$$

$(\text{—C=C—})_2 + O_2 \longrightarrow$ spectrographically inert products capable of taking up 2 mols of oxygen per mol of original β-eleostearic acid

7. The rate of oxygen absorption by β-eleostearic acid becomes insignificant after an uptake of 2 mols of oxygen per mol of β-eleostearic acid.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

This amount of oxygen can be recovered in a dibasic acid which is probably a dimer of the original acid. Three-fourths of the absorbed oxygen in this product is removed by treatment with alkali.

Cross-Sectional Areas of Molecules Adsorbed on Solid Surfaces[1a]

BY H. K. LIVINGSTON[1b]

The data relating to the cross-sectional areas of molecules in insoluble monolayers adsorbed on water are quite extensive. Adam[2] has listed limiting area values for 26 different classes of molecules. Recently, an increasing number of adsorption studies for gases and vapors adsorbed on solid surfaces of *known area* have been reported.[3] This is principally due to the development of an adsorption theory[4] which permits the calculation of the specific surface of any solid for which vapor adsorption data are available. Therefore, it should be possible to establish a body of area data for vapor molecules adsorbed on solid surfaces analogous to the data for insoluble molecules adsorbed on liquid surfaces.

As will be explained in the following section, cross-sectional area data for molecules adsorbed on solid surfaces are subject to restriction in that they are based on specific surface data which, in turn, are based on cross-sectional area data. If the experimental results are properly interrelated, however, it is possible to obtain accurate relative values for molecular cross-sectional areas.

Theoretical.—Brunauer, Emmett and Teller[4] have developed an equation in the form

$$q_m = \frac{q(p_0 - p)(p_0 - p + cp)}{cpp_0} \qquad (1)$$

q_m = quantity of vapor adsorbed when a monomolecular layer exists, g. per g. of adsorbent.
q = quantity of vapor adsorbed at any pressure, g. per g. of adsorbent.
p = pressure; p_0 = saturation pressure.
c = $(a_1b_1/a_ib_i)\exp.(E_1 - RT.E_i)/$
E = energy of adsorption.
a and b are probability factors in the equations:
ap = number of molecules condensing per unit area;
$b \exp.(E/RT)$ = number of molecules evaporating per unit area.
Subscripts "1" refer to first layer of adsorbed molecules.
Subscripts "i" refer to all other layers (average values).

As pointed out in their paper, the equation may be transposed to give

$$p/q(p_0 - p) = 1/cq_m + p(c - 1)/cq_mp_0 \qquad (2)$$

Since p and q can be measured, this straight-line form of the equation can be used to evaluate c and q_m. The specific surface of the adsorbent is given by the equation

$$\Sigma = Nq_m\sigma/M \qquad (3)$$

Σ = specific surface, sq. cm. per g. of adsorbent.
N = Avogadro number.
σ = cross-sectional area of a single molecule (in plane of adsorbent surface), sq. cm.
M = molecular weight.

Therefore if σ is known, Σ can be calculated. Emmett[5] has given a detailed treatment of this method as applied to the low temperature adsorption of nitrogen.

When pressure–area curves are determined for insoluble monolayers spread on water, the area per molecule is obtained from the equation

$$A = MS/WN \qquad (4)$$

A = area per molecule, sq. cm.
W = weight of insoluble material spread on surface, g.
S = total area available to monolayer, sq. cm.

In the same manner, the area available to each molecule adsorbed on a solid surface can be calculated from the analogous equation

$$A = M\Sigma/qN \qquad (5)$$

With pressure–area data for insoluble monolayers, it is possible to recognize one portion of the curve as corresponding to close-packed chains. The area per molecule in this region is accepted as being equivalent to the actual area of the molecule in a plane parallel to the adsorbing surface, that is, the cross-sectional area (hereafter referred to as "section area"). This section area is found to be approximately equal to that which would be predicted from measurements of molecular dimensions in the normal condensed phases (liquid or solid).

Section area data obtained from pressure–area data for insoluble monolayers are known to vary with the temperature or surface pressure. It would be expected that similar results would be obtained with adsorbed layers on solids, and therefore σ-values used in equation (3) would vary somewhat with temperature, surface pressure, and solid surface.

By use of equation (2), the adsorption corresponding to a complete monolayer can be calculated. The molecular area, A, at this point is equivalent to the actual cross-sectional area occupied by the molecules measured in a plane parallel to the adsorbing surface. Accordingly, when

$q = q_m$, $A = \sigma$, and equation (5) is identical with equation (3) at this point. Thus, A is the area available to each molecule, which will be very great at the beginning of adsorption, while σ is the area which is effectively occupied by each molecule. This area will be very similar to that which is determined from considerations of the atomic volumes involved, but will depend on the packing which the molecules adopt.

It should be emphasized that this treatment is based on the monomolecular adsorption as calculated by the equation of Brunauer, Emmett and Teller, and the results are subject to the same limitations as is their theory. Recent publications have questioned the validity of the equation. Kistler, Fischer and Freeman[6] have objected to the derivation on two counts. They point out that if E_1 is greater than E_i (see equation (1)), as Brunauer, Emmett and Teller assume, molecules in the second layer will distill to fill any bare space in the first layer if that layer is not yet complete. However, one would not expect the energy of adsorption on the bare solid surface to be a constant throughout the process of adsorption. It would seem that E_1 represents an average value, and when the solid surface is almost completely covered, the energy of adsorption on the few bare spaces remaining is so small that condensation in the second or subsequent layers is more probable. Statistically, however, the rate of evaporation over the entire first layer remains equal to b exp. (E_1/RT). Thus E_1 and E_i, like a and b, are constants of the equation and should be interpreted primarily as such. The second objection of Kistler, Fischer and Freeman is that capillary condensation is neglected in equation (1). Inasmuch as the equation fits experimental data very well for pressures up to $p/p_0 = 0.3$, even for many porous solids, the objection is not serious for the portion of the isotherm which determines q_m. This would be especially true for crystalline nonporous adsorbents such as those used in the present work.

Rowley and Innes[7] have applied a two-dimensional phase rule to determine that multilayers adsorbed from vapors onto solids must exist as gaseous two-dimensional films. They conclude that the energy of vaporization in layers after the first cannot be a factor in equation (1). Again, this objection does not appear to invalidate the equation in its original form. Although Brunauer, Emmett and Teller have suggested that E_i is approximately equal to the energy of vaporization of the bulk liquid, this assumption has no effect on the fundamental theory. It is only necessary that E_i be equal to the energy involved in multilayer formation, whatever the source of the energy. The layers may be gaseous, liquid, or solid without affecting the result. If E_i is not equal to the energy of vaporization, equation (1) must be modified to a form in which p_0 is replaced by a new constant. The writer has studied this possibility and found that the value of this constant has relatively little effect on the form of the theoretical isotherm when p/p_0 is less than 0.3; that is, in the range where the equation fits experimental data.

In this connection, it is interesting that the new adsorption isotherm of Jura and Harkins[8] is based on the assumption that the adsorbed films obey the pressure–area relations developed for condensed monolayers on water surfaces. This would seem to contradict the conclusion of Rowley and Innes to the effect that the films are gaseous rather than condensed. The Gibbs equation for vapor–solid adsorption (see Boyd and Livingston,[9] equation (15)) is

$$\pi = (RT/M\Sigma)\int_0^p (q/p)\,dp \qquad (6)$$

π = surface pressure of the adsorbed film on the solid surface. If equations (1) and (3) are substituted into this equation

$$\pi = (RT/N\sigma)\ln[(p_0 - p + cp)/(p_0 - p)] \qquad (7)$$

This is the relation between π, the surface pressure, and the gas pressure for adsorptions to which the equation of Brunauer, Emmett and Teller applies. It can be shown that pressure–area plots constructed from equations (7) and (5) show a considerable portion which is approximately a straight line. That is, the basic equation of Jura and Harkins

$$\pi = a - bA \qquad (8)$$

is in agreement with the equation of Brunauer, Emmett and Teller over a considerable range of pressure. For example, the data of Table I can be fitted to the equation

$$(N\sigma/RT)\pi = 2.58 - 1.65\,A/\sigma \qquad (9)$$

over the pressure range $p/p_0 = 0.07$ to $p/p_0 = 0.5$. This is very similar to the range of agreement reported for the isotherm of Jura and Harkins.

TABLE I

THEORETICAL PRESSURE–AREA DATA

Calculated from equations (7), (1) and (5), with $c = 50$.

p/p_0	$(N\sigma/RT)\pi$	A/σ
0.01	0.176	2.95
.05	.559	1.31
.06	.622	1.23
.075	.704	1.15
.09	.774	1.09
.10	.816	1.06
.125	.910	0.996
.15	.992	.946
.175	1.06	.903
.20	1.13	.865
.30	1.35	.733
.40	1.54	.619
.50	1.71	.510

Accordingly, the new isotherm seems to be closely related to that of Brunauer, Emmett and

Teller, although it is perhaps superior at higher pressures. The success of the Jura–Harkins isotherm increases our confidence in the Brunauer–Emmett–Teller theory.

Measurements.—Emmett and Burnauer have described the adsorption apparatus which they have used for measurement with oxygen or nitrogen at or near their boiling points.[10] A facsimile of this apparatus has been used in this work for determining the nitrogen isotherms. Boyd and Livingston[9] have described an apparatus which is very satisfactory for adsorption studies with vapors which liquefy at room temperature and atmospheric pressure. They use a gravimetric method employing the McBain–Bakr silica spring balance,[11] which is especially designed for use with organic vapors which attack stopcock grease. This apparatus was used for determining the adsorption isotherms of water, *n*-propyl alcohol, and *n*-heptane on the same sample of four different crystalline powders: quartz, anatase, barium sulfate and graphite. These adsorption isotherms have been reported previously.[9] All of the isotherms have been fitted to the Brunauer–Emmett–Teller equation with least square calculations, using the straight line form, equation (2). Thus, for any single sample of powdered solid, it was possible to determine the constants of the Brunauer, Emmett and Teller equation with several different vapors. These are reported in Table II.

TABLE II

THE CONSTANTS OF THE BRUNAUER–EMMETT–TELLER EQUATION

Adsorption measurements at 24°

Solid	Water q_m	Water c	Propyl alcohol q_m	Propyl alcohol c	Heptane q_m	Heptane c
Anatase	2.32	82.2	4.09	66.8	2.22	37.6
Quartz	0.85	72.0	1.47	106.8	0.92	29.1
$BaSO_4$	0.57	218	0.86	132	0.64	44.1
Graphite					9.36	72.0

The Section Area of Adsorbed Molecules.—For many molecules there are a number of independent methods for determining the molecular area, so that a most probable value can be developed from the consideration of the several methods. The effective dimensions of a molecule can be calculated from the density of the bulk phase if the nature of the packing is known and the molecules are spherical. The value of σ can be calculated for all combinations of the three simplest three-dimensional packings and the two simplest two-dimensional packings. The equation which is used is

$$\sigma = F(M/N\rho)^{2/3} \qquad (10)$$

where ρ = the density of the bulk phase. The values of F, the packing factor, are given in Table III.

For the closest possible packing, $F = 1.091$. This is the factor which Emmett and Brunauer[10] have used in their calculations. For nitrogen, this leads to cross-sectional areas of 16.2 and 13.8 Å. per molecule, based on liquid density at −196° and solid density at −252°, respectively. In their early publications, Emmett and Brunauer used both areas, but Emmett and DeWitt[13] used the liquid value exclusively. Ruhemann[14] reports that β-nitrogen (the form which is stable above 35° K.) crystallizes in the form of spheres with closest possible packing. This indicates that 1.091 is the correct packing factor and the section area at −196° is between 13.8 and 16.2 sq. Å.

TABLE III

PACKING FACTORS[12]

Type of three-dimensional lattice	Packing Factor: Square Two-dimensional packing, 4 nearest neighbors	Packing Factor: Hexagonal Two-dimensional packing, 6 nearest neighbors
Simple cubic, 6 nearest neighbors	1.000	0.866
Body-centered cubic, 8 nearest neighbors	1.190	1.023
Face-centered cubic, 12 nearest neighbors	1.260	1.091

The water molecule is not spherical, but the volume of hydrogen is so small in comparison with oxygen that the molecule must be almost a sphere. Ice crystals exhibit low symmetry, indicating that packing is somewhat looser than for any of the types referred to in Table III. It is very difficult to predict the area of the water molecule by use of equation (10), but if F is taken to be 1.091, the section area can be calculated to be 11.1 sq. Å., based on the solid density at 0°, or 10.6 sq. Å., based on the liquid density at 24°.

From X-ray crystallographic measurements, Müller[15] has concluded that the distance of nearest approach between normal hydrocarbon molecules is 4.75 Å. and the length of the molecules is 1.29 Å. per carbon. Accordingly, the *n*-heptane molecule may be treated as a cylinder 4.8 Å. in diameter and 9.1 Å. long. Stewart[16] has studied the X-ray diffraction pattern of liquid hydrocarbons at room temperature and reported 4.63 Å. as the distance of nearest approach. With either of these values, the area occupied by a *n*-heptane molecule with the long axis perpendicular to the solid surface would be approximately 20 sq. Å. If the molecule were oriented with the long axis parallel to the solid surface, the area would be 42.3 sq. Å. for the closest possible packing. This value would be greater for a less ordered arrangement.

From X-ray studies of the long-chain alcohols, Bernal[17] has concluded that their molecular di-

mensions are similar to those for hydrocarbons, except that the molecular length is increased by 1.0 Å. by the hydroxyl group. His data indicate that the *n*-propyl alcohol molecule is 4.9 Å. long and 4.8 Å. in diameter. Stewart and Morrow[18] found liquid *n*-propyl alcohol molecules to give a diffraction pattern corresponding to 4.3 Å. for the distance of closest approach and 5.1 Å. for the molecular length (4.8 Å. from a smooth curve). If the propyl alcohol molecule is considered to be a sphere 4.8 Å. in diameter, the section area will be 23.0 sq. Å. per molecule if square packing is assumed, and 19.9 sq. Å. per molecule for close packing. Film balance measurements can be used to determine the cross-sectional area of alcohol molecules oriented with the hydroxyl to the water surface. The extrapolation to zero pressure of the pressure–area curve for liquid films is considered to give the area of the alcohol group. The best available data are those of Copeland, Harkins and Boyd[19] for eicosyl alcohol at 24°, which give 22.4 sq. Å. molecule. It is not certain that this zero pressure value has much relation to the area of a propyl alcohol molecule which is on a solid surface under a surface pressure[9] of 60 dynes per cm.

Results.—On the basis of the considerations developed in the preceding paragraphs, values of σ have been chosen which will give satisfactory agreement among all the adsorption data. It was concluded that the section areas are in the ratio

$$N_2:H_2O:PrOH:Heptane = 15.4:10.6:20.0:55.0$$

The data supporting this conclusion are presented in Table IV. The high section area obtained for heptane indicates that the molecules are oriented with the long axis parallel to the solid surface, or at least that the molecules are spaced so that there is room for such a flat orientation.

The q_m values from the nitrogen isotherms were used for calculating the specific surface of the finely-divided solids, according to the method outlined by Emmett.[5] Equation (3) was used, with 15.4 sq. Å. taken as the section area of the nitrogen molecule, instead of 16.2 which Emmett prefers. This value of 15.4 coincides with the most frequent and also the average value reported by Jura and Harkins[20] on the basis of 60 isotherms. This value was obtained by reference to a sample of anatase the area of which had been measured by a calorimetric technique which was independent of cross-sectional area data for the adsorbed molecules.[21] This new technique offers an interesting method of checking section area values.

TABLE IV

COMPARISON OF SPECIFIC SURFACE AND SECTION AREA VALUES

Vapor	Value of σ used, Å.² per molecule	Specific surface, sq. m./g., corresponding to each value of σ TiO_2	SiO_2	$BaSO_4$	Graphite
Nitrogen	16.2	8.70	3.20	2.39	27.6
	15.4	8.27	3.05	2.27	26.2
Water	10.6	8.28	3.03	2.03

The specific surface of the solids (in sq. m. per g.) determined by this method were TiO_2, 8.27; SiO_2, 3.05; $BaSO_4$, 2.27; graphite, 26.2.

The adsorption isotherms presented in a previous publication[9] have been recalculated and transposed into a form which emphasizes the agreement between the various sets of data. These isotherms have been plotted in Figs. 1, 2 and 3. The ordinate for these plots is Γ, the molar adsorption per unit area, obtained from the equation

$$\Gamma = q/M\Sigma \qquad (11)$$

The Σ-value which was obtained from the nitrogen isotherms was used in every case. It will be seen that for quartz, anatase and barium sulfate, the break in the isotherms which corresponds to a complete monolayer[4] occurs at very nearly the same value of Γ.[22] For any vapor, the adsorbed molecules in the monolayer occupy the same area on each of these three solid surfaces. The isotherms for adsorption on graphite are not in agreement with the others. This may be due in part to impurities in the graphite sample (Dixon 0708) or to the extreme difficulty of outgassing graphite surfaces.[23]

The isotherm for heptane on graphite appears to be normal except for the higher Γ-value at the break of the curve. This suggests that heptane has a closer packing on the graphite surface than on quartz or the other solids. For heptane molecules on graphite, the section area is found to be 44 sq. Å., as compared to 55 sq. Å. for heptane on other surfaces (see Table IV). This value is very near the minimum area for the flat orientation (42.3). It is interesting that the section area value for heptane adsorbed on solids corresponds to an orientation with the long axis parallel to the solid surface. X-Ray studies of aliphatic molecules have consistently indicated an orientation with the long axis normal to the solid surface.[24]

Conclusions.—The modified McBain–Bakr adsorption technique which was described by Boyd and Livingston[9] has been used to determine isotherms for organic molecules and water. The technique can be used to study the cross-sectional area of organic molecules which are too volatile to be used in film balance work with insoluble monolayers on water.

It has been mentioned that a comparison between specific surface values obtained when different vapors were used with the same solid would make it possible to assemble a complete set of data regarding the section area of adsorbed molecules. All values would be relative; however, X-ray, density, and film balance measurements could be used to calculate area values for each molecule which should be interrelated with the relative values from adsorption data. There would be a degree of uncertainty because some molecules would pack more closely on one surface than on another. This seems to be the case for heptane on graphite, in the present study. Such differences could be recognized easily, as could differences in orientation. The final result of a series of such adsorption measurements would be a table presenting the area of molecules adsorbed as monolayers on solids, and would be analogous to the tabulated data which now exist for substances which form insoluble films on water.[2]

Acknowledgment.—The writer appreciates the interest and encouragement of Dr. G. E. Boyd, who was senior author of an earlier publication[9] based on the same experimental data used in the present work.

Summary

For four different finely-divided solids, adsorption isotherms have been measured both by the Brunauer–Emmett low temperature nitrogen adsorption technique and by the McBain–Bakr method, using vapors from substances which boil well above room temperature. By comparison of the various isotherms, the cross-sectional area values for the adsorbed molecules (in Å.^{2} per molecule) have been found to be H_2O, 10.6; PrOH, 20.0; heptane, 55.0, if nitrogen is taken to be 15.4. These areas are in every case in good agreement with the molecular areas of the molecules as determined from density, X-ray, or film balance measurements. The modified McBain-Bakr technique offers a method for measuring the section areas of adsorbed organic molecules of all types. It can also be used for determining the surface area of finely-divided solids from adsorption measurements at room temperature, using the vapors from ordinary volatile liquids.

An Electron Diffraction Investigation of the Monomers and Dimers of Formic, Acetic and Trifluoroacetic Acids and the Dimer of Deuterium Acetate[1]

BY J. KARLE[2] AND L. O. BROCKWAY

Introduction.—Recent spectroscopic studies[3,4] of the monomers and dimers of formic and acetic acids have indicated that the carbon to oxygen distances in the carboxyl group are not equal. Since an early electron diffraction study[5] on formic acid indicated equal carbon to oxygen distances, a repetition of the original study was suggested. In addition to this problem there arises the question concerning what changes, if any, occur in the monomers of the acids on association.

Robertson and Ubbelohde[6] studied the structure of deuterated oxalic acid dihydrate and observed an increase in length of the crystallographic unit cell in the direction of the hydrogen bridge. If the increase is located only in the bridge portion of the molecule, it would correspond to an expansion of the hydrogen bond of 0.044 Å. on substituting deuterium for hydrogen. Since an isotope effect in the dimer of acetic acid of 0.04 Å. might be detected by an electron diffraction investigation, the structure of the dimer of deuterium acetate was investigated.

Trifluoroacetic acid is a very strong acid whereas acetic acid is moderately weak. It was considered interesting therefore to attempt to observe a change in the acetic acid structure introduced by a trifluoromethyl group.

Experimental.—The method of obtaining electron diffraction photographs and a description of the apparatus have been given.[7]

Theoretical intensity curves were calculated using the formula

$$I(s) = \sum_i \sum_j Z_i Z_j (\sin s r_{ij})/s r_{ij}$$

where $s = 4\pi\sin(\theta/2)/\lambda$. The structural parameters determined were compared to those obtained from radial distribution curves calculated by the Walter and Beach[8] formula assuming a_k, the approximate half width of the maxima and minima, to be 0.7 s unit.

In order to study the monomers of the acids, an apparatus was required for photographing the equilibrium vapor at approximately 150°. This was accomplished by means of a 500-ml. glass container and a nozzle which could be heated independently to the desired temperature. In the nozzle, the copper tube through which the vapor flows was heated by a spiral winding of resistance wire insulated by a Pyrex tube with beads fused on for spacing the turns of wire. The large glass container was heated by means of an electric oven.

An interesting feature of this apparatus is the type of vacuum seal used. The glass to metal tapered joint, which is employed for room temperature studies, was not used because of the danger of breakage and leakage at the higher temperatures. Instead, the seal was produced by attaching the upper end of the container which consisted of a flat, well ground ring of glass, whose inner and outer radii differed by about 5 mm., to a flat metal surface on the bottom of the nozzle. Between the glass and metal surfaces a very useful high temperature vacuum grease was employed. This grease, made from aluminum stearate and SAE 50 motor oil, is described by Puddington.[9] It also was used to lubricate the stopcock on the container of vapor and a vacuum was conveniently maintained at 160°. No attempt was made to reach higher temperatures.

The degree of dissociation of the dimer at the elevated temperature was calculated from T_1 (the observed room temperature), p_1 (the total pressure at T_1), K_1 (the equilibrium constant at T_1), ΔH (the heat of dissociation assumed constant over the temperature range) and T_2 (the temperature of the diffraction measurements). The equilibrium constants and heats of dissociation for formic and acetic acids were taken from the work of Coolidge[10] and MacDougall[11]; the equilibrium constant for trifluoroacetic acid was determined from the vapor density measurements described below and its heat of dissociation was assumed to be the same as that for acetic acid. Table I gives the dissociation data for the three acids.

TABLE I

F = Formic, A = acetic and T = trifluoroacetic acids.

Acid	T_1, °K.	P_1, mm.	K_1, mm.	ΔH, kcal.	T_2, °K.	P_2, mm.	$K_2 \times 10^{-4}$, mm.	α
F	303	22.5	3.6	14	403	48	1.13	0.93
A	303	21.0	0.7	16	416	50	0.95	0.91
T	305	22.5	5.0	16	390	46	1.56	0.95

These calculations are necessarily approximate in character due to the assumptions involved in employing the formulas. However, the small contribution to the electron scattering of the long distances occurring in the dimer are negligible for the amounts of the dimers indicated above. Also, the degree of dissociation which appears in Table I is the one for the first exposure and the dissociation for successive photographs must continuously increase since the total pressure in the system is decreasing. An average of fifteen exposures were taken from a single sample in the container. Since no detectable difference was observed between the first and last photographs of any of the monomers, it is therefore concluded that the dimer makes a negligible contribution to the scattering in these high temperature experiments.

No dissociation data for the vapor of trifluoroacetic acid could be found in the literature. Experiments were therefore performed to obtain a value corresponding to the conditions of the diffraction study. Since the intensity curves are not sensitive to differences in dissociation of one or two per cent., no attempt was made to make very precise measurements. The apparatus used was a two-liter bulb which could be filled to a measured pressure with vapor from a weighing bottle. The temperature was room temperature and α, the degree of dissociation, was calcu-

lated using the perfect gas law. The uncertainty is estimated to be within 20% of the average of the values obtained in Table II.

TABLE II

Expt.	P, mm.	V, ml.	T, °K.	w, g.	α
1	97.35	2128	300.5	2.3013	0.10
2	89.15	2128	299.0	2.1181	.10
3	100.40	2129	302.5	2.3215	.11
4	103.20	2128	302.5	2.3896	.11

The first two experiments were performed after a single vacuum distillation and the last two were performed on samples which were also pumped through phosphorus pentoxide.

Formic Acid Monomer.—The formic acid was prepared by passing hydrogen sulfide over the lead salt. It was further purified by the fractional vaporization method of Coolidge.[10] With regard to the question of possible decomposiion at the temperature of the experiment for the monomer, a set of photographs were taken and then the container was allowed to cool. About four hours later another series of photographs were taken at the high temperature. No change in patterns was observed indicating no significant decomposition.

A total of nineteen models were studied in which the longer carbon to oxygen distance (C—O) varied from 1.29 to 1.45 Å., the shorter carbon to oxygen distance (C=O) varied from 1.22 to 1.29 Å. and the enclosed angle (O—C=O) varied from 115 to 130°. Figure 1 represents a plot of C—O/C=O ratios *versus* the O—C=O angle, the range of uncertainty being enclosed within the dotted lines and the scale is fixed by setting C=O equal to 1.22 Å. in model K, equal to 1.24 Å. in models A, B, C, D, E, J, L and M, equal to 1.25 Å. in models I, N, O, Q and R, equal to 1.27 Å. in models P and S and equal to 1.29 Å. in models F, G and H. Figure 2 shows some of the corresponding intensity curves. All the curves except those marked with an *h* neglect the scattering due to the hydrogen distances in the molecule. In curves Ah and Bh, the C–H distance was assumed to be 1.09 Å. and the O–H distance to be 0.95 Å.

Curves A and B compare quite favorably with the observed features of the photographs. They contain an O—C=O angle of 117° and C—O/C=O ratios of 1.40/1.24 and 1.43/1.24, respectively. It is observed by comparison with curves Ah and Bh that the introduction of scattering terms due to the hydrogen distances does not alter the positions of the maxima and minima although there is a small effect on the qualitative features which must be taken into consideration.

Model I, which is unsatisfactory, is interesting since it occurs as the structural unit of the dimer possessing an O—C=O angle of 121° and a C—O/C=O ratio of 1.36/1.25.

Two significant peaks were obtained in the radial distribution curve in Fig. 3, one at 1.38 Å. composed of the unresolved C—O and C=O distances and the second at 2.27 Å. representing the distance between the oxygen atoms.

TABLE III

OBSERVED AND CALCULATED MAXIMA AND MINIMA OF FORMIC ACID MONOMER

Max.	Min.	I_k	S_0	S_A/S_0	S_B/S_0
2		15	6.23	0.979	0.970

			Average	1.008	0.995
			Average deviation	±0.013	.013

On the basis of the quantitative agreement indicated in Table III, the following model is chosen for the monomer of formic acid: C—O = 1.42 ± 0.03 Å., C=O = 1.24 ± 0.03 Å., and ∠ O—C=O = 117 ± 2°. The average of the carbon to oxygen distances chosen is 1.33 Å. and the oxygen to oxygen distance is 2.27 Å.

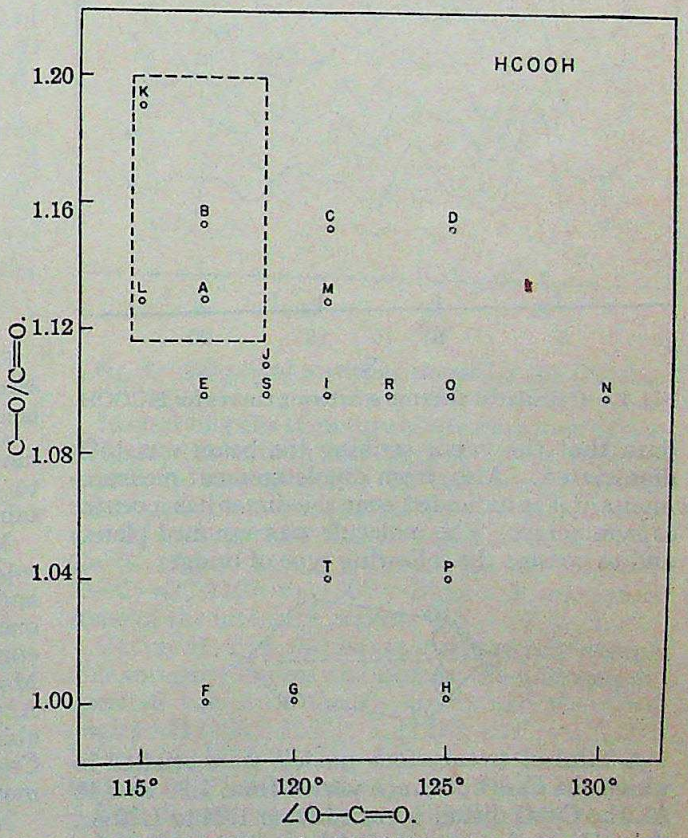

Fig. 1.—Models calculated for HCOOH. Dotted line encloses the models giving best agreement with the photographs.

Formic Acid Dimer.—In studying the dimer of formic acid it was assumed from vapor density

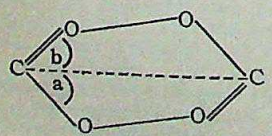
data that the vapor striking the beam was 15% dissociated. Also, from dipole moment measurements,[12] it is indicated that the dimer has a center of symmetry. The molecule was assumed planar and to possess the following type of bridge



A total of twenty-four models were studied in which the C—O distance varied from 1.29 to 1.43 Å., the C=O distance varied from 1.24 to 1.29 Å., the OH—O distance varied from 2.65 to 2.80 Å., the O—C=O angle varied from 117 to 130° and angle *b* varied from 54 to 62.5°. Some of the intensity curves are reproduced in Fig. 4. The great complexity of a five parameter problem makes a complete survey prohibitive. It is believed however that the models considered lead to reasonable conclusions and limits of uncertainty.

Models F and G which possess a C—O/C=O ratio of 1.36/1.25, angle O—C=O equal to 121° and angle *b* equal to 58°, are chosen as the best ones. Model F possesses an OH–O distance equal to 2.70 Å. whereas that of G is 2.76 Å. Models having equal carbon to oxygen distances, A, B and C, are unsatisfactory. Also unacceptable are models I and J which possess a C—O/C=O ratio comparable to that of the chosen monomer, 1.43/1.24.

Model B compares with the best model of Pauling and Brockway in which, however, they suggested 2.67 Å. instead of 2.65 Å. for the OH–O distance across the bridge. Better photographs and a study of a wider range of models account for a choice of structure different from that of model B.

The effect of a change of the OH–O distance to 2.65 Å., without changing the other parameters from their values in models F, is shown in curve

E. Curves D and K show the effect of making angle O—C═O 119° and 123°, respectively, the only change. A decrease of five per cent. from the value of the C—O/C═O ratio used in model F produces an almost negligible change in curve H although the latter model contains an oxygen to oxygen separation differing a little more from the radial distribution peak than that of model F.

The shape of the intensity curves is very sensitive to changes in angles *a* and *b*. Model L differs from G by a 2° change in these angles and the difference in appearance is striking. In model M these angle changes are accompanied by a change in the C—O/C═O ratio to 1.40/1.24 and in the OH–O distance to 2.74 Å.

Attempts to obtain a suitable model of the dimer from a structural unit based on the chosen monomer were unsuccessful.

Model N is interesting since it is based on the most suitable model for the dimer of acetic acid which has an O—C═O angle of 130°. A comparison of curves N and Nh shows the negligible effect of including the scattering due to hydrogen distances in the theoretical intensity curves.

The significant maxima in the radial distribution curve in Fig. 3 occur at 1.30 Å. composed of the unresolved C—O and C═O distances, at 2.30 Å. representing the O–O distance and at 2.75 Å. representing the OH–O distance.

On the basis of the quantitative results in Table IV, the following model is chosen for the dimer of formic acid C—O = 1.36 ± 0.04 Å.; C═O = 1.25 ± 0.03 Å.; ∠ O—C═O = 121 ± 2°; O—H—O = 2.73 ± 0.05 Å.; ∠ b = 58 ± 1°. In the previous investigation[5] the two C–O distances were reported equal at 1.29 Å.

			Average deviation	±0.006	.007

Acetic Acid Monomer.—The acetic acid was made by the General Chemical Company and assayed at 99.5%. A melting point determination verified this figure and so no further purification was attempted.

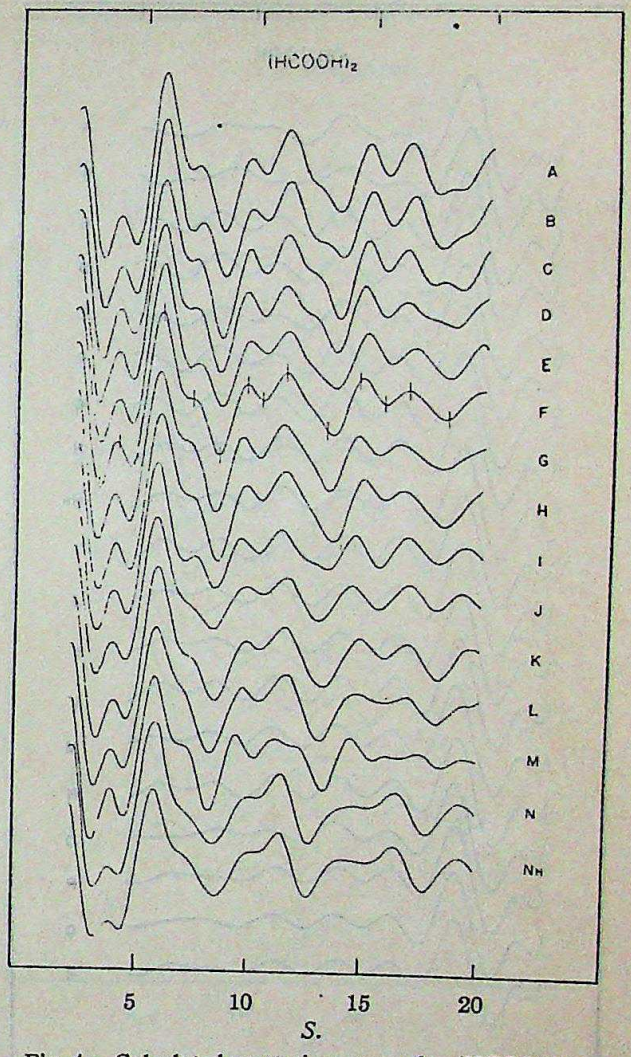

Fig. 4.—Calculated scattering curves for $(HCOOH)_2$.

In studying the structure of the monomer of acetic acid, the carbon and oxygen atoms were assumed to be coplanar. In the twenty models calculated the parameter ranges considered were: C—C, 1.48 to 1.54 Å.; C—O, 1.29 to 1.43 Å.; C═O, 1.22 to 1.29 Å.; O—C═O, 120° to 140°; C—C═O, 110° to 130°. Figure 5 reproduces some of the intensity curves.

Curves H, L, I and N are qualitatively acceptable intensity curves and possess the following respective values of the O—C═O and C—C═O angles: H (125°, 125°); L (127°, 123°); I (130°, 120°); N (135°, 115°). In each the C—O/C═O ratio is 1.43/1.24 and the C—C distance is 1.54 Å. A little less satisfactory are J (125°, 120°) and K (130°, 115°) with the bonded distances unchanged. and M (125°, 125°) with C—O/C═O equal to 1.40/1.24. No satisfactory intensity curve could be obtained with an O—C═O angle as low as 120°, illustrated by models A, B, P and Q. Curve R, the only one calculated with an O—C═O of 140°, is also unacceptable. Models C, D, E, F and G show the reversed intensities

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

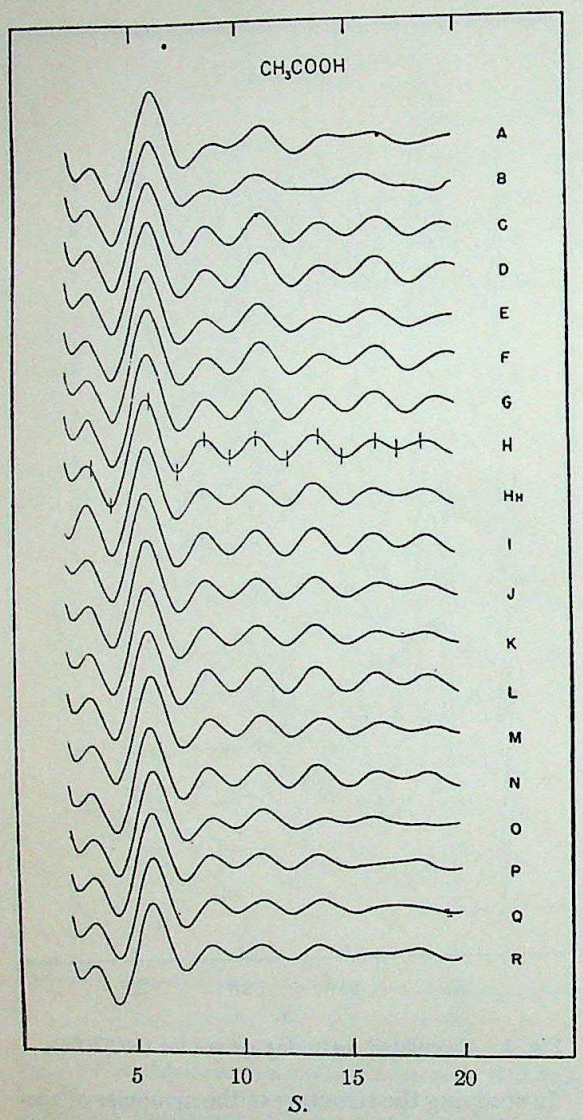

Fig. 5.—Calculated scattering curves for CH_3COOH.

produced by C—O/C=O ratios varying from 1.29/1.29 to 1.36/1.25 with the other parameters similar to those of the more acceptable curves. Model G, based on the structural unit of the dimer of acetic acid is also unsatisfactory because of the reversed relative intensities of some of the peaks.

A comparison of curves A and B shows the effect of changing the C—C distance from 1.48 to 1.54 Å. It is noted that the intensity curves are rather sensitive beyond the fourth maximum to changes in the C—C distance.

A comparison of curve H with Hh, which includes all of the hydrogen distances based on a structure with a tetrahedral arrangement of the CH_3 group, shows that the effect on the curves of neglecting the non-bonded hydrogen distances is negligible.

Since no sharp distinction is possible between the favorable curves, the values of the C—C=O and O—C=O angles must be considered very uncertain. In the acceptable range the monomer of acetic acid has its three longer distances arranged in an approximately equilateral triangle. Since, in calculating the intensity curves, two of the coefficients for the scattering terms are the same for these long distances and the third is only three halves larger, changes in the bond angles necessarily alter the resultant curves only very slightly.

The radial distribution curve for the monomer of acetic acid in Fig. 3 shows a rather broad peak at 1.41 Å. and thus the C—O, C=O and C—C distances are not resolved. Also unresolved are the longer carbon to oxygen distances and the oxygen to oxygen distance as shown by the largest peak which occurs at 2.43 Å. In this case the radial distribution curve is of no aid in fixing the structure of the molecule.

The following values are obtained for the structure of the monomer of acetic acid: C—O = 1.43 ± 0.03 Å.; C=O = 1.24 ± 0.03 Å.; ∠ O—C=O = 122–138°; C—C = 1.54 ± 0.04 Å.; ∠ C—C=O = 113–128°.

Table V shows that these values, based on the qualitatively acceptable curves, are in agreement with the quantitative results.

TABLE V

OBSERVED AND CALCULATED MAXIMA AND MINIMA OF ACETIC ACID MONOMER

6		3	16.40	0.997	0.994
	7		17.36	1.010	1.010
7		3	18.46	1.010	1.010
			Average	0.998	0.997
			Average deviation ±	.007	.009

Acetic Acid Dimer.—The association of acetic acid is assumed to involve the same type of coupling of single molecules as occurs in formic acid. It was also assumed that all four carbon atoms were on the same axis, since in a test an angular displacement of the methyl group through 7° made only a small change in the calculated intensity curves (M and N). The vapor striking the beam was considered to be 9% dissociated.

In the seventeen models calculated the parameter ranges considered were: C—C, 1.48 to 1.54 Å.; C—O, 1.29 to 1.43 Å.; C=O, 1.22 to 1.29 Å.; OH—O, 2.67 to 2.82 Å.; O—C=O, 120° to 130°; b, 55 to 65°. Some of the intensity curves appear in Fig. 6.

Model H is chosen as the best one possessing an O—C=O angle of 130°, an angle b of 60°, an

CC-0. Mumukshu Bhawan Varanasi Collection. Digitized by eGangotri

OH–O distance of 2.76 Å., a C–C distance of 1.54 Å. and a C—O/C=O ratio of 1.36/1.25. Models J and K with a ratio of 1.43/1.24 are unsatisfactory as are models A, B, C and D with equal carbon to oxygen distances and O—C=O angles ranging from 120 to 130°. Model G differs from H in possessing an OH–O distance 0.06 Å. smaller and model I possesses an OH–O distance 0.06 Å. larger. A comparison of curves F and G wherein the ratios are 1.32/1.27 and 1.36/1.25, respectively, shows only slight sensitivity to changes of the carbon to oxygen distances over this range.

Model E differs from F and model L differs from J in possessing an O—C=O angle of 125° instead of 130°. The difference in intensity curves produced is striking.

Model N is based on the most suitable model for the dimer of formic acid and is observed to produce a very unsatisfactory intensity curve.

The calculated models contain the bonded hydrogen distances whose lengths were assumed to be the same as applied to the monomer of formic acid. Curve Hh contains all the distances due to the hydrogen atoms and may be compared with curve H. A negligible difference is observed.

The radial distribution curve for the dimer of acetic acid in Fig. 3 contains only one useful peak. It is the relatively small one at 2.76 Å. corresponding to the OH—O separation across the bridge.

The structure chosen for the dimer of acetic acid in agreement with the quantitative results in Table VI is as follows: C—O = 1.36 ± 0.04 Å.; C=O 1.25 ± 0.03 Å.; ∠ O—C=O = 130 ± 3°; O—H—O = 2.76 ± 0.06 Å.; ∠ b = 60 ± 2°; C—C = 1.54 ± 0.04 Å.

Deuterium Acetate Dimer.—No difference was observed in the qualitative appearance of the photographs of the dimer of deuterium acetate and those of acetic acid. Table VI shows that the molecules also cannot be distinguished quantitatively. It must be concluded then that any difference in structure that exists between the dimer of deuterium acetate and that of acetic acid is within the uncertainty of the determination of the structure of the latter compound.

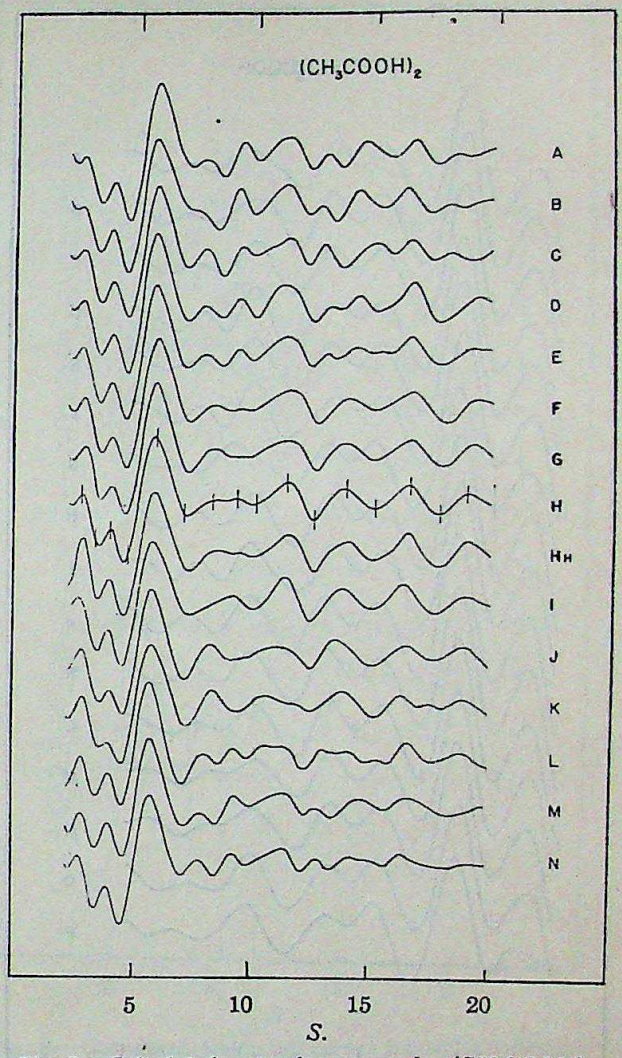

Fig. 6.—Calculated scattering curves for $(CH_3COOH)_2$.

The deuterium acetate used in these experiments was kindly supplied by Dr. Paul Gross of Duke University.

Trifluoroacetic Acid Monomer.—The trifluoroacetic acid used in the diffraction study and the vapor density study reported previously was kindly supplied by Dr. A. L. Henne of The Ohio State University.

In calculating the intensity curves, the CF_3 group was considered to be trigonally symmetric about the carbon to carbon axis, and the carbon and oxygen atoms were assumed to be coplanar. In the twenty-four models studied the parameter ranges considered were: C—C, 1.42 to 1.54 Å.; C—F, 1.33 to 1.36 Å.; C—O, 1.26 to 1.36 Å.; C=O, 1.25 to 1.36 Å.; F—C—F, 107.5° to 112°; O—C=O, 102° to 130°; C—C=O, 115° to 129°; orientation of the CF_3 group, fixed positions to a study of free rotation. Figure 7 shows some of

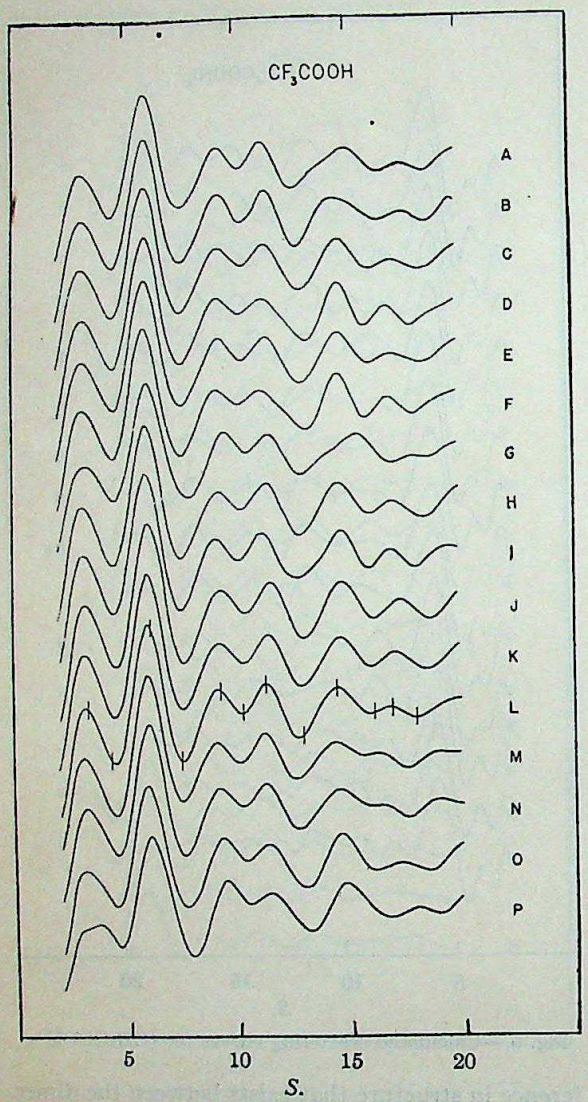

Fig. 7.—Calculated scattering curves for CF_3COOH.

the intensity curves. Although eight parameters present an exceedingly complex structure problem, a study of less than eight effective parameters was anticipated due to the possibility of a marked lack of sensitivity of the intensity curves to changes in some of the structural features.

A 15° orientation of a C—F bond out of the plane of the carboxyl group produces an intensity curve indistinguishable from one closely resembling a curve for free rotation within the range of variation of the shape of the carboxyl group considered in this paper. This is shown by a comparison of curve C possessing a 15° orientation with curve E composed of an average of twenty-four positions and is further substantiated by the similarity of curves D and F possessing C—O/C=O ratios of 1.29/1.29 and 1.36/1.25, respectively, and of models C and L wherein there occurs a change of 10° in the O—C=O angle in addition to a change in the C—O/C=O ratio. The models studied in which a C—F bond was placed in the plane of the carboxyl group were unsatisfactory as illustrated by curves B, A and G.

The relative intensities of the two maxima following the largest one in curves O and P do not agree with the visual interpretation of the photographs. These models possess O—C=O angles of 110° and 102°, respectively, and the qualitative effect may be ascribed to an increase in the oxygen to fluorine distances in the molecule.

It is possible to select eight more or less satisfactory intensity curves, curves D, F, C and H which have an O—C=O angle of about 120° and curves I, J, K and L with an O—C=O angle of 130°. All these curves possess a C–F distance of 1.36 Å. and a C–C distance of 1.48 Å. except J which has a C–C distance equal to 1.44 Å. However, it is noted that curve J is shifted with respect to the s_0 values, indicating some unusually small distances in the molecule. The orientation of the CF_3 group in these models is 15 and 30° with respect to the carboxyl group measured from the C—O side and the remaining parameters almost cover the maximum range of variation discussed above.

It is possible to draw definite conclusions only with regard to the structure of the CF_3 group in the monomer of trifluoroacetic acid: C—F = 1.36 ± 0.05 Å.; ∠ FCF = 110 ± 4°. As far as the orientation of the CF_3 group is concerned, there may be a preferred position excluding the one in which there is a C—F bond in the plane of the carboxyl group, there may be vibrations of rather large amplitude or there may be free rotation. No significant conclusions can be drawn about the C—O/C=O ratio and the C—C=O and O—C=O angles and it is not possible to fix with certainty the C—C distance since a change in the distance of 0.06 Å. is fairly well compensated for by a change in the F—C—F angle of 2°, as indicated by a comparison of curves M and N.

A radial distribution curve was not calculated because resolution of the many intramolecular

distances was not expected from the number of maxima and minima available for the calculation.

Trifluoroacetic Acid Dimer.—In addition to the assumptions which applied to the study of the monomer, a center of symmetry is believed to exist for the carbon and oxygen atoms and the same type of bridge was assumed as occurs in the dimers of formic and acetic acids. The four carbon atoms were assumed to be on a straight line and on the basis of the experiments reported above the vapor striking the electron beam was considered to be 11% dissociated. Thus there is one parameter in the dimer in addition to the eight required to fix the structure of the monomer, the distance across the hydrogen bridge. Unlike the monomer, the number of parameters which have a negligible effect on the resultant intensity is too small to lead to a structure determination whose degree of uncertainty may be readily estimated. However, the large number of qualitative features in the patterns are advantageous in limiting the range of variation.

A total of fifteen models were studied in which the C—F was equal to 1.36 Å., the C=O distance varied from 1.25 to 1.33 Å., the OH—O distance varied from 2.67 to 2.76 Å., the O—C=O angle varied from 110 to 130° and the C—C=O angle[13] varied from 115 to 125°. The remaining parameters covered the same range as in the study of the monomer. Figure 8 contains some of the intensity curves.

Model B is the most acceptable model and is based on the structure for the dimer of acetic acid except that the C—C distance is shortened from 1.54 to 1.48 Å. It possesses in addition a tetrahedral CF_3 group in which the C–F distance is equal to 1.36 Å. and a 15° orientation of a C–F bond with respect to the plane of the carboxyl group. Models A and C are similar but possess orientations of 0 and 30°, respectively.

As pointed out above, a marked sensitivity to changes in several of the parameters can be observed. A comparison of models N and B shows the effect of changing the C–C distance to 1.54 Å. Model E produces a very poor intensity curve and it differs from B in possessing equal C—C=O and C—C—O angles and equal C—O and C=O distances whose average is about 0.04 Å. less than that of model B. Model F has the same structure in the carboxyl group as does E with a C–C distance smaller by 0.04 Å. and an OH–O separation smaller by 0.06 Å. A comparison of curve G with curve H shows the relatively small change arising from a difference of 0.08 Å. in the OH–O distance.

The series of models K, L and M have the same orientation relation as models A, B and C. This is also true for models H, I and J. Models K, L and M have a CF_3 group similar to that of A, B and C but the structure of the carboxyl group is modeled after the one which occurs in formic acid dimer. Models H, I and J differ slightly in possessing an O—C=O angle of 120°, equal carbon to oxygen distances of 1.29 Å. and equal C—C=O and C—C—O angles.

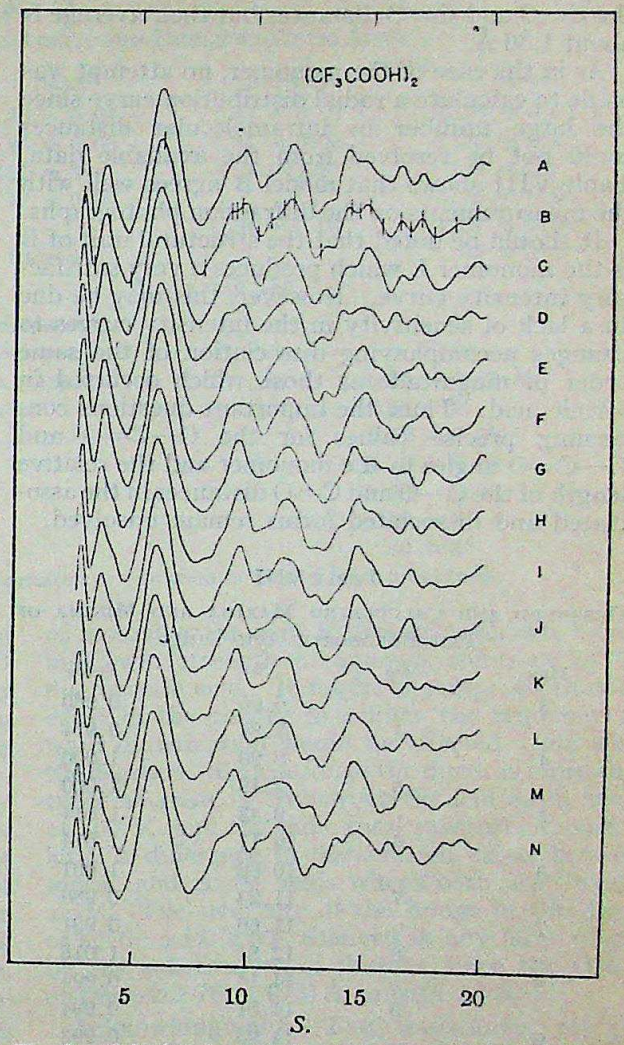

Fig. 8.—Calculated scattering curves for $(CF_3COOH)_2$.

From reasoning similar to that applied to the study of the monomer and the observation that the portion of the intensity curve of the dimer due to the scattering of the distances across the monomeric units is insensitive to changes in the orientation of the CF_3 group, a 15° orientation of a C—F bond out of the plane of the carboxyl group may be interpreted as producing an intensity curve which closely represents a curve of free rotation.

The following values are obtained for the parameters in the dimer of trifluoroacetic acid: C—F = 1.36 ± 0.03 Å.; ∠ FCF = 109 ± 2°; C—C = 1.48 ± 0.03 Å.; O—H—O = 2.76 ± 0.06 Å.; ∠ O—C=O = 130 ± 3°; ∠ b = 60 ± 3°. The CF_3 group probably rotates freely or vibrates in arcs of large amplitude. Nothing definite can be said about the relative length of

(13) On the assumption that all four carbon atoms are on a straight line, ∠C—C=O is the supplement of angle *b* used to fix the structures of the dimers previously discussed.

the C—O and C=O distances but their average is about 1.30 Å.

As in the case of the monomer, no attempt was made to calculate a radial distribution curve since the large number of intramolecular distances could not be resolved from the available data. Table VIII shows that model B agrees well with the measurements on the diffraction photographs.

It should be noted that the structural unit of B is the monomer L which produces a very satisfactory intensity curve. However, this may be due to a lack of sensitivity in the intensity curves to changes accompanying dissociation of the same order of magnitude as those which occurred in formic acid. Thus, the important questions concerning precise values for the O—C=O and C—C=O angles in the monomer and the relative length of the C—O and C=O distances in the associated and dissociated forms remain unsolved.

Discussion

Several interesting structural features of the carboxyl group are shown by the foregoing results on formic and acetic acids. The two C–O distances in the unassociated carboxyl are distinctly different; indeed, the longer distance is the same as that observed in ether linkages while the shorter corresponds to the C—O linkage in ketones. It may be concluded from these results that the hydrogen atom is much closer to one oxygen than to the other. The attachment of the hydrogen to one of the two oxygens makes their attachments to the carbon as distinct from each other as an ordinary single and double bond. It is still expected that in the free carboxylate ion the two C–O links would be equivalent.

When the dimer is formed the longer C—O bond becomes about 0.06 Å. shorter than it was in both formic and acetic monomers, while the shorter C—O bond is unchanged. The difference between the two C—O bonds in the carboxyl is thereby reduced to about 0.1 Å. It appears, then, that although both of the carboxyl oxygens have an adjacent hydrogen in the dimer and are therefore more nearly alike than they were in the monomer, a considerable difference persists in the behavior of the two oxygens. The observed non-equivalence of the two C—O bonds requires a non-equivalence of the two O—H linkages; or in other words the diffraction results lead to the conclusion that the two hydrogen atoms in the carboxyl dimer are not located in the center positions in the respective OH—O bonds.

A further difference between the monomer and dimer is noted in formic acid in the O—C=O angle, which is 4° larger in the dimer. Since the O—O distance across the carboxyl is the same in both forms, it seems probable that the repulsion between the oxygen atoms prevents the decrease in their separation, which would have accompanied the shortening of the C—O distance if the O—C=O angle had remained unchanged.

The only significant difference between the results on formic and acetic acids is in the O—C=O angles. In the formic acid dimer this angle is 121° while in acetic acid dimer it is 130°. This angle happens to be indeterminate over a wide range (122–138°) in acetic acid monomer so that the monomer comparison cannot be made. The OH–O distance in the dimers is substantially the same, 2.73 and 2.76 Å.

Spectroscopic results on carboxylic acids are in general agreement with the above conclusions. Hofstadter[14] working on heavy formic acid and Herman and Hofstadter[15] on light and heavy acetic acids found an increase in the O–H and O–D distances from about 0.97 Å. in the monomers to about 1.07 Å. in the dimers. This increase would have to be up to 1.35 Å. if the hydrogen (or deuterium) atom were in the center of the OH—O dimer bond. Sutherland and Davies[4] report a somewhat smaller change in the O–H distance in the dimerization of acetic acid. They also report a difference of about 0.1 Å. between C—O and C=O although each distance is somewhat shorter than the diffraction values given in this paper.

Force constants of 5.4×10^5 dynes/cm. for the C—O and 11.8×10^5 dynes/cm. for the C=O in the formic acid monomer are reported by Hofstadter and Bonner.[3] The first value is close to that for an alcoholic C—O (4.5×10^5 dynes/cm.) while the second is essentially that for a carbonyl group. This comparison is consistent with the conclusions based on the diffraction results.

The isotope effect (increase in distance between associated carboxyl groups on substitution of D for H) found by Robertson and Ubbelohde in oxalic acid dihydrate was also studied by them in phthalic acid, α-resorcinol, β-resorcinol, sodium bicarbonate and in succinic and benzoic acids. No such effect was detected in phthalic acid or β-resorcinol while the other substances all show effects smaller than in oxalic acid. Our hope of checking on this effect in acetic acid vapor was not realized since the uncertainty of the determination of the OH–O distance is as large as the magnitude of the effect observed in oxalic acid dihydrate. The similarity of the electron diffraction photographs of light and heavy acetic acids does not exclude the possibility of an isotope effect as large as that occurring in some of the above-mentioned compounds.

In trifluoroacetic acid the structure of the carboxyl group could not be determined as completely as in the other acids because of the relatively high scattering power of the CF_3 group. In the dimer the average value of the C—O and C=O distances is 1.30 Å. as in the other acid dimers, but the individual values are indeterminate. The CF_3 group in both the monomer and dimer has about the same structure found in other compounds containing this group, *i. e.*, the C–F distance is 1.36 Å., and the F—C—F angle is near the regular tetrahedral value. The group is free to rotate or at least to oscilllate with large amplitude about the C—C axis.

In the dimer with a CF_3 group at each end some additional distances were determined. The C–C distance is only 1.48 Å., or 0.06 Å. shorter than in acetic acid. The effect of shortening the bond to the attached atom when fluorine is substituted for the hydrogen in a methyl group occurs in many other compounds as well, but here the fluorine substitution has the further interesting effect of loosening the acid hydrogen as shown by the high acid strength of aqueous solutions of trifluoroacetic acid. It might be supposed that because of the change in acidity the tendency toward dimerization would be affected; but while the degree of dissociation of the dimer is more than twice as great in trifluoroacetic acid as in acetic at 300°K. and the same total pressure, almost as large a difference in dissociation exists between formic and acetic acids where both are "weak" acids. The structure of the bridge in the dimer of acetic acid is not changed in any large degree by the substitution of fluorine since the OH–O distance is 2.76 ± 0.06 Å. in both acids.

Acknowledgment.—The assistance of the Board of Governors of the Horace H. Rackham School for Graduate Studies and of the Midgley Foundation in providing funds for the construction of the diffraction apparatus is gratefully acknowledged. We also wish to thank Mrs. J. Karle for tracing the theoretical intensity curves.

Summary

The structures of the monomeric and dimeric forms of formic, acetic and trifluoroacetic acids in the vapor state have been investigated by the electron diffraction method with the results summarized in Table IX. The two C—O bonds in the carboxyl group differ in both the monomer and the dimer. The OH–O distance across the bridge is substantially the same in all three dimers, while in the acetic acid the C—C bond is 0.06 Å. longer than in the fluorine substituted acid.

Acetic acid and the deuterated acid, $(CH_3COOD)_2$, show no detectable difference in their diffraction photographs.

Measurements were made on the vapor density and the dissociation constants of the dimeric trifluoroacetic acid.

A high temperature nozzle for introducing samples into the gas diffraction camera over the range from room temperature up to 160° is described.

ANN ARBOR, MICHIGAN RECEIVED JANUARY 14, 1944

[A CONTRIBUTION FROM THE CHEMICAL LABORATORIES OF HARVARD UNIVERSITY]

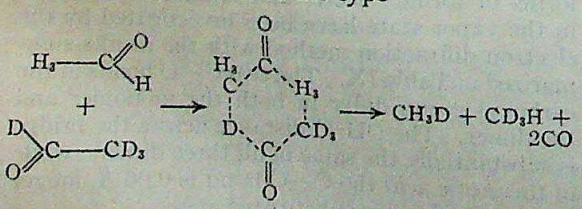
The Thermal Decomposition of Acetaldehyde

BY J. CARRELL MORRIS

Recent studies on the mechanism of the thermal decomposition of acetaldehyde into carbon monoxide and methane have indicated that the reaction proceeds, at least in part, by means of a reaction chain involving free radicals. Thus Burton, Ricci and Davis[1] were able to demonstrate that radio-lead was transported in a Paneth-type experiment in which acetaldehyde was decomposed under normal conditions. This undoubtedly showed the presence of free radicals in their experiments. Rice and Polly[2] and later, in a more extensive fashion, Smith and Hinshelwood[3] found that the normal thermal decomposition was inhibited by the addition of propylene to the gaseous acetaldehyde in the reaction vessel. These studies on inhibition, generally considered a very reliable test for the detection of radical chain reactions, led to an estimate that a minimum of about $^2/_3$ of the reaction occurred by means of free-radical chains.

In an attempt to confirm this conclusion and perhaps to check on more detailed phases of the mechanism of the reaction a somewhat different approach to the problem was devised. Mixtures of ordinary acetaldehyde and acetaldehyde-d_4 were allowed to decompose together and the resulting products were analyzed as to the isotopic composition of the methanes formed.

Such a determination might be expected to give a rather intimate knowledge of actual processes occurring in the reaction. For, if the decomposition were an intramolecular one, then the CH_3CHO could give just CH_4 and CO, while CD_3CDO would yield only CD_4 and CO. Consequently, if this mechanism were operative, the analysis should show none of the partially deuterated methanes. If the decomposition were a bimolecular one, then reactions of the type



should occur, yielding CD_3H and CH_3D as well as CH_4 and CD_4. One would not anticipate finding CH_2D_2, however. In the third plausible case, if the reaction took place by a chain mechanism, processes of the type

$$CH_3 + CD_3CDO = CH_3D + CD_3 + CO$$
$$CD_3 + CH_3CHO = CD_3H + CH_3 + CO$$

would be expected to produce CD_3H and CH_3D and perhaps also CH_2D_2, if the reactions were more complicated than those illustrated.

So, while it might not be possible by this method to distinguish between the latter two possibilities, such an analysis should certainly provide evidence differentiating the first possibility from the other two.

Benedict, Morikawa, Barnes and Taylor[4] have shown that such mixtures of the isotopic methanes may be analyzed readily by means of their infrared spectra. In particular, the absorption in the range 1000–1500 cm.$^{-1}$ is very characteristic of the particular isotopic methanes present in a mixture and their relative proportions. In the present study this method of analysis was followed by measuring the infrared absorption over the range 1000–1500 cm.$^{-1}$ of the samples of gas obtained from the decomposition of the mixtures of acetaldehyde and acetaldehyde-d_4. The results obtained led to the conclusion that the thermal decomposition of such mixtures produced CH_4 and CD_4 almost exclusively.[5] This is definite evidence that, contrary to the findings of previous authors,[1,2,3] the decomposition of acetaldehyde proceeds mainly by a unimolecular mechanism.

Confirmation for this point of view was obtained by an analysis of data on the absolute rate of the thermal decomposition of acetaldehyde. During the course of the present research it was noted that the rate of decomposition of "pure" acetaldehyde was materially decreased if the aldehyde were treated with hydroquinone and freshly distilled from it before use. The rates found after such treatment were considerably lower than the "normal" rates of Smith[6] or of Smith and Hinshelwood[3] and approached the "inhibited" rates found by the latter authors. A reasonable conclusion is that the positive indications of a chain reaction found in this decomposition were caused by a superimposed induced process initiated by an impurity.

Experimental.—The acetaldehyde was an Eastman Kodak Co. product which was purified further by several distillations in the vacuum system from baths at 0° to baths at −80°. During the series of distillations the acetaldehyde was several times outgassed by causing ebullition while the bulb containing the liquid was connected directly to the vacuum pump. In addition the aldehyde was twice frozen in liquid air and pumped out to 10^{-5} mm. to remove any final traces of oxygen, which is known to accelerate the reaction.[7] Attempts to purify the acetaldehyde by distillation from a dry-ice bath to a liquid-air bath were unsuccessful because of the formation of the white, solid polymer which has been observed before under the same conditions.[8] The vapor pressure of the final material at 0° checked that given in the literature[9] within a few mm. and remained substantially constant during the use of 80% of the liquid. This material is called the "untreated" sample.

A portion of the above sample was further purified by distilling it into a bulb containing some solid hydroquinone crystals and allowing it to remain there for several days. It was then distilled off from the hydroquinone in small samples just before use. This latter is called the "treated" sample and gave a rate of decomposition only one-half to one-third as great as the previous material.

The deuteroacetaldehyde came from two sources. First runs were made on a sample prepared from C_2D_2 and D_2O by slight modification of the method of Zanetti and Sickman,[10] while later a quantity of 99.5% deuteroacetaldehyde was purchased from Norsk Hydro. Each was subjected to the same purification procedure as the CH_3CHO, the final samples having a vapor pressure at 0° which checked that given by Zanetti and Sickman.[10] Both samples were shown to contain better than 99% C—D bonds by means of their infrared absorption spectra.[11]

With the deuteroacetaldehyde also subsequent treatment with hydroquinone was found to give a sample which decomposed more slowly than the untreated sample, but the decrease in this case was not nearly as marked, and additional treatments failed to lower the rate any further.

The decompositions were carried out in a cylindrical Pyrex vessel of approximately 300-ml. capacity, which had an outside diameter of about 5 cm. and was mounted snugly in a cavity bored in an aluminum block of 10-cm. diameter. The block was wound with insulated resistance wire and was surrounded by several inches of magnesia insulation. To maintain the block at 500° a current of about 3 amperes was required. The reaction vessel was connected by means of capillary tubing to a three-way stopcock and to a variable-level mercury manometer, which gave a total dead space amounting to less than 1 ml.

By passing the heating current through a voltage controller such a uniform heating was obtained that temperatures constant within 0.5° could be maintained indefinitely and no additional temperature regulation was necessary. The temperature was measured with a two-junction thermocouple inserted in a well of 8-mm. glass tubing which ran into the center of the reaction vessel. The thermocouple was standardized against boiling sulfur and by comparison with a Bureau of Standards platinum resistance thermometer at several temperatures.

For the infrared analyses the reacted mixture of gases was allowed to expand into a 300-ml. bulb which had its lower end chilled in dry-ice to condense any unreacted acetaldehyde. Usually, however, this was an unnecessary precaution, for the mixtures were generally allowed to react completely before withdrawing them from the reaction vessel. It was not necessary to eliminate the carbon monoxide since it does not absorb in the portion of the spectrum used. The sample of methanes and carbon monoxide was then transferred by means of a Töpler pump to the infrared absorption cell, which was 30 cm. in length and 2.5 cm. in diameter with plane rock salt ends cemented on with Apiezon wax. This was attached to the apparatus by a ground glass joint so that it could be transferred easily to the spectrograph. Ordinarily the cell was filled with 200 mm. of the carbon monoxide–methanes, corresponding to 100-mm. pressure for the methanes present. This pressure was found empirically to give the most suitable amount of absorption for the significant frequencies.

The spectrograph used was the one described by Gershinowitz and Wilson.[12] It was necessary to use only the rock salt prism to obtain the 1000–1500 $cm.^{-1}$ spectra with sufficient precision. The technique of measurement and recording of the spectra was the same as that outlined in the Gershinowitz and Wilson paper.

I am grateful to Prof. E. Bright Wilson for permission to use the spectrograph for these analyses.

Results of Infrared Analyses.—A number of preliminary spectra were determined to ascertain the exact results to be expected from various possibilities. First, the spectrum for the case of no mixing of the methanes was measured by mixing 100 mm. of $CD_4 + CO$ from the decomposition of CD_3CDO alone with 100 mm. of $CH_4 + CO$ from the decomposition of CH_3CHO and determining the infrared spectrum for the mixture. The absorption spectrum obtained is shown as curve I of Fig. 1. The significant features of this curve are the double absorption maximum caused by the CD_4 at 990 and 1035 $cm.^{-1}$, the double maximum caused by CH_4 at 1305 and 1350 $cm.^{-1}$ and the absence of appreciable absorption in between. If there were partially substituted

deuteromethanes present, there should be additional maxima of absorption at 1160 cm.$^{-1}$ for CH_3D, at 1090 and 1235 cm.$^{-1}$ for CH_2D_2 and at 1290 cm.$^{-1}$ for CHD_3.[4]

Since it is known that traces of oxygen will induce a chain reaction in the decomposition of acetaldehyde,[13] it was concluded that a representation of the absorption curve to be expected if the thermal reaction occurred by a chain mechanism might be obtained by analyzing the sample obtained from decomposing a mixture of the aldehydes in the presence of a trace of oxygen. Accordingly, 148 mm. of CD_3CDO, 150 mm. of CH_3CHO and 0.05 mm. of oxygen were mixed and allowed to react overnight at a temperature of 435°. The temperature was chosen low enough to make the ordinary thermal reaction negligible. When a sample of the products was subjected to infra-red analysis, curve VII in Fig. 2 was obtained. The expected maxima listed above are all apparent, some of them occurring with great intensity. The appearance of the maximum at 1090 cm.$^{-1}$ for CH_2D_2 means that the chain processes are more complicated than the simple ones listed in the introduction to the paper.

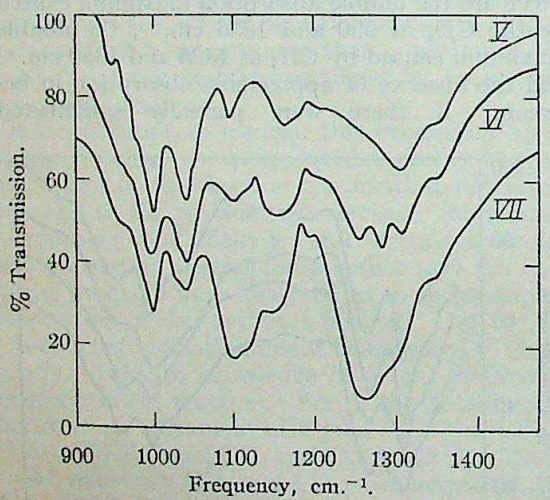

Fig. 2.—Infrared absorption spectra of methanes resulting from the decomposition of mixed acetaldehyde and acetaldehyde-d_4: (V) two hundred mm. of mixture formed by decomposition of 145 mm. of "treated" CD_3CDO with 152 mm. of "treated" CH_3CHO; (VI) two hundred mm. of mixture formed by decomposition of 209 mm. of "untreated" CD_3CDO with 239 mm. of "untreated" CH_3CHO (scale displaced by 10%); (VII) two hundred mm. of mixture formed by decomposition of 150 mm. of CH_3CHO, 148 mm. of CD_3CDO and 0.05 mm. of O_2 (scale displaced by 30%).

A run was now made to make sure that if mixed deuteromethanes were found in the later experiments, they had resulted from processes taking place in the actual decomposition of the acetaldehydes and not from side exchange reactions. A sample consisting of 206 mm. of CH_4 + CO and 203 mm. of CD_4 + CO was heated in the reaction vessel at 500° for five days to test whether the methanes would exchange among themselves at this temperature. The spectrum of a sample taken at the end of this time is shown as curve II of Fig. 1. The increased absorption between 1200 and 1300 cm.$^{-1}$ indicates the formation of a small amount of CHD_3, but the exchange has been very slight, as indicated by the general similarity of the curve with curve I.

It was still possible, however, that exchange might take place between molecules of acetaldehyde and of methane. Or, if there were methyl radicals present as a result of chain processes, the reactions

$$CH_3 + CD_4 = CH_3D + CD_3$$
$$CD_3 + CH_4 = CD_3H + CH_3$$

might have complicated the conclusions. Therefore, two additional preliminary runs were carried out. In the first, 215 mm. of CH_3CHO was allowed to decompose completely at 480° in the presence of 400 mm. of CD_4 + CO, obtained from the previous decomposition of 201 mm. of CD_3CDO. In the second the process was reversed and 183 mm. of CD_3CDO was allowed to decompose completely at the same temperature in the presence of 370 mm. of CH_4 + CO, obtained from the decomposition of 189 mm. of CH_3CHO. The absorption spectra of samples taken from these runs are shown in curves III and IV, respectively. Both indicate only slight exchange and therefore reactions of the type shown above will not affect the conclusions to be drawn from the mixed decomposition experiments.

Curves V and VI in Fig. 2 show the results of the spectroscopic analysis of the methanes resulting from the decomposition of mixtures of CH_3CHO and CD_3CDO. For curve VI a mixture of 209 mm. of "untreated" CD_3CDO and 239 mm. of "untreated" CH_3CHO was allowed to react for two days at 480°, after which it was transferred to the absorption cell and analyzed. A marked increase in absorption in the 1100–1300 cm.$^{-1}$ range over that shown in curves I–IV is noted. Pronounced maxima are found at 1100, 1160, 1260 and 1290 cm.,$^{-1}$ showing the presence of all of the partially deuterated methanes and indicating that chain processes had been instrumental in the decomposition in this instance.[14] However, none of the maxima for the intermediate deuteromethanes are as strong as those obtained in curve VII for the reaction induced by oxygen. Hence, it is probable that only a portion of the reaction proceeded by means of the chain mechanism. This is in accord with the results of other

(13) M. Letort, *J. Chim. Phys.*, **34**, 428 (1937).

(14) This result offers some experimental verification for the proposition that the reaction CH_3 + CH_3CHO is a much faster process than CH_3 + CH_4, since the reactions which yielded the samples for curves III and IV, which showed no exchange, were also carried out with the "untreated" aldehydes. (See "The Aliphatic Free Radicals," F. O. Rice and O. K. Rice, Johns Hopkins Press, 1935, for an

workers on the nature of the "normal" decomposition of acetaldehyde.[1,2,3]

In contrast curve V shows the absorption spectrum of the sample resulting from the reaction together of 145 mm. of "treated" CD_3CDO and 152 mm. of "treated" CH_3CHO at 542°. The temperature is not of major importance, for an almost identical curve was obtained from a similar mixture decomposed at about 480°. It can be seen that the absorption between 1100 and 1300 cm.$^{-1}$, while greater than that for curves I–IV, is nevertheless much less than that for curve VI, indicating a much smaller amount of chain reaction in this case. By a comparison of curve V with curve VII, assuming that the latter represents 100% chain reaction, it may be concluded that not more than 10–20% of the reaction with the "treated" aldehydes proceeded by means of a chain mechanism. Because of the difficulty in obtaining perfectly pure acetaldehyde, even by means of the treatment with hydroquinone, it seems likely that the residual 10% of chain reaction may have resulted from a slight remainder of induced chain reaction, and that the decomposition of acetaldehyde itself is completely a molecular reaction.

Results on the Rate of Decomposition of Acetaldehyde.—Table I presents a summary of experiments on the absolute rate of decomposition of CH_3CHO, both before and after treatment with hydroquinone, along with a comparative tabulation of the results of other researches.[3,6,13,15] For the "untreated" acetaldehyde the rates check the values calculated from the results of Smith for the "normal" decomposition of acetaldehyde. It was for samples like these that the infrared experiments showed a considerable amount of chain reaction, perhaps 50%, and the inhibition experiments of Smith and Hinshelwood[3] pointed to 60–70% of chain reaction. However, the second part of Table I shows that these rates can be considerably decreased by further purification. The absolute rates after treatment with hydroquinone are equal to about half the values for the "normal" reaction of Smith and are reduced almost to the values recorded by Smith and Hinshelwood for the completely inhibited reaction. The results of Letort, who used a very rigid purification procedure, are also lower than those of Smith or of the present untreated samples, although they are not as low as the rates for the "treated" samples in the present study. However, they constitute additional evidence that thoroughly purified acetaldehyde decomposes at a slower rate than previously supposed. The implication is that the more rapid rates are caused by traces of impurity which initiate a chain reaction.

In addition there is evidence here that the slower rates represent a molecular reaction in agreement with the infrared analyses. For, the inhibited rates of Smith and Hinshelwood presumably

542	313	40	97	35	49

[a] These figures were calculated from the results of R. E. Smith (ref. 6) by the following procedure. Since the values tabulated by Smith were found to conform to the relation $-dx/dt = kx^{1.6}$, the half-life times were converted to initial rates by the equation: initial rate, $R = 1.15t_{50}/p_0$. Then large-scale plots of log R against $1/T$ were constructed and values of R at the required temperatures for a number of different pressures were read off from the straight line relationships. These values of R were used to evaluate k at each temperature in the table, and from these latter the rates at the specific pressures in the table were computed from the first equation above. It is estimated that errors of calculation should be certainly less than 10%. [b] The values in this column were calculated from the data of J. R. E. Smith and C. N. Hinshelwood (ref. 3) by the same method as (a). [c] Computed from the equation $-dx/dt = kx^{1.5}$, where $k = 4.44 \times 10^{12}e^{-46,000/RT}$ (moles/liter)$^{-1/2}$ min.$^{-1}$, given by M. Letort (refs. 13, 15).

signify a suppression of all chain reaction, leaving a residuum which is entirely a molecular reaction. Moreover, the results in the second part of Table I demonstrate that it is possible to reduce the rate of reaction almost to this minimum point without the use of inhibitors in the reaction vessel. Consequently this too must represent a reaction which is almost entirely molecular.

In Table II are shown similar results on the decomposition of CD_3CDO. In this instance the reduction in rate after treatment with hydroquinone was a maximum of about 20%. As in the previous table the "untreated" results agree with those calculated from the data of Smith, while the "treated" values are lower.

It is of interest to speculate on the nature of the impurity which causes the acceleration in these decompositions. Some qualitative observations have been made. It was found that in a series of duplicate runs the rates of successive runs would gradually tend to increase as more and more of the liquid acetaldehyde in the storage reservoir was used up. This pointed toward an accelerant which was less volatile than the acetaldehyde and therefore could not have been gaseous oxygen. It was also noted that even following the treatment with hydroquinone to remove the impurity, the rate of decomposition of samples of the acetaldehyde was

again accelerated when the liquid acetaldehyde was allowed to stand after distillation from the hydroquinone. The formation of either an autoxidation product or a polymerization product of the acetaldehyde as the substance responsible for the accelerating chain reaction would account for this result. The cause of the effectiveness of hydroquinone in removing the impurity was not discovered, though it may be connected with its reducing power.

The amount of impurity necessary to produce such an acceleration is very small. Chain lengths of 4000 have been reported by Letort[13] in the oxygen accelerated reaction at this temperature. If the same chain length held in the induced reaction under consideration, then less than 0.1% of impurity would be needed to triple the rate of reaction. Few physical tests can detect the presence of this quantity of material.

The fact that the rate of decomposition of deuteroacetaldehyde was not subject to the same rapid acceleration as the ordinary acetaldehyde may be accounted for in a number of ways. One would be that the rate of formation of impurity is considerably smaller in CD_3CDO than in CH_3CHO so that there was a lesser quantity of the impurity present to cause acceleration. Or, the quantity of accelerant may have been about the same, but the rate of the induced reaction compared to the rate of the molecular reaction may have been smaller for the heavier isotope.

Discussion.—Both approaches to the problem of the mechanism of the thermal decomposition of pure acetaldehyde lead to the same conclusion that the reaction takes place substantially through a molecular process. However, a further conclusion may be drawn from the infrared analyses. The meager formation of intermediate deuteromethanes in the reaction of the pure mixed aldehydes provides definite evidence for the first of the possible reaction mechanisms mentioned earlier—the decomposition of individual particles of acetaldehyde to give methane and carbon monoxide in a single act. This means that the reaction must be truly unimolecular.

One might picture the operation of such a mechanism as an amplification of the normal bending vibration frequency of acetaldehyde in which the aldehyde hydrogen and the methyl group vibrate toward one another by means of a decrease in the C–C–H angle, while the carbonyl group recedes sufficiently to maintain the balance of the system. In discussing the spectrum of acetaldehyde this frequency has been called the "H-wagging frequency,"[11] since the hydrogen atom contributes most of the motion because of its lightness.

The dependence of the rate of reaction on concentration, however, is intermediate between a first-order and a second-order relation. This is another example of the common phenomenon that the kinetic order of a chemical reaction may not tell us its fundamental mechanism. A probable reason for such a difference in this case is that the rate of activation of acetaldehyde molecules by collision is not sufficiently rapid to maintain an equilibrium concentration of the activated species as it decomposes. This implies that the decomposition of the activated acetaldehyde molecules must be fast enough so that a sizable fraction will have decomposed before they have a chance to become deactivated by subsequent collision. The rate of activation of the molecules by collision then becomes a rate-determining step of comparable magnitude to the rate of decomposition of the activated molecules. If this is the case experiments with purified acetaldehyde at very high pressures should show a first-order relation and at very low pressures the reaction should become more nearly second order.

Insufficient experiments were performed in these researches to determine a kinetic equation for the decomposition of the completely purified acetaldehyde with any certainty.

Although the absolute rate is smaller, the dependence on concentration and the activation energy seem to be quite similar to those of previous kinetic studies. Consequently, one might obtain a satisfactory equation either by multiplying the constant factor in the equation of Letort[15] by 0.75 or by adopting the equation given by Smith and Hinshelwood[3] for the completely inhibited reaction as that for the decomposition of pure acetaldehyde.

The present data give a different value for the relative rates of decomposition of light and heavy acetaldehyde from that recorded by Smith.[6] Over a wide set of conditions he found a ratio for the rate of reaction of CH_3CHO to that of CD_3CDO of about 2.4. However, since the rate of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

reaction of the CH_3CHO was decreased by treatment much more than that of the CD_3CDO, it means that the true ratio must be lower. As in the case of the kinetic equation, no accurate evaluation of this ratio is possible because of the lack of sufficiently extensive figures, but they indicate that the value over the temperature range of the present experiments is 1.3–1.4.

Summary

1. The thermal decomposition of mixtures of acetaldehyde and acetaldehyde-d_4 has been carried out and the resulting methanes have been analyzed by means of their infrared absorption spectra. The results indicate that the thermal decomposition of acetaldehyde is a true unimolecular reaction and that chain processes play a very minor part, if any.

2. This conclusion has been confirmed by studies on the absolute rate of the thermal decomposition of acetaldehyde, which show the true rates to be only half as great as those previously observed.

3. The relative rate of thermal decomposition of acetaldehyde to that of acetaldehyde-d_4 is approximately 1.3–1.4.

Quinoidation of Triaryl Compounds—Hydroxyphenylbiphenylcarbinols

BY LEIGH C. ANDERSON AND W. A. FISHER[1]

Previous papers from this Laboratory[2] have presented data on the absorption spectra of several hydroxytriarylcarbinols and the corresponding fuchsones. A comparison of the absorption spectra of colored carbinols, of triphenylmethyl salts[3] and of triphenylmethyl[4] with those of quinone and the fuchsones indicated the existence of quinonoid structures for all these substances. Quinone, the free radical in ether solutions and the quinonoid carbinols have quinonoid bands which are low when compared to the corresponding bands in the fuchsones, the free radical in sulfur dioxide, and the triphenylmethyl salts. No attempt has yet been made to give an interpretation for the difference. This investigation presents data on triarylcarbinols wherein *p*-biphenyl groups have replaced one or both of the unsubstituted phenyl groups of *p*-hydroxytriphenylcarbinol. The absorption spectra obtained from these carbinols appear to offer an explanation for the variation in height of the quinonoid bands.

Two biphenylhydroxyphenylcarbinols have been studied: 4-hydroxy-4′-phenyltriphenylcarbinol and 4-hydroxy-4′,4″-diphenyltriphenylcarbinol. They were made by the condensation between phenol and *p*-biphenyldichlorophenylmethane and di-*p*-biphenyldichloromethane, respectively. Unless the correct conditions are adhered to, this condensation produces diphenoxymethane and tetraphenylmethane derivatives as chief products. The carbinols were also made by the aluminum chloride demethylation of the methoxy derivatives which were prepared by the reaction between *p*-anisylmagnesium bromide and 4-phenylbenzophenone and 4,4′-diphenylbenzophenone, respectively. The monobiphenylcarbinol was isolated in two forms: an intensely colored yellow form and a colorless modification. The dibiphenylcarbinol was isolated in two yellow modifications: one intensely colored and one which was considerably lighter in color. The fuchsone of each carbinol was prepared also.

The ultraviolet absorption spectra of ether solutions of these compounds show that a broad high band replaces the double band in the benzenoid portion of the spectrum when a *p*-biphenyl group is substituted for one of the phenyl groups of 4-hydroxytriphenylcarbinol (Fig. 1). This band is very similar to the one obtained from an hexane solution of biphenyl and is due, undoubtedly, to the biphenyl group in the carbinol. That its maximum is about 0.3 unit higher and its position about 200 mm.$^{-1}$ further toward the visible are effects easily attributable to the presence of the carbinol substitutent on the biphenyl. A second *p*-biphenyl group substituted in the carbinol merely increases the height of this band, emphasizing its source in the biphenyl groups.

The change in benzenoid absorption when a phenyl group in 4-hydroxytriphenylcarbinol is replaced by a biphenyl group seems to indicate that the biphenyl group acts as a unit in producing absorption and not as two phenyl groups. The absorption spectra of molecules containing both phenyl and biphenyl groups show that the phenyl absorption is completely blotted out beneath the biphenyl band (Figs. 1 and 2). The fact that the only appreciable change in this biphenyl band upon the introduction of more biphenyl groups into the molecule is in its height (Figs. 1 and 2) shows that each biphenyl group is acting more or less independently in producing the absorption

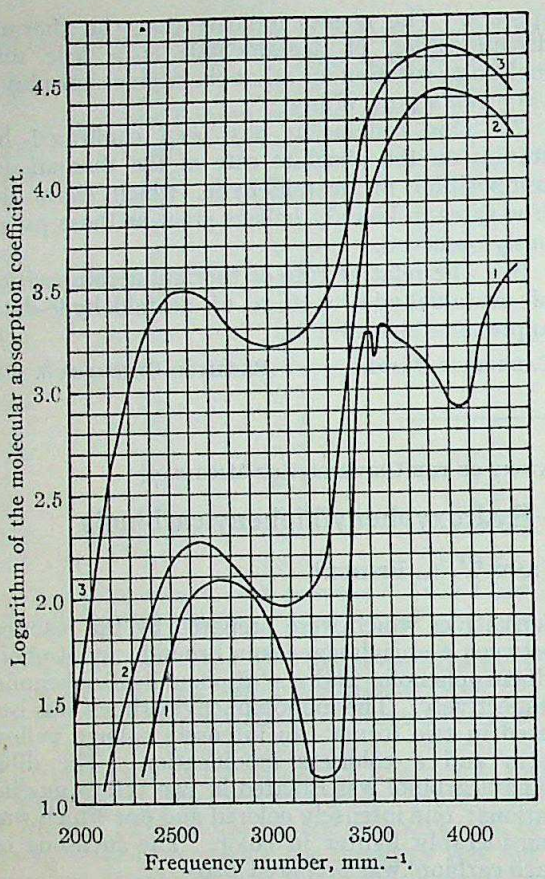

Fig. 1.—Absorption in ether solution of the quinonoid forms of: 1, 4-hydroxytriphenylcarbinol; 2, 4-hydroxy-4′-phenyltriphenylcarbinol; 3, 4-hydroxy-4′,4″-diphenyltriphenylcarbinol.

band. There is no great interaction with the rest of the molecule even in the quinonoid forms of the carbinols where a double bond is on the carbon next to the biphenyl group.

When a comparison is made of the absorption in ether of the three fuchsones: diphenylquinomethane, *p*-biphenylphenylquinomethane and di-*p*-biphenylquinomethane (Fig. 3), a regular shift of the two bands toward the visible is observed when the biphenyl groups are introduced. This is accompanied, as far as the band nearest the visible is concerned, by a slight regular increase in height. The higher frequency band in the fuchsones does not appear at the position where the biphenyl group absorbs in the carbinols nor does it have the shape of the biphenyl band.[5] Since the characteristic biphenyl band does not show up in this series of compounds, the electronic structure of the biphenyl group in the fuchsones is changed in some manner which does not occur with the carbinols. Resonance may occur with

(5) A similar change has been observed in the absorption spectra of all the fuchsones from hydroxytriphenylcarbinols which have been made in previous work. Each of them has had a second band which was different in both shape and position from the benzenoid bands found in the corresponding methanes and carbinols.

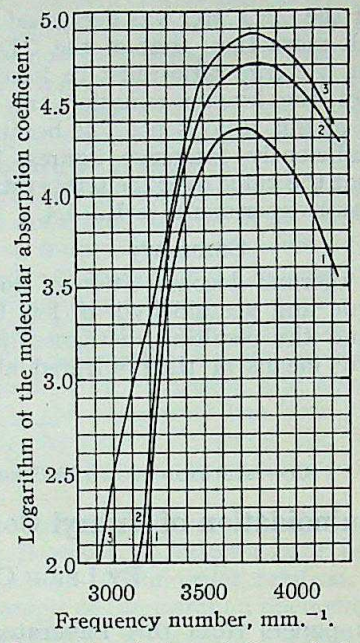

Fig. 2.—Absorption of ether solutions of: 1, 4-(*p*-anisyl)-triphenylcarbinol; 2, 4-(*p*-anisyl)-4′-phenyltriphenylcarbinol; 3, 4-(*p*-anisyl)-4′,4″-diphenyltriphenylcarbinol.

the fuchsones by a simple change in the nature of the double bond to the oxygen but the same type of resonance cannot occur with the hydroxycarbinols since there is no double bonded oxygen present. For example, the fuchsone of *p*-hydroxytriphenylcarbinol may be represented by

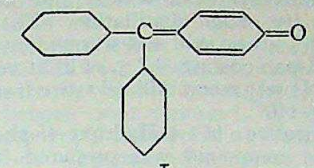
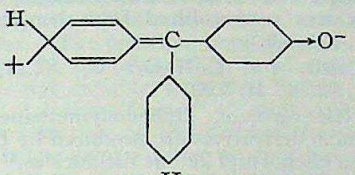
the conventional structure (I) in resonance with electronically isomeric structures such as II

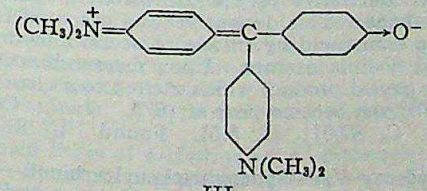


I

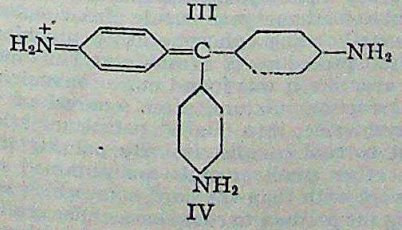


II

Because of this resonance in the fuchsones, the structure of the benzenoid groups is now altered while in the hydroxycarbinols any biphenyl group exercises its own absorption. A preferred position for the positive charge in II cannot be indicated. The introduction of biphenyl groups with the corresponding increase of possible resonance structures should increase the probability of occurrence of the phenolic ring structure. That any structure containing a biphenoquinone nucleus does not play a major part in the total makeup of the molecule is indicated because there is no abrupt change in the nature of the absorption in this series. It will be shown in the paper which follows that the absorption of 4-methoxy-*p*-biphenyldiarylmethyl cations is very different from *p*-methoxyphenyldiarylmethyl cations and that this marked change in absorption may be accounted for by a quinoidation which involves the biphenyl group. The above concept of resonance in the fuchsone molecules is in harmony with data obtained by Hantzsch from 4,4′-tetramethyldiaminofuchsone.[6] He found the absorption of this compound to be strikingly similar to that of a water solution of *p*-fuchsine, a salt, and not at all like that of fuchsone. This can be attributed to the presence of a resonance structure III like those in the salt cation IV



III



IV

According to this conception, there should be a similar relationship between the absorption of diphenylquinomethane and the triphenylmethyl ion. The curves for the latter two compounds do have almost identical absorption between 2000 and 3000 mm.$^{-1}$.

The light absorption of these fuchsones does not, then, occur in a manner which would be expected of the classical formula, but instead indicates that the molecule is the result of several resonance structures which may be similar to those indicated. Since, according to this hypothesis, the absorption of the fuchsones in the quinonoid region of the spectrum cannot be attributed to the carbonyl containing ring only, no surprise can be evidenced at the great increase in intensity of fuchsone absorption over that of quinone, whose absorption bands in this region are very low. Furthermore, the low intensity of the quinonoid carbinols may be explained by their lack of the resonance present in the fuchsone molecule and consequent dependence on the quinone ring only for absorption in this region.

The absorption curves for the quinonoid forms of these carbinols are from samples produced under similar conditions. The quinonoid forms were secured by crystallizing the carbinols from 60–70% acetic acid solutions. Since these carbinols undoubtedly exist as the corresponding cations in acetic acid solutions, the crystallization of the quinonoid variety from such solutions lends support to the idea that the hydroxy containing ring is quinonoid in the cations.

The benzenoid forms were made by precipitating the hydroxycarbinols from dilute sodium hydroxide solution by means of carbon dioxide and recrystallizing the products from aqueous alcohol containing a trace of ammonia. In an alkaline solution the phenolic character of the hydroxy containing ring is stressed and this results in the occurrence of the benzenoid form. If a very weak acid such as carbon dioxide is used to convert the salt of the phenol to the hydroxy compound and recrystallization is carried out in a slightly alkaline medium, there is little chance for conversion to the quinonoid cation and the solid benzenoid form is obtained.

In general, the conditions for producing the benzenoid forms of the carbinols which have been studied in previous investigations gave samples whose absorption in the quinonoid region was entirely removed or at least reduced in intensity to well below 1 unit. This is not true, however, in the case of 4,4′-diphenyl-4″-hydroxytriphenylcarbinol which was prepared under conditions which yield the benzenoid variety with other hydroxycarbinols. Though the height of the quinonoid band for this sample was almost 1.5 units less than in the case of the quinonoid variety, yet its peak was still at 2.1. Such a decrease with most of the other carbinols which have been studied would have meant the complete disappearance of the band. Other investigators have shown gradations in the ability of various hydroxytriarylcarbinols to exist in both the

Digitized by Arya Samaj Foundation Chennai and eGangotri

benzenoid and quinonoid forms. Gomberg and Lange reported that 4-hydroxydiphenyl-α-naphthylcarbinol was not stable in the benzenoid form.[7] It may be pointed out that an α-naphthyl group or two *p*-biphenyl groups present on each of the ethane carbon atoms in a hexaarylethane strongly favor dissociation of the ethane[8]; apparently they are equally effective in inhibiting the formation of the benzenoid carbinols under discussion.

The fuchsones, *p*-biphenylphenylquinomethane and di-*p*-biphenylquinomethane, were made by heating the corresponding carbinols under reduced pressure until the vigorous evolution of water vapor had ceased and were then recrystallized from benzene.

Experimental

4-Hydroxy-4′-phenyltriphenylcarbinol.—A mixture of 10 g. of dichloro-*p*-biphenylphenylmethane[9] and 10.5 g. of phenol was allowed to react for fifteen hours at room temperature with exclusion of moisture. The excess phenol was then removed from the mixture by steam distillation. The residue was cooled, crushed, and extracted with 2.5% sodium hydroxide solution. The insoluble 4-phenylbenzophenone was removed by filtration. Some ketone is held in the alkaline solution and it cannot be satisfactorily removed by ether extraction as can be done in the case of 4-hydroxytriphenylcarbinol.[10] The alkaline solution was acidified with dilute acetic acid and the precipitated hydroxycarbinol was recrystallized from 60–70% acetic acid giving a light yellow material melting around 120° with evolution of water. The principal impurity in this crude carbinol is the ketone with a small amount of 4,4′-dihydroxy-4″-phenyltetraphenylmethane. The pure carbinol is best prepared by hydrolysis of pure phenyl-*p*-biphenylquinomethane.

Phenyl-*p*-biphenylquinomethane.—A sample of 4-hydroxy-4′-phenyltriphenylcarbinol was dehydrated by placing it in an evacuated flask heated by means of an oil-bath to 130–140°. The sample was maintained at this temperature until the vigorous evolution of water vapor had ceased. The product crystallizes from benzene–ether in orange needles, m. p. 166–167°. Its solubility in ether is 4 g. per liter. *Anal.* Calcd. for $C_{25}H_{18}O$: C, 89.79; H, 5.43. Found: C, 89.88; H, 5.54.

Quinonoid Form of 4-Hydroxy-4′-phenyltriphenylcarbinol.—Four grams of phenyl-*p*-biphenylquinomethane was dissolved in 100 cc. of warm 70% acetic acid and the solution allowed to cool. Water was added to the cold solution until a permanent cloudiness had appeared, and the material was allowed to crystallize. The resulting acid concentration was 60–65%. The precipitate was dried in a vacuum desiccator over soda-lime, m. p. 139–140°.

Benzenoid Form of 4-Hydroxy-4′-phenyltriphenylcarbinol.—To prepare the benzenoid form, either the pure quinonoid variety or the fuchsone was dissolved in 2.5% sodium hydroxide solution and the resulting solution acidified by passing in a stream of carbon dioxide. The precipitate was removed by filtration and dissolved in alcohol containing a trace of ammonia. Upon the gradual addition of water the carbinol crystallized with only a slight color, m. p. 155–157°.

4-Hydroxy-4′-phenyltriphenylcarbinol from 4-Methoxy-4′-phenyltriphenylcarbinol.—Six grams of anhydrous aluminum chloride was added to a hot solution of 4 g. of 4-methoxy-4′-phenyltriphenylcarbinol[11] in 100 cc. of benzene. This mixture was refluxed with exclusion of moisture for thirty minutes. The product was decomposed with ice and dilute hydrochloric acid, and the benzene was then removed by steam distillation. The residue was dissolved in 70% acetic acid and warmed on a steam-bath for an hour. Upon cooling, 3.7 g. of light yellow material was secured. It was recrystallized twice from 75% acetic acid, m. p. 134–140°.

Acetyl Derivative of 4-Hydroxy-4′-phenyltriphenylcarbinol.—This compound was prepared from the carbinol by means of acetic anhydride and anhydrous sodium acetate. It was recrystallized from benzene–petroleum ether, m. p. 134–136°.

Anal. Calcd. for $C_{27}H_{22}O_3$: C, 82.21; H, 5.62. Found: C, 82.26; H, 5.69.

Besides the carbinol, diphenoxymethane and tetraphenylmethane derivatives are produced by the condensation between phenol and ketone dichlorides.[12] The conditions under which the reaction is carried out determine the major product. These derivatives were made both in this case, the condensation between phenol and dichloro-*p*-biphenylphenylmethane, and in the subsequently described condensation between phenol and di-*p*-biphenyldichloromethane in order to determine their properties and thus facilitate their removal from the carbinols.

Phenyl-*p*-biphenyldiphenoxymethane.—Thirteen grams of dichloro-*p*-biphenylphenylmethane was added to a boiling solution of 14 g. of phenol in 250 cc. of anhydrous benzene. The mixture was refluxed with exclusion of moisture for one hour. At the end of this time hydrogen chloride evolution had ceased. The solution was then concentrated to one-half its original volume and 100 cc. of 60–75° petroleum ether was added to the residue. When the mixture had cooled, 12 g. of product precipitated. Upon recrystallization from alcohol, small white needles were obtained, m. p. 149–150°.

Anal. Calcd. for $C_{31}H_{24}O_2$: C, 86.89; H, 5.65. Found: C, 87.06; H, 5.70.

4,4′-Dihydroxy-4″-phenyltetraphenylmethane.—A mixture of 13 g. of dichloro-*p*-biphenylphenylmethane and 20 g. of phenol was heated on a steam-bath for five days. Moisture was excluded during this time. The excess phenol was then removed by steam distillation and the solid residue was extracted with 2.5% sodium hydroxide solution. After the insoluble material had been removed by filtration, the alkaline solution was acidified with carbon dioxide. The product became colorless after three recrystallizations from benzene–petroleum ether. A 55% yield of material which begins to soften at 157° and melts at 163–165° was secured.

Anal. Calcd. for $C_{31}H_{24}O_2$: C, 86.89; H, 5.65. Found: C, 86.65; H, 5.95.

Diacetyl Derivative of 4,4′-Dihydroxy-4″-phenyltetraphenylmethane.—This derivative was prepared from the dihydroxy compound by means of acetic anhydride and anhydrous sodium acetate. Upon recrystallization from alcohol it gave a product which melted to a cloudy liquid at 168–170° and became clear at 187°. *Anal.* Calcd. for $C_{35}H_{28}O_4$: C, 82.01; H, 5.51. Found: C, 81.82; H, 5.57.

4-Hydroxy-4′,4″-diphenyltriphenylcarbinol.—Di-*p*-biphenyldichloromethane was made from 4,4′-diphenylbenzophenone[13] using phosphorus pentachloride and following the procedure of Straus and Dutzmann.[14] In this latter reaction it was found more convenient to pour the warm reaction mixture, after removal of the phosphorus oxychloride, into 60–75° petroleum ether before allowing it to cool completely. By pouring it into the petroleum ether small crystals are obtained which are easier to work with than the hard mass which is obtained by allowing the product to cool alone. The crude dichloro compound (m. p. 130–135°) was used without further

purification; 25 g. of this material was mixed with 20 g. of phenol and the resulting reaction allowed to continue for fifteen hours at room temperature with exclusion of moisture. The excess phenol was then removed from the mixture by steam distillation. After the residue had been dried and crushed, it was digested with 200 cc. of cold alcohol and the mixture was left overnight; 6 g. of 4,4′-diphenylbenzophenone was removed by filtration. The residue after removal of the alcohol was recrystallized from 70% acetic acid. Crystallization occurs only with difficulty. The compound can be secured in a solid form by quickly pouring the dilute acetic acid solution into a large excess of water. The principal impurities are the ketone, which in spite of its insolubility in alcohol and dilute acetic acid is not entirely separated by the above procedure, and 4,4′-dihydroxy-4″,4‴-diphenyltetraphenylmethane. Preparation of the carbinol from the corresponding fuchsone gives a purer product but the method is not as easy as was found with 4-hydroxy-4′-phenyltriphenylcarbinol since separation of this fuchsone and ketone is not so readily carried out. The tetra compound is slightly more soluble in most solvents than the ketone or the fuchsone. The carbinol is readily soluble in ether, alcohol and benzene and is only slightly soluble in dilute alkali. *Anal.* Calcd. for $C_{31}H_{24}O_2$: C, 86.89; H, 5.65. Found: C, 86.59; H, 5.87.

Di-*p*-biphenylquinomethane.—A sample of 4-hydroxy-4′,4″-diphenyltriphenylcarbinol was placed in an evacuated flask heated by means of an oil-bath to 130–140°. It was maintained at this temperature until the vigorous evolution of water vapor had ceased. The product crystallizes from benzene in orange needles. If it is heated gradually it melts over a range 140–155°. If it is placed in a melting point-bath at 150° and then heated, it melts at 159–161.5°. This compound is soluble in ether to the extent of about 2 g. per liter. *Anal.* Calcd. for $C_{31}H_{22}O$: C, 90.70; H, 5.40. Found: C, 90.49; H, 5.60.

Di-*p*-biphenylquinomethane from 4-Methoxy-4′,4″-diphenyltriphenylcarbinol.—Two grams of anhydrous aluminum chloride was added to a boiling solution of 2.2 g. of 4-methoxy-4′,4″-diphenyltriphenylcarbinol[11] in 50 cc. of benzene and the mixture was refluxed with exclusion of moisture for fifteen minutes. The product was decomposed with ice and dilute hydrochloric acid. The benzene solution was separated, dried, and evaporated to dryness. The resulting solid was dehydrated at 130–140° in an evacuated flask until water evolution had ceased. Recrystallization of the product from benzene yielded 0.5 g. of orange needles, m. p. 155–157°. The melting point of a mixture of this material with that prepared by dehydration of the hydroxycarbinol indicated the identity of the two products.

Quinonoid Form of 4-Hydroxy-4′,4″-diphenyltriphenylcarbinol.—3.5 g. of di-*p*-biphenylquinomethane was dissolved in 300 cc. of 70% acetic acid by heating on a steam-bath for two hours. Sufficient water was then added to reduce the concentration of the acetic acid to 60–65% and the solution allowed to stand. Crystallization occurred after long standing. The product was red-orange in color, m. p. 106–107.5°.

Benzenoid Form of 4-Hydroxy-4′,4″-diphenyltriphenylcarbinol.—Attempts to prepare the benzenoid form of this carbinol resulted in a product lighter in color than the quinonoid variety but by no means colorless. Though the solubility of this carbinol in dilute sodium hydroxide is not great, some solution will take place. An alkaline solution of a sample of the quinonoid variety was filtered and then acidified with carbon dioxide. Recrystallization of the precipitate from aqueous alcohol containing a trace of ammonia gave a yellow-orange product, m. p. 124–126°.

Acetyl Derivative of 4-Hydroxy-4′,4″-diphenyltriphenylcarbinol.—This compound was prepared from the carbinol by means of acetic anhydride and anhydrous sodium acetate. It was recrystallized twice from benzene–petroleum ether mixtures, m. p. 149–152°. *Anal.* Calcd. for $C_{33}H_{26}O_3$: C, 84.23; H, 5.57. Found: C, 83.90; H, 5.76.

Di-*p*-biphenyldiphenoxymethane.—Fifteen grams of di-*p*-biphenyldichloromethane was added to a boiling solution of 10 g. of phenol and 5 g. of pyridine in 100 cc. of anhydrous benzene. This mixture was refluxed with exclusion of moisture for four hours. The product was extracted with water several times to remove pyridine hydrochloride, pyridine and phenol. The volume of the benzene solution was then reduced to 75 cc. and an equal volume of 60–75° petroleum ether was added. The ketone which precipitated was removed by filtration and the filtrate evaporated nearly to dryness. The product was crystallized from petroleum ether, yield 10 g., m. p. 118–120°. This compound is very soluble in benzene, high boiling petroleum ether and slightly soluble in alcohol. *Anal.* Calcd. for $C_{37}H_{28}O_2$: C, 88.06; H, 5.59. Found: C, 87.87; H, 5.86.

4,4′-Dihydroxy-4″,4‴-diphenyltetraphenylmethane.—A mixture of 20 g. of phenol and 12 g. of di-*p*-biphenyldichloromethane was heated on a steam-bath for five days with the exclusion of moisture. Water was then added and the excess phenol was removed by steam distillation. The residue crystallized slowly from a mixture of benzene and 60–75° petroleum ether giving 10 g. of material. Recrystallized from alcohol, m. p. 253–255.5°. This compound dissolves in hot 2.5% sodium hydroxide solution. It is moderately soluble in ether and in benzene and slightly soluble in alcohol.

Diacetyl Derivative of 4,4′-Dihydroxy-4″,4‴-diphenyltetraphenylmethane.—This substance was prepared from the dihydroxy compound by means of acetic anhydride and anhydrous sodium acetate; recrystallized from benzene and 60–75° petroleum ether, m. p. 256–258°. *Anal.* Calcd. for $C_{41}H_{32}O_4$: C, 83.65; H, 5.48. Found: C, 83.20; H, 5.54.

Summary

1. 4-Hydroxy-4′-phenyltriphenylcarbinol and 4-hydroxy-4′,4″-diphenyltriphenylcarbinol have been made. Each carbinol has been isolated in the benzenoid and quinonoid forms and various derivatives are described.

2. The ultraviolet absorption spectra of these carbinols and certain derivatives have been determined. The *p*-biphenyl group in these carbinols acts almost as an isolated unit in absorption, producing a characteristic, high, broad absorption band near 3800 mm.$^{-1}$ which resembles the band others have reported for biphenyl itself.

3. A study of the ultraviolet absorption for the fuchsones of the above carbinols indicates that resonance structures of the following type appear to be an important factor in the absorption of ether solutions of fuchsones

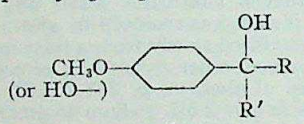
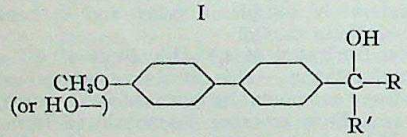
Quinoidation of Triaryl Compounds—Hydroxybiphenyldiarylmethyl Cations

BY LEIGH C. ANDERSON AND W. A. FISHER

Data have been presented from this Laboratory on the preparation and absorption spectra of *p*-hydroxyphenylbiphenylcarbinols.[1] This paper discusses investigations which have been made on biphenylcarbinols in which a hydroxyl or methoxyl group has been substituted on the terminal carbon of the biphenyl group in order to obtain data on the biphenoquinone type of structure. Two types of carbinols were used in this investigation: methoxy or hydroxyphenyldiarylcarbinols illustrated by I and methoxy or hydroxybiphenyldiarylcarbinols illustrated by II where the aryl groups R and R′ are either phenyl or *para*-biphenyl groups. The absorption spectra



I



II

of the cations produced by solutions of these carbinols in acid have been ascertained.

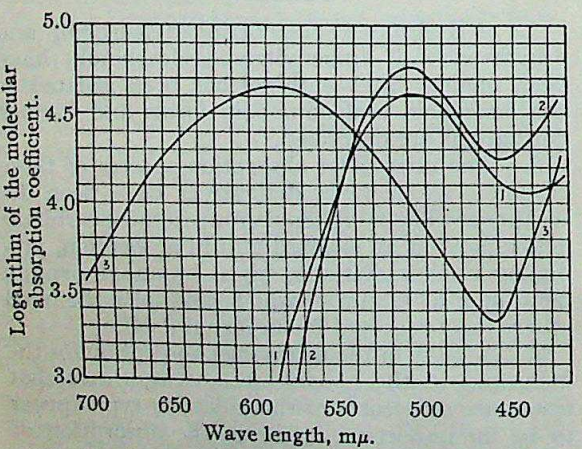


Fig. 1.—Absorption of acetic–sulfuric acid solutions of: 1, 4-phenyltriphenylmethyl sulfate; 2, 4-methoxy-4′-phenyltriphenylmethyl sulfate; 3, 4-(*p*-anisyl)-triphenylmethyl sulfate.

The effect on the absorption spectrum of the triphenylmethyl group when a *p*-anisyl group is substituted in a para position has been investigated for the first time. The chemical investigation of 4-(*p*-hydroxyphenyl)-triphenylcarbinol gave no evidence that the substance would become quinonoid through the biphenyl group. A study of the absorption curves gives evidence that the cations derivable from this compound and others containing the 4-hydroxybiphenyl or 4-methoxybiphenyl group contain predominating electronic structures which include quinoidation of the biphenyl group in a manner similar to that shown for fuchsones in the preceding paper. Considering the ions: 4-phenyltriphenylmethyl, 4-methoxy-4′-phenyltriphenylmethyl, and 4-(*p*-anisyl)-triphenylmethyl, the absorption of the first two is found to be similar while that of the third is markedly different (Fig. 1). It absorbs over a much broader region of the spectrum and has its absorption maximum much further toward the infrared. The structural change between the second and third ion is only in the position of the methoxy group; in the second it is on a phenyl group and in the third case it is on a biphenyl. The striking difference in absorption of the third ion as compared to that of the second is most logically explained by assuming that a predominating electronic structure for the third ion is that in which the biphenyl group has become quinonoid. A study of the absorption of the ions: 4,4′-diphenyltriphenylmethyl, 4-methoxy-4′4″-diphenyltriphenylmethyl, and 4-(*p*-anisyl)-4′-phenyltriphenylmethyl leads one to similar conclusions (Fig. 2).

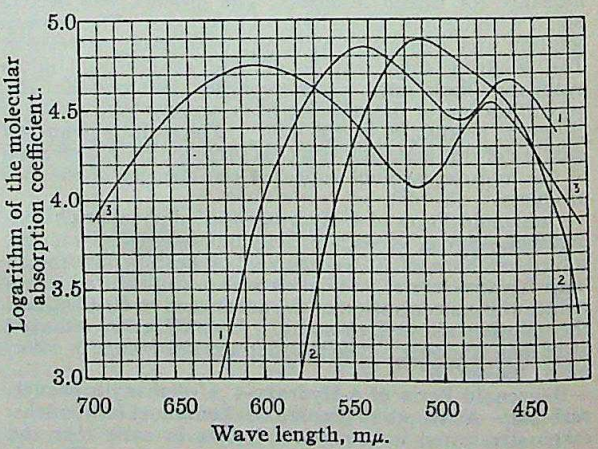

Fig. 2.—Absorption of acetic–sulfuric acid solutions of: 1, 4,4′-diphenyltriphenylmethyl sulfate; 2, 4-methoxy-4′,4″-diphenyltriphenylmethyl sulfate; 3, 4-(*p*-anisyl)-4′-phenyltriphenylmethyl sulfate.

If the methoxy group can fix the positive charge out at the end of the biphenyl group as the evidence indicates, there is no reason for assuming that the methoxy situated on the phenyl group has any less effect in causing the phenyl group to become quinonoid. This determines the predominating electronic structure of the 4-methoxy-

4′-phenyltriphenylmethyl ion. A preferred position for the location of the charge on the 4-phenyltriphenylmethyl ion is not indicated by these data although the lack of similarity of its absorption to that of the substituted biphenyl compound makes it improbable that the charge is on the end of the biphenyl group.

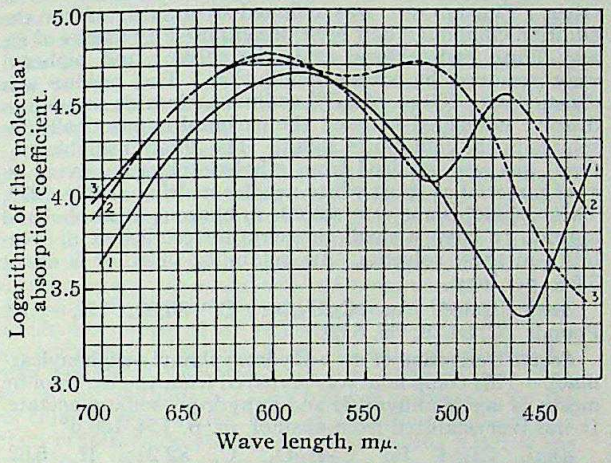

Fig. 3.—Absorption of acetic–sulfuric acid solutions of: 1, 4-(*p*-anisyl)-triphenylmethyl sulfate; 2, 4-(*p*-anisyl)-4′-phenyltriphenylmethyl sulfate; 3, 4-(*p*-anisyl)-4′,4″-diphenyltriphenylmethyl sulfate.

A para-anisyl group substituted in a para position of the triphenylmethyl ion is more strongly bathochromic than that of any other single substituent which has been reported (Fig. 3). This is consistent with data of Morton and Emerson, who found the maximum absorption of the 4,4′,4″-tri-(*p*-anisyl)-triphenylmethyl ion at 638 mμ.[2] These data appear to rule out conclusively any structural theory relating color to the central carbon atom. It is not reasonable to assume that replacing the methoxyphenyl group in a carbinol by a methoxybiphenyl group and thus increasing the distance between the substituted methoxy group and the central carbon atom would increase the effect of the methoxy on this atom. Dilthey and Harenberg[3] have claimed that groups far away from the central carbon atom have only a slight influence on the color. This is undoubtedly correct in the case of the methoxy groups in the 4,4′,4″-tri-(*p*-methoxyphenoxy)-triphenylmethyl ion they were investigating. They concluded that this was evidence against the quinonoid theory on the assumption that the diphenylether group might be expected to become quinonoid by having a tetracovalent ether oxygen. There is no evidence for this since tetravalent oxygen has usually been assumed to possess three covalences, the fourth being an ionic valence.

That the hydroxy or methoxy group is strongly concerned in attracting the charge is further evidenced by the absorption of corresponding pairs of

(2) Morton and Emerson, THIS JOURNAL, 59, 1947 (1937); 60, 284 (1938).

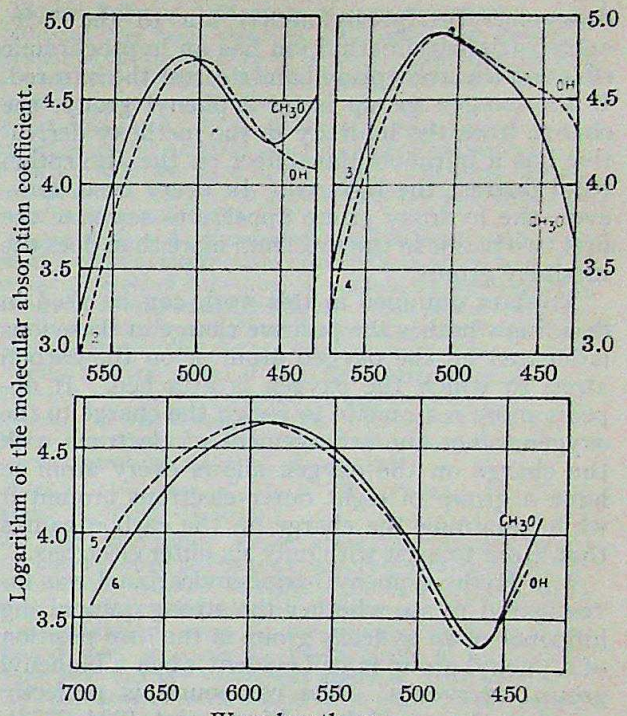

Fig. 4.—Comparison of the absorption of methylated and unmethylated hydroxytriarylmethyl sulfates: 1, 4-methoxy-4′-phenyltriphenylmethyl sulfate; 2, 4-hydroxy-4′-phenyltriphenylmethyl sulfate; 3, 4-methoxy-4′,4″-diphenyltriphenylmethyl sulfate; 4, 4-hydroxy-4′,4″-diphenyltriphenylmethyl sulfate; 5, 4-(*p*-hydroxyphenyl)-triphenylmethyl sulfate; 6, 4-(*p*-anisyl)-triphenylmethyl sulfate.

these compounds, one containing a hydroxy group and the other a methoxy. The absorption curves of ether solutions of 4-(*p*-hydroxyphenyl)-triphenylcarbinol and the corresponding methoxy compound cannot be distinguished from one another. On the other hand, the change from hydroxy to methoxy groups in the case of the ions causes a displacement of the absorption bands. The direction of the displacement depends upon whether a phenyl or a biphenyl group is substituted (Fig. 4). The change from the 4-(*p*-hy-

droxyphenyl)-triphenylmethyl ion to the 4-(*p*-anisyl)-triphenylmethyl ion has an hypsochromic effect on the absorption band nearest the infrared. If the oxygen group is on a phenyl group, the change from the hydroxy to the methoxy derivative has a bathochromic effect on the absorption band nearest the infrared. In every case, however, the hydroxy group appears to separate the first two bands in the spectrum more than does the methoxy group.

No data obtained in this work can be used in deciding whether the positive charge in these ions is located on the oxygen atom or on the carbon atom to which the oxygen is attached. It appears more reasonable to assign the charge to the oxygen, since the arrangement of electrons with the charge on the oxygen allows every atom to have a group of eight outer electrons around it while retaining the charge on the carbon causes that atom to exist with only six outer electrons.

4-(*p*-Hydroxyphenyl)-triphenylcarbinol was investigated to see whether the strong quinonizing influence of an hydroxy group in the *para* position of a phenyl group is still evident when a biphenyl group intervenes. The compound is perfectly colorless, has a high melting point (224–227°), and shows no tendency whatsoever to exist in a quinonoid form in the solid state. If it is maintained above its melting point, it decomposes quite rapidly with the evolution of gas. The product, however, could not be obtained crystalline and it did not have an intense color as should be characteristic of such a compound as diphenylbiphenoquinomethane. The color, though a deep purple-brown, seemed to be possessed by only a small amount of the material even when the copious gas evolution had ceased. It is thought likely that any evolution of water took place between molecules resulting in condensation rather than intramolecularly leading to a quinonoid biphenyl group. An attempt to make diphenylbiphenoquinomethane by the reaction between biphenoquinone and diphenylketene was also unsuccessful.

Experimental

4-Methoxy-4′-phenyltriphenylcarbinol.—This carbinol was described by Bowden, Harris and Roberts[4] while this investigation was being carried on. We prepared it by two procedures: (1) the reaction between *p*-anisylmagnesium bromide and *p*-phenylbenzophenone, and (2) the methylation of 4-hydroxy-4′-phenyltriphenylcarbinol by means of dimethyl sulfate.

4-Methoxy-4′,4″-diphenyltriphenylcarbinol.—A mixture of 15 g. of *p*-anisylmagnesium bromide in ether–benzene solution and 20 g. of 4,4′-diphenylbenzophenone was refluxed for three hours. After standing overnight, the product was hydrolyzed with ice and dilute hydrochloric acid and then steam distilled. The carbinol was extracted from the unreacted ketone by ether, in which the ketone is almost insoluble. The ether in the carbinol solution was replaced by benzene, 60–75° petroleum ether was added, and 10 g. of carbinol crystallized. Recrystallization of the carbinol from 90–100° petroleum ether containing a small amount of benzene gave small white needles, m. p. 144–146°. In contrast to 4-methoxytriphenylcarbinol and 4-methoxy-4′-phenyltriphenylcarbinol, this compound crystallizes readily and is less soluble in the common solvents.

Anal. Calcd. for $C_{32}H_{26}O_2$: C, 86.85; H, 5.92. Found: C, 87.08; H, 6.14.

4-(*p*-Hydroxyphenyl)-triphenylcarbinol.—Thirty grams of 4-hydroxy-4′-benzoylbiphenyl dissolved in 200 cc. of benzene was added to the Grignard reagent made from 55 g. of bromobenzene, 7.9 g. of magnesium and 100 cc. of ether. The mixture was refluxed overnight. After the addition compound had been decomposed by means of ice and dilute hydrochloric acid, the solvent and biphenyl were removed by steam distillation. The residue was digested with 500 cc. of 2.5% sodium hydroxide solution to dissolve unreacted ketone; the carbinol is practically insoluble in the cold dilute alkali. The alkali insoluble material was recrystallized from ethylene chloride giving 30 g. of material as short white needles melting at 224–227°. This carbinol is not very soluble in benzene or alcohol and appears to have a small temperature coefficient of solubility in these solvents. Its solubility in ether is about 3.5 g. per liter.

Anal. Calcd. for $C_{25}H_{20}O_2$: C, 85.20; H, 5.72. Found: C, 84.79; H, 5.99.

Acetyl Derivative of 4-(*p*-Hydroxyphenyl)-triphenylcarbinol.—This compound was prepared from the carbinol by means of acetic anhydride and anhydrous sodium acetate. It was recrystallized from alcohol, m. p. 154–156.5°.

Anal. Calcd. for $C_{27}H_{22}O_3$: C, 82.21; H, 5.62. Found: C, 82.13; H, 5.73.

4-(*p*-Anisyl)-triphenylcarbinol.—4-Methoxy-4′-benzoylbiphenyl was prepared from 4-methoxybiphenyl according to the method of Fieser and Bradsher.[5] This ketone was treated with a large excess of phenylmagnesium bromide. After the addition compound had been hydrolyzed with ice and ammonium chloride, the solvent and biphenyl were removed by steam distillation. The carbinol was recrystallized four times from 90–100° petroleum ether, m. p. 108–109°.

Anal. Calcd. for $C_{26}H_{22}O_2$: C, 85.22; H, 6.05. Found: C, 85.08; H, 6.14.

4-(*p*-Hydroxyphenyl)-triphenylcarbinol from 4-(*p*-Anisyl)-triphenylcarbinol.—Aluminum chloride was more satisfactory than acetic–sulfuric acid and acetic–hydrobromic acid mixtures in our attempts to demethylate 4-(*p*-anisyl)-triphenylcarbinol. A partial demethylation occurred when a mixture of two parts by weight of anhydrous aluminum chloride and one of the methoxy carbinol dissolved in benzene was refluxed for one hour. The product was decomposed with ice and dilute hydrochloric acid and the benzene layer was washed with water and dried. The hydroxycarbinol crystallized from the solution prior to the methoxycarbinol upon the addition of petroleum ether. The hydroxycarbinol was recrystallized several times from benzene–petroleum ether. Experiments showed it to be the same as the previously described 4-(*p*-hydroxyphenyl)-triphenylcarbinol.

Attempts to Make Diphenylbiphenoquinomethane.—Two methods were employed in attempting to make this compound: (1) the dehydration of 4-(*p*-hydroxyphenyl)-triphenylcarbinol, and (2) the reaction between diphenylketene and biphenoquinone. The dehydration procedure was tried by heating the carbinol in inert solvents for extended periods of time, and by heating the solid carbinol under reduced pressure in inert atmospheres. For example, a sample of carbinol was placed in a flask immersed in a sulfuric acid bath; the flask was evacuated and a small amount of carbon dioxide introduced. When the sample was heated at 220–230°, a vigorous evolution of water occurred. After heating for thirty minutes, the product was a purple gum which could not be crystallized. It did not have the intense color which diphenylbiphenoquinomethane might be expected to have, and the purple color seemed to be a property of only part of the material.

It is thought likely that the decomposition which occurred took place by evolution of water between molecules rather than intramolecularly.

The biphenoquinone necessary for the other attempted preparation was made according to the directions of Willstätter and Kalb[6] by the oxidation of 4,4′-dihydroxybiphenyl which was prepared from benzidine as described by Hirsch.[7] This dihydroxy compound is much less soluble in water than Hirsch indicated. Recrystallization of the material from water using a soxhlet extractor gave a better product than recrystallization from glacial acetic acid as suggested by Bratz and von Niementowski.[8]

The formation of fuchsones from diphenylketene and quinones has been investigated by Staudinger and by Staudinger and Bereza.[9] In contrast to the quinones used previously, biphenoquinone is quite insoluble in most solvents. For this reason the reaction was run in nitrobenzene in which it is somewhat soluble. A suspension of biphenoquinone in nitrobenzene containing diphenylketene was stirred under a carbon dioxide atmosphere for forty-eight hours. No diphenylbiphenoquinomethane was isolated from the yellow gum which precipitated when petroleum ether was added to the filtered product.

4-(*p*-Anisyl)-4′-phenylbenzophenone.—4-Phenylbenzoyl chloride was prepared by refluxing a mixture of 20 g. of 4-phenylbenzoic acid and 50 cc. of thionyl chloride for thirty minutes. The excess thionyl chloride was then removed by distillation under reduced pressure. To the acid chloride were added 19 g. of 4-methoxybiphenyl and 400 cc. of tetrachloroethane, and the resulting solution was cooled to −10°; 16 g. of anhydrous aluminum chloride was added and the mixture allowed to warm to room temperature while being stirred vigorously. After standing overnight, the product was decomposed with ice and dilute hydrochloric acid and the tetrachloroethane was removed by steam distillation. The solid residue was dried and then digested with 600 cc. of ether. The ether insoluble 4-(*p*-anisyl)-4′-phenylbenzophenone was recrystallized from *o*-dichlorobenzene giving plates which melted at 246–248°. *Anal.* Calcd. for $C_{26}H_{20}O_2$: C, 85.69; H, 5.53. Found: C, 85.30; H, 5.61.

2-Methoxy-4′,5-diphenylbenzophenone.—This compound is the ether soluble fraction from the above reaction. The ether was evaporated and the residue recrystallized from methyl alcohol giving white needles, m. p. 127–130°. The assignment of the formulas for these two compounds was made on the basis of their melting points and the analogy between this reaction and that occurring between benzoyl chloride and 4-methoxybiphenyl. The total yield in this reaction was 75%; 50–65% of this was 4-(*p*-anisyl)-4′-phenylbenzophenone. *Anal.* Calcd. for $C_{26}H_{20}O_2$: C, 85.69; H, 5.53. Found: C, 85.48; H, 5.57.

4-(*p*-Anisyl)-4′-phenyltriphenylcarbinol.—A solution of 4 g. of 4-(*p*-anisyl)-4′-phenylbenzophenone dissolved in 75 cc. of ether was added to the Grignard reagent prepared from 5.4 g. of bromobenzene and 0.8 g. of magnesium. The mixture was refluxed for two hours and allowed to stand. After the addition compound had been hydrolyzed with ice and dilute hydrochloric acid, the solvent and biphenyl were removed by steam distillation. The residue was twice recrystallized from benzene–petroleum ether giving 4 g. of material, m. p. 141–143°.

Anal. Calcd. for $C_{32}H_{26}O_2$: C, 86.85; H, 5.92. Found: C, 86.94; H, 6.08.

4-Methoxy-4′-carboxybiphenyl.—This compound was made by the oxidation of 4-methoxy-4′-acetylbiphenyl. Fieser and Bradsher have prepared this acid by alkaline permanganate oxidation of the acetyl compound.[10] In the present work the oxidation was carried out with permanganate and with sodium hypoiodite.

Methyl Ester of 4-Methoxy-4′-carboxybiphenyl.—This compound has been reported by Fieser and Bradsher. Because of the insolubility of both the ester and the acid in methanol, it was found convenient to carry out the esterification of large quantities of the acid by the use of a soxhlet apparatus; 20 g. of the acid was placed in the soxhlet extractor and 600 cc. of methanol containing 5 cc. of sulfuric acid was used in the flask. The ester crystallized from the solution in plates with the previously reported melting point, 172–173°.

4-(*p*-Anisyl)-4′,4″-diphenyltriphenylcarbinol.—An excess of *p*-biphenylmagnesium bromide was added to 5 g. of the methyl ester of 4-methoxy-4′-carboxybiphenyl and the mixture was refluxed for five hours. The product was decomposed with ice and dilute hydrochloric acid and then steam distilled. The residue was extracted with one liter of ether leaving most of the tetraphenyl undissolved. The ether solvent was replaced by benzene and 6 g. of the carbinol was precipitated by the addition of petroleum ether. The product was recrystallized several times from benzene–petroleum ether, m. p. 130–132°.

Anal. Calcd. for $C_{38}H_{30}O_2$: C, 88.00; H, 5.83. Found: C, 87.63; H, 6.06.

All the compounds whose absorption spectra were determined showed no change in absorption after recrystallization from suitable solvents. Curve 1, Fig. 2, was taken from the published work of Burawoy.[11]

The absorption curves for the triarylmethyl ions were obtained from solutions of the carbinols in an acetic–sulfuric acid mixture which was prepared by dissolving 5 cc. of concentrated sulfuric acid in 95 cc. of glacial acetic acid. Increasing the amount of sulfuric acid in the solvent had no effect on the absorption. The absorption of 4-(*p*-hydroxyphenyl)-triphenylcarbinol was also determined in a solution of *p*-toluenesulfonic acid in glacial acetic acid and found to be identical with that of the acetic–sulfuric acid solution except for intensity. Using 10 g. of *p*-toluenesulfonic acid in 100 cc. of glacial acetic acid gave an absorption maximum of 4.3 units as compared to 4.65 units for the acetic–sulfuric acid solution. By using 25 g. of the sulfonic acid in 100 cc. of acetic acid, this maximum was raised to 4.55 units. The acetic–sulfuric acid solutions of these carbinols were stable for weeks.

Summary

1. 4-(*p*-Hydroxyphenyl)-triphenylcarbinol and the corresponding methoxy compound have been made, as well as the series of related compounds secured by replacing one and then both of the phenyl groups in the methoxy compound by *p*-biphenyl groups.

2. A comparison of the visible absorption of the 4-phenyltriphenylmethyl, 4-methoxy-4′-phenyltriphenylmethyl and 4-(*p*-anisyl)-triphenylmethyl ions and the corresponding ions containing an additional 4-phenyl substituent indicates that the biphenyl group is quinonoid in the 4-(*p*-anisyl) compounds.

3. Replacing an hydroxyl group by a methoxy group in these ions causes a shift in the absorption maximum of the principal band, which is different in direction depending on whether the substituted group is on a phenyl or biphenyl group.

4. 4-(*p*-Hydroxyphenyl)-triphenylcarbinol shows no tendency to exist in a quinonoid form in the solid state and attempts to prepare diphenylbiphenoquinomethane from it by dehydration failed.

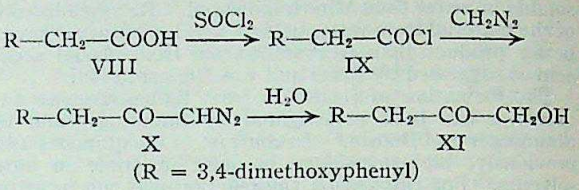
Studies on Lignin and Related Compounds. LXXIX. Synthesis and Properties of 3-Hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone[1]

BY HERBERT E. FISHER, MARSHALL KULKA AND HAROLD HIBBERT

In a previous communication[2] the allylic and dismutation rearrangements attendant upon the conversion of the two halides, 1-bromo-1-(3,4-dimethoxyphenyl)-2-propanone and 3-chloro-1-(3,-4-dimethoxyphenyl)-2-propanone, to the corresponding alcohols, acetates and ethyl ethers were reported, and the bearing of these transformations on the relative validity of the Freudenberg and Hibbert theories of lignin structure was discussed.

During the course of that investigation, the synthesis of seventeen of the eighteen possible compounds formed by substitution of bromine, acetyl, hydroxyl and ethoxyl groups in the side chains of 1-(3,4-dimethoxyphenyl)-2-propanone (I) and 1-(3,4-dimethoxyphenyl)-1-propanone (II) was completed and the properties of these derivatives summarized. This communication deals with the synthesis and properties of the eighteenth member of this series (A(iii), Table I), namely, 3-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone, the veratryl analog of the keto form of β-oxyconiferyl alcohol. Its properties provide further support for the mechanism[2,3,4] suggested to account for the presence of the ethyl ethers of the benzoins, 1-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone[5] and 2-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone[6] in the ethanolysis products of spruce wood.



(R = 3,4-dimethoxyphenyl)

Synthesis of the homoveratric acid (VIII) involved considerable investigation. Among methods investigated were those of Hahn, Stiehl and Schultz,[7] Julian and Sturgis[8] and Arndt and Eistert.[9] A modification of the last-named procedure was finally adopted. This involved rearrangement of the diazoketone (VI) to the methyl ester (VII) followed by saponification of the latter to homoveratric acid (VIII), rather than conversion of (VI) to homoveratric amide and subsequent hydrolysis as employed in the original procedure. This rapid modified Arndt–Eistert synthesis yielded easily purifiable intermediate products in a higher yield (60% based on veratric aldehyde (III)) than by other methods. Conversion of the homoacid (VIII) to homoveratroyl chloride (IX) with thionyl chloride, thence to homoveratroyl diazomethane (X) using diazomethane in ether was effected by the procedure used by Haworth and Atkinson[10] for the synthesis of 3-chloro-1-(3,4-dimethoxyphenyl)-2-propanone. Hydrolysis

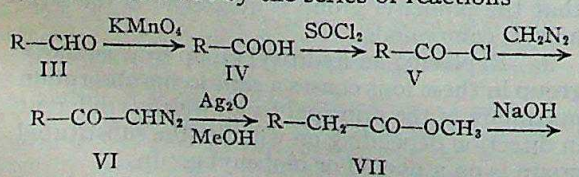
The synthesis of the new ketol, 3-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone (A(iii), Table I), was carried out by the series of reactions



of the diazoketone was carried out by Wolff's method[11] using water at 100°, as in his conversion of diazoacetophenone to benzoyl carbinol. The ketol (A(iii), Table I) obtained (56% yield based on homoveratric acid) analyzed correctly, and differed in physical properties from the three other isomers (B(iii), C(iii) and D(iii), Table I). Its refractive index, $n^{25}D$ 1.5485, differed considerably from that of 2-hydroxy-1-(3,4-dimethoxyphenyl)-1-propanone (C(iii), Table I) $n^{25}D$ 1.5590 while 1-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone (B(iii), Table I) and 3-hydroxy-1-(3,4-dimethoxyphenyl)-1-propanone (D(iii), Table I) are

known solids, m. p. 77–78° and 83–84°, respectively. Moreover the semicarbazone of the new ketol, m. p. 123–124°, differed from those of the known ketols. Final conclusive evidence for its structure was obtained by acetylation with acetyl chloride and pyridine.[12] The reaction product was identified as 3-acetoxy-1-(3,4-dimethoxyphenyl)-2-propanone (A(ii), Table I) by melting point and mixed melting point determinations with an authentic sample.[2]

The behavior of 3-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone (XI) toward acidic and basic reagents was studied. On heating with dilute (5%) sulfuric acid at 100° it yielded a relatively small amount (20%) of amorphous polymer, but more concentrated acid (72%), under the conditions of the Klason lignin procedure, brought about polymerization to the extent of over 60%. Strong bases, even in high dilution, caused marked polymerization particularly in aqueous media. Thus treatment with aqueous 1% sodium hydroxide at 100° for twenty-four hours gave more than 50% of a polymer, while 3% aqueous sodium hydroxide, even at room temperature, polymerized it to the extent of 80% in three days. With 3% aqueous-ethanolic (1:1) sodium hydroxide, under the former conditions, only 17% of polymer was formed.

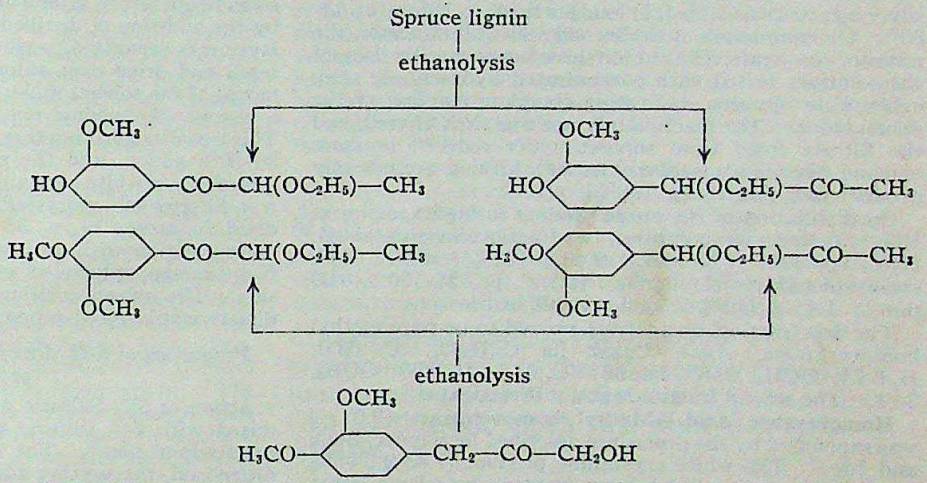
On treatment of (XI) with 5% aqueous potassium acetate under the same conditions which brought about rearrangement[2] of (B(iii)) to (C(iii)), no change was apparent, the ketol (XI) (75%), identified as its semicarbazone, being recovered unchanged.

Treatment of (XI) with ethanolic hydrogen chloride (2%) under the same conditions used for the ethanolysis of wood[5] yielded a bisulfite insoluble fraction containing a mixture of 2-ethoxy-1-(3,4-dimethoxyphenyl)-1-propanone (C(iv), Table I) and the corresponding isomer, 1-ethoxy-1-(3,4-dimethoxyphenyl)-2-propanone (B(iv), Table I) in a ratio of 3 to 7, the combined yield being 80%. The very small bisulfite soluble fraction apparently contained no 1,2-diketone.

These results, taken in conjunction with those obtained previously[2] on the hydrolysis of the corresponding halides and acetates ($R—CH_2—CO—CH_2X$; X = Br, Cl, $OCOCH_3$) supply strong experimental support for the theory that formation of the two isomeric ethyl ethers takes place by the following series of reactions[2]

$$R—CH_2—CO—CH_2OH \rightleftarrows R—CH=C(OH)—CH_2OH \rightleftarrows R—CHOH—C(OH)=CH_2 \rightleftarrows$$
$$R—CHOH—CO—CH_3 \rightleftarrows R—C(OH)=C(OH)—CH_3 \rightleftarrows R—CO—CHOH—CH_3$$
$$\downarrow EtOH,HCl \qquad\qquad \downarrow EtOH,HCl$$
$$R—CH(OC_2H_5)—CO—CH_3 \qquad R—CO—CH(OC_2H_5)—CH_3$$

The connection of these products with the postulated lignin progenitor, β-oxyconiferyl alcohol (keto-form), is shown below.



The occurrence of the guaiacyl analogs among the ethanolysis products of spruce and maple wood thus finds a satisfactory explanation in the assumption of their presence as stabilized end-products arising from a more reactive native lignin building unit, namely, β-oxyconiferyl alcohol or its keto-isomer[2,4] and provides further support in favor of the validity of Hibbert's and the non-validity of Freudenberg's theory of lignin structure.[2,4,13]

Experimental

Synthesis of Homoveratric Acid: Modified Arndt–Eistert Method

Veratric Acid.—Veratric aldehyde (25 g.) was oxidized to the corresponding acid with aqueous potassium permanganate according to the directions of Shriner and Kleiderer[14]; yield, 24.7 g. (90%). Recrystallized from absolute ethanol, m. p. 180–181°, the product gave no depression in melting point when mixed with an authentic sample of veratric acid.

Veratroyl Chloride.—Veratric acid (15.0 g.) was converted to the chloride with freshly purified[15] thionyl chloride, according to the procedure of Arndt and Eistert[9]; yield of crude product, 16.7 g. (100%). A small amount, purified by distillation, melted at 70–71°. The melting point of veratroyl chloride is 70° according to Mayer.[16]

Veratroyl Diazomethane.—Crude veratroyl chloride (16.7 g.) was treated with a solution of diazomethane in ether by the procedure of Arndt and Eistert,[9] yielding a yellow solid (17.0 g. (100%)) which, after recrystallization from benzene–petroleum ether (b. p. 30–50°), gave fine

yellow needles, m. p. 76–77° (Arndt and Eistert, m. p. 75°).

Methyl Homoveratrate.—Recrystallized veratroyl diazomethane (12.4 g., m. p. 76–77°) was dissolved in absolute methanol (200 cc.) and warmed to 55–60° in a three-necked flask equipped with reflux condenser, stirrer and thermometer. At ten-minute intervals four portions of a slurry of freshly prepared silver oxide (from 2.5 g. of silver nitrate in 35 cc. methanol) were added to the rapidly stirred solution, which was maintained under an atmosphere of carbon dioxide throughout the reaction period, and the solution then refluxed for four hours.

The sludge of metallic silver and silver oxide was removed by filtration, and fresh silver oxide (from 2 g. of silver nitrate) was added, in four portions, as before, at 55–60°. On completion of the second series of additions, the mixture was again refluxed for three hours, until a drop of the solution, tested with concentrated hydrochloric acid, evolved no nitrogen, indicating complete reaction of the diazoketone. The reaction mixture was then filtered, and the filtrate freed from solvent under reduced pressure (carbon dioxide atmosphere) at 50°, leaving a crude oily product weighing 12.4 g. (98%).

On distillation of the crude product in high vacuum at 135–145° (bath temperature), two fractions were obtained: (I) b. 110–113° (0.03 mm.); 9.10 g. (72%); $n^{25}D$ 1.5300; straw-colored mobile liquid. (II) b. p. 128–130° (0.03 mm.); 1.48 g. (12%); semi-crystalline.

The first fraction, on analysis, proved to be pure methyl homoveratrate. *Anal.* Calcd. for $C_{11}H_{14}O_4$: C, 63.0; H, 6.74; OCH_3, 29.6. Found: C, 63.1; H, 6.90; OCH_3, 29.4. The second fraction was not investigated.

Homoveratric Acid.—Methyl homoveratrate (9.0 g.) was saponified by the procedure described by Snyder, Buck and Ide.[17] The white crystalline product (7.85 g., 95% yield) was recrystallized from benzene–petroleum ether (60–70°); white plates, m. p. 98–99°. A mixed melting point with homoveratric acid showed no depression.

Synthesis of 3-Hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone

Homoveratroyl Chloride.—Homoveratric acid (10.0 g.) was refluxed gently for forty-five minutes with freshly purified[15] thionyl chloride (20 cc.) in an all-glass apparatus under an atmosphere of carbon dioxide. Four portions (25 cc.) of benzene were successively added and removed by distillation under reduced pressure (carbon dioxide) in order to free the acid chloride from excess thionyl chloride. The dark red oil (10.9 g., 100% yield) was treated, without purification, as follows:

Homoveratroyl Diazomethane.—The homoveratroyl chloride (10.9 g.) was dissolved in benzene (50 cc.) and added slowly, with stirring, at 0° to a solution of diazomethane (from 40 g. nitrosomethyl urea) in ether (400 cc.). The solution was allowed to warm slowly to room temperature and react overnight. On removal of the solvents under reduced pressure (carbon dioxide) at room temperature, a red oily product weighing 11.2 g. (100%) was obtained.

3-Hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone.—The homoveratroyldiazomethane (11.2 g.) was dissolved in absolute ethanol (90 cc.) and added, over a period of thirty minutes, to water (500 cc.) heated to 70°, with stirring. After addition of the diazoketone was complete, the reaction mixture was refluxed for three hours, cooled, and concentrated at room temperature under reduced pressure (carbon dioxide) to remove ethanol. The aqueous solution was then extracted five times with chloroform, the extract concentrated to a small volume (50 cc.) under reduced pressure (carbon dioxide) and precipitated three times successively in a thin stream from this solvent into rapidly stirred petroleum ether (b. p. 30–50°). The latter solvent was then removed and the residual oil distilled at 150–160° (bath temperature) and 0.05 mm., yielding a pale yellow oil, $n^{25}D$ 1.5485, weighing 6.0 g. (56%). *Anal.* Calcd. for $C_{11}H_{14}O_4$: C, 63.0; H, 6.74; OCH_3, 29.6. Found: C, 62.8; H, 6.78; OCH_3, 29.6.

Semicarbazone of 3-Hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone.—White microscopic needles from water, m. p. 123–124°. *Anal.* Calcd. for $C_{12}H_{17}O_4N_3$: C, 53.9; H, 6.42; OCH_3, 23.2. Found: C, 53.7; H, 6.83; OCH_3, 23.1.

Characterization of 3-Hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone

Acetylation.—Oily 3-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone (0.505 g.) was acetylated with acetyl chloride (4 g.) in toluene (30 cc.) to which pyridine (6 cc.) had been added. The mixture was allowed to react for eleven hours at room temperature, after which the complex was decomposed by the addition of distilled water (500 cc.). The toluene layer was separated, washed three times with water, filtered and dried over anhydrous sodium sulfate. On removal of the solvent under reduced pressure (CO_2) at 35°, a viscous oily product remained weighing 0.450 g. (75%). This was dissolved in ether, filtered, petroleum ether (b. p. 30–50°) added, and the solution chilled to −15°. On scratching, a white crystalline product was obtained which was filtered off, recrystallized from dilute ethanol, and dried *in vacuo;* m. p. 55–56°. A mixed melting point determination with an authentic sample of 3-acetoxy-1-(3,4-dimethoxyphenyl)-2-propanone[2] showed no depression. The mixed melting point with 2-acetoxy-1-(3,4-dimethoxyphenyl)-1-propanone was 45°.

Properties of 3-Hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone

Action of 5% Sulfuric Acid.—The ketol (0.529 g.) was mixed with 5% sulfuric acid (50 cc.) and refluxed for twenty-four hours. The amorphous black residue was filtered off, the portion adhering to the flask dissolved in chloroform, the main product added, and the solution evaporated to dryness; yield, 0.103 g. (19.5%).

Action of 72% Sulfuric Acid.—The ketol (0.505 g.) was treated with 72% sulfuric acid (4 cc.) at room temperature for two hours. The dark solution was then diluted to 150 cc. with distilled water, refluxed for four hours, cooled, and the amorphous dark brown lignin-like product filtered, washed with water, and dried in an Abderhalden drier at 61°; product, 0.101 g. The filtrate from the amorphous precipitate was extracted three times with chloroform, the extract concentrated, under reduced pressure, to a small volume (7 cc.) and precipitated into rapidly-stirred low-boiling petroleum ether (75 cc.). An additional quantity of amorphous product, dry weight 0.215 g., was thus obtained; total yield 0.316 g. (62.5%).

Action of 1% Sodium Hydroxide at 100°.—The ketol (0.514 g.) was refluxed with dilute (1%) aqueous sodium hydroxide (50 cc.) for twenty-four hours. After neutralization (congo red) of the mixture with dilute sulfuric acid, the product was filtered, the amorphous residue dissolved in chloroform, evaporated to dryness, and the residue dried similarly and weighed; yield of amorphous product, 0.276 g. (54%).

Action of 3% Aqueous Sodium Hydroxide at Room Temperature.—The ketol (0.250 g.) was allowed to stand at room temperature for seventy-two hours with 3% aqueous sodium hydroxide. After neutralization of the mixture with 10% hydrochloric acid (4 cc.) the polymer was filtered off, washed with water, and dried; yield of amorphous brown product, 0.200 g. (80%).

Action of 3% Ethanolic Sodium Hydroxide at Room Temperature.—The ketol (0.120 g.) was dissolved in ethanol (5 cc.) and 6% aqueous sodium hydroxide (5 cc.) added. After standing at room temperature for three days, chloroform (5 cc.) was added, and carbon dioxide allowed to bubble through the solution for three days. After extraction of the reaction mixture with six portions of chloroform, the extract was washed with water, dried over anhydrous sodium sulfate, concentrated to a small volume (3 cc.) and precipitated, in a fine stream, into rapidly-stirred petroleum ether (b. p. 30–50°). The flaky white polymer was filtered and dried; wt., 0.020 g. (17%).

(17) Snyder, Buck and Ide, "Organic Syntheses," 15, 31 (1935).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Action of 5% Aqueous Potassium Acetate.—The ketol (1.02 g., $n^{25}D$ 1.5490) was refluxed with 5% aqueous potassium acetate (100 cc.) for twelve hours in an atmosphere of carbon dioxide. The resulting solution was extracted four times with chloroform, the extract dried as above and the solvent removed at room temperature under reduced pressure (CO_2). Distillation of the residual oil at 150–160° bath temperature and 0.015 mm. pressure yielded a pale yellow oil weighing 0.75 g. (75%); $n^{25}D$ 1.5485.

Seeding a small portion of the product with the isomeric ketol, 1-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone produced no effect, and its relatively low refractive index (1.5485) indicated absence of the isomeric 2-hydroxy-1-(3,4-dimethoxyphenyl)-1-propanone ($n^{25}D$ 1.5610). The semicarbazone of the product was prepared and recrystallized from water; m. p. 122–123°. A mixed melting point determination with an authentic sample of the semicarbazone of 3-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone showed no depression. Thus so far as could be ascertained, treatment of 3-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone with 5% aqueous potassium acetate did not induce rearrangement of the ketol.

Action of 2% Ethanolic Hydrogen Chloride.—3-Hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone (2.85 g.) was refluxed for forty-eight hours under an atmosphere of carbon dioxide in an all-glass apparatus with 2% ethanolic hydrogen chloride (300 cc.).[5] At the conclusion of the reaction period the solution was cooled, water (5 cc.) added, and the solution neutralized (congo red) by the addition of small portions of solid sodium bicarbonate. After filtration, the solution was evaporated to dryness under reduced pressure (carbon dioxide) at room temperature. The residue was dissolved in benzene, the solution filtered, then extracted three times with 10% sodium bisulfite solution. After the bisulfite extract had been back-extracted twice with benzene, the combined benzene solutions were washed once with water, treated with decolorizing charcoal, and dried over anhydrous sodium sulfate (Extract I).

The bisulfite extract, after neutralization (congo red) with dilute sulfuric acid, was freed from sulfur dioxide under reduced pressure (carbon dioxide) and extracted three times with benzene. The benzene extract was washed with water, 1% aqueous sodium bicarbonate, again with water, and dried over anhydrous sodium sulfate (Extract II).

Extract I.—After removal of the solvent under reduced pressure (carbon dioxide) the residual oil was distilled at 125–135° (bath temperature) and 0.01 mm. pressure, yielding a pale yellow distillate, weighing 2.304 g., which slowly crystallized to a semi-solid yellow mass on cooling. The undistilled residue (polymerized by heat) weighed 0.276 g. The total bisulfite-insoluble fraction weighed 2.580 g. (80% of the theoretical ethylated product). The semi-solid product was washed with warm petroleum ether (10 cc.), then filtered on a glass nail and dried *in vacuo*; weight of crystalline product, 0.640 g. (28%). Recrystallization from dilute ethanol yielded a white crystalline material, m. p. 82–83°. A mixed melting point determination with an authentic sample of 2-ethoxy-1-(3,4-dimethoxyphenyl)-1-propanone showed no depression.

The 2,4-dinitrophenylhydrazone of the non-crystalline material ($n^{25}D$ 1.5220) recovered from the petroleum ether washings, after recrystallization from absolute ethanol, melted at 139–141°. A mixed melting point determination with an authentic sample of 1-ethoxy-1-(3,4-dimethoxyphenyl)-2-propanone 2,4-dinitrophenylhydrazone gave no depression.

Extract II.—Removal of the solvent under reduced pressure (carbon dioxide) left a crystalline residue weighing 0.350 g. The residue was washed with diethyl ether, this removing a portion of the material, and then with absolute ethanol, which dissolved the remainder. Addition of petroleum ether to this ethanol solution and chilling to 0° for several days resulted in the formation of a very small amount of long, light red, rod-like crystals; m. p. 138–139°. (A possible product of the reaction, 1-(3,4-dimethoxyphenyl)-1,2-propanedione, m. p. 68–69°, was thus eliminated.) The product was not identified.

No result was observed on addition of petroleum ether to the ether washings, and chilling to 0°. The combined ethanol and ether washings were evaporated to dryness, and tested for the presence of the diketone (1-(3,4-dimethoxyphenyl)-1,2-propanedione) by dissolving the residue in ethanol (10 cc.), adding water (50 cc.), hydroxylamine sulfate (0.2 g.), sodium acetate (1.0 g.) and 5% aqueous nickel chloride (1.5 cc.) and refluxing the solution gently under an atmosphere of carbon dioxide for twenty-four hours. Only a small amount (0.02 g.) of amorphous brown precipitate was formed; the characteristic red crystalline nickel glyoxime of the diketone was not obtained.

The action of 2% ethanolic hydrogen chloride on 3-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone thus produced the allylic rearrangement product, 1-ethoxy-1-(3,4-dimethoxyphenyl)-2-propanone, and its dismutation isomer 2-ethoxy-1-(3,4-dimethoxyphenyl)-1-propanone, in yields of 56 and 24%, respectively, together with a small amount of unidentified bisulfite soluble material.

Acknowledgment.—The authors wish to express their thanks to the Gottesman Foundation fund for the award of a scholarship to one of them (H. F.) through which this work was rendered possible.

Summary

1. The synthesis of 3-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone has been carried out, the process involving a modification of the Arndt–Eistert synthesis for the preparation of the intermediary homoveratric acid.

2. Acids, and to a greater degree alkalies, readily convert the ketol into a lignin-like product in high yield.

3. When subjected to the ethanolysis procedure, as used for the extraction of lignin from wood, 3-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone gives a mixture of 1-ethoxy-1-(3,4-dimethoxyphenyl)-2-propanone and 2-ethoxy-1-(3,4-dimethoxyphenyl)-1-propanone in a combined yield of 80%.

4. The formation of these products undoubtedly takes place through the medium of an allyl shift followed by dismutation changes. Such transformations are regarded as providing valuable support for Hibbert's postulation of their presence (as guaiacyl derivatives) in the ethanolysis mixture from spruce wood as the result of similar reactions involving a β-oxyconiferyl type of lignin building unit present in spruce native lignin.

Studies on Lignin and Related Compounds. LXXX. The Ethanolysis of 1-Acetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone and its Relation to Lignin Structure[1]

BY LEONARD MITCHELL[2] AND HAROLD HIBBERT

In recent communications of this series[3,4] ample experimental evidence has been provided in confirmation of the theory[3,5] that the water-soluble spruce lignin ethanolysis products 2-ethoxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone (I)[6] and 1-ethoxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone (II)[7] obtained by the action of ethanol containing 2% hydrogen chloride represent stabilized end-products originating from an oxyconiferyl alcohol type of lignin building unit present in the spruce native lignin. Experimental evidence supporting this theory and also proving that the two remaining propyl phenol ethanolysis units, namely, the diketone, 1-(4-hydroxy-3-methoxyphenyl)-1,2-propanedione (III)[8,9] and the desoxybenzoin, 1-(4-hydroxy-3-methoxyphenyl)-2-propanone (IV)[10] belong in the same category is provided in the present communication.

The authors find that ethanolysis of 1-acetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (V) under the identical conditions used in the ethanolysis of wood[7] gives a mixture containing I, II, III and IV in yields of 54.6, 16.7, 7.3 and 1.3%, respectively, together with a petroleum–ether (b. p. 30–50°) insoluble polymer (10%). Inasmuch as the acetyl groups are readily removed under the experimental conditions, the four products may be regarded as formed from the corresponding free dihydroxy derivative, namely, 1-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone (VI). This latter, however, in the form of its phenolic methyl ether, is readily obtained[4] under the same experimental conditions from the phenolic methyl ether of β-oxyconiferyl alcohol, (3-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone) as the result of an allylic shift

$$RCH_2COCH_2OH \rightleftharpoons RCH{=}C(OH)CH_2OH \rightleftharpoons RCHOHC(OH){=}CH_2 \rightleftharpoons RCHOHCOCH_3$$

(R = veratryl)

so that all four ethanolysis products may be envisaged as originating from β-oxyconiferyl alcohol (β,γ-dioxyisoeugenol). As stated previously,[3] it is probable the four products originate from a simple lignin building unit rather than from a higher lignin polymer. The value of the present discovery is much enhanced by the isolation for the first time in any synthetic ethanolysis mixture of the 1,2-diketone (III) and the desoxybenzoin (IV). Their relation to spruce lignin and the probable mechanism for the formation of all four products are both illustrated in the chart.

The results are thus in startling agreement with the earlier suggestion of Erdtman,[11] and accepted by the senior author (H. H.),[5] that the ethanolysis derivatives from spruce wood are stabilized end-products from a more reactive lignin progenitor, postulated by Hibbert as β-oxyconiferyl alcohol.

Experimental

The starting material for this investigation, 1-acetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone was prepared from 1-bromo-1-(4-acetoxy-3-methoxyphenyl)-2-propanone[12] by the action of silver acetate in aqueous dioxane solution at room temperature. The conditions of ethanolysis and the procedure for isolation of the ethanolysis products were identical with those used previously in connection with the isolation of the ethanolysis products from wood.[7]

Synthesis of 1-Acetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone.—1-Bromo-1-(4-acetoxy-3-methoxyphenyl)-2-propanone[12] (15 g.) was dissolved in aqueous dioxane (1:1) (180 cc.), freshly-precipitated silver acetate (13 g.) added, and the mixture stirred at room temperature for thirty-six hours. The silver bromide was removed by filtration, the liquor extracted thoroughly with chloroform, and the solvent removed under reduced pressure (15 mm.) leaving a very light yellow oil which solidified on standing. The crude crystalline product (13.5 g.) was recrystallized from dilute methanol; yield 11.0 g. (80%); m. p. 95–96°. By repeated recrystallization from dilute methanol, or ether-petroleum ether (b. p. 30–50°), the melting point was raised to 97–98°. *Anal.* Calcd. for $C_{14}H_{16}O_6$: C, 60.0; H, 5.85; OCH_3, 11.05. Found: C, 60.2; H, 5.58; OCH_3, 10.95.

Ethanolysis of 1-Acetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone.—1-Acetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (11.0 g.) was refluxed with 2% ethanolic hydrogen chloride (500 cc.) for forty-eight hours in an atmosphere of carbon dioxide. The reaction mixture was neutralized with the calculated amount of sodium bicarbonate, concentrated to 50 cc., filtered free of sodium chloride and the filtrate poured in a fine stream, and with vigorous stirring, into petroleum ether (b. p. 30–50°) (1000 cc.). The precipitated dark tarry oil (probably a condensation polymer) was allowed to settle overnight and then separated by decantation. Removal of solvent from it, *in vacuo*, left a dark brittle resin (0.87 g.).

Concentration of the petroleum ether–ethanol solution, followed by removal of the last traces of solvent under reduced pressure, left an orange-red oil (8.1 g.). This was dissolved in benzene (100 cc.), extracted with five 15-cc. portions of aqueous sodium bisulfite (20%) and the bisulfite extract back-extracted with three 15-cc. portions of benzene which were then combined with the main benzene solution. This treatment resulted in a rough separation of the ethanolysis oil into a bisulfite-soluble (A) and a so-called "phenol" fraction[7] (B).

*This reaction may actually proceed *via* an intermediary, unstable six-membered ring, as indicated in the following communication, this Series, Pt. LXXXI.

Investigation of the Bisulfite-soluble Fraction (A).—The bisulfite solution (A) was acidified (congo red) with dilute sulfuric acid, the sulfur dioxide expelled (using a carbon dioxide bubbler under reduced pressure) and then extracted with eight 15-cc. portions of benzene. The united benzene extracts were dried with sodium sulfate and the solvent removed under reduced pressure. Distillation of the residual oil between 140–160° (bath temperature) (0.10 mm.) yielded a clear yellow oil (0.90 g.) from which the diketone, 1-(4-hydroxy-3-methoxyphenyl)-1,2-propanedione, and the desoxybenzoin, 1-(4-hydroxy-3-methoxyphenyl)-2-propanone, were isolated as follows:

(a) **Isolation of 1-(4-Hydroxy-3-methoxyphenyl)-1,2-propanedione.**—The above oil (0.90 g.), nickel chloride (5 cc. of 5% solution), hydroxylamine sulfate (0.75 g.) and sodium acetate (5.0 g.) were dissolved in water (200 cc.) and treated in the manner described previously[9] for the quantitative isolation of the nickel glyoxime salt of the diketone; yield of the latter (0.66 g.), equivalent to 0.60 g. diketone.

Distillation of the crude diketone obtained on hydrolysis[9] of the nickel glyoxime salt gave an oil (0.39 g.) which solidified on standing. After recrystallization from dilute ethanol the product melted at 69–70° and showed no melting point depression when mixed with an authentic sample of 1-(4-hydroxy-3-methoxyphenyl)-1,2-propanedione.

(b) **Isolation of 1-(4-Hydroxy-3-methoxyphenyl)-2-propanone.**—The aqueous filtrate left after separation of the insoluble nickel glyoxime salt was extracted continuously with benzene for twenty-four hours. Evaporation of the solvent and hydrolysis[10] of the residual oxime yielded an orange-yellow oil (0.12 g.). The crude semicarbazone (0.10 g.) of this melted at 155–156° and, after recrystallization from ethanol, at 156–158°; no depression when mixed with an authentic sample of the semicarbazone of 1-(4-hydroxy-3-methoxyphenyl)-2-propanone.

Investigation of the "Phenol" Fraction.—The original benzene solution (B) left after extraction with bisulfite and containing the "phenol" fraction mentioned previously was dried and evaporated to dryness under reduced pressure leaving a yellow oil (8.0 g.) which was dissolved in anhydrous ether (200 cc.).

(a) **Isolation of 2-Ethoxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone.**—Dry ammonia gas was passed through the ether solution in the manner described for the separation of this component of the spruce wood ethanolysis "phenol" fraction.[7] The yellow ammonium salt (C) was filtered, washed with anhydrous ether and dried; weight, 5.1 g., equivalent to 4.9 g. of 2-ethoxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone.

Preparation of the Methyl Ether.—The ammonium salt (C) (5.1 g.), dissolved in sodium hydroxide (30 cc. of 5% solution), was methylated at room temperature in an atmosphere of nitrogen by the slow simultaneous addition, over a period of one-half hour, of dimethyl sulfate (15 cc.) and strong sodium hydroxide (15 cc. of 30% solution), the reaction mixture being stirred throughout, and then for a further period of two hours. The oily mixture was extracted thoroughly with benzene and the benzene solution back-extracted with dilute sodium hydroxide (5% solution). Removal of the benzene left a brownish oil which on distillation yielded an oil boiling constantly at 150–155° (bath temp.) (0.05 mm.), yield, 4.5 g. The oil solidified immediately and completely in the receiver; m. p. 80–81°. Recrystallization from dilute ethanol raised the m. p. to 82–83°; no depression when mixed with an authentic sample of 2-ethoxy-1-(3,4-dimethoxyphenyl)-1-propanone.

(b) **Isolation of 1-Ethoxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone.**—The ethereal solution remaining after separation of the insoluble ammonium salt (C) of 2-

ethoxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone was evaporated to dryness and the residual light brown oil (1.8 g.) then distilled *in vacuo* (b. p. 150–170° (bath temperature) (0.25 mm.)) yielding relatively pure 1-ethoxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone (1.5 g.). This crude distillate solidified partially after inoculation with a trace of pure crystalline product (m. p. 62–63°). The partially crystalline material was recrystallized, although with difficulty and in poor yield, from dilute ethanol (m. p. 61–62°). It showed no depression in melting point when mixed with a pure sample.

The semicarbazone was prepared from a portion of the crude semi-solid oil (0.20 g.); yield 0.125 g. (60%). Recrystallized from ethanol–ethyl acetate (1:1) this derivative melted at 171.5–172.5° (yield, 0.110 g.) and gave no depression when mixed with a sample of the semicarbazone of the pure compound.

Acknowledgment.—The authors wish to thank the National Research Council of Canada for the award of a Studentship and the Canadian Pulp and Paper Association for financial assistance to one of them (L. M.).

Summary

1. The synthesis of 1-acetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone has been effected. When subjected to the same treatment as employed in the ethanolysis of spruce wood, the reaction mixture was found to contain the same four ethanolysis products as isolated from the wood, namely, 2-ethoxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone (54.6%), 1-ethoxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone (16.7%), 1-(4-hydroxy-3-methoxyphenyl)-1,2-propanedione (7.3%), 1-(4-hydroxy-3-methoxyphenyl)-2-propanone (1.3%).

2. Since the acetyl groups in 1-acetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone are readily removed in the ethanolysis treatment, the results provide clear proof of the ease with which the corresponding 1-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone is convertible to the same stabilized ethanolysis end-products.

3. The remarkable ease with which the phenolic methyl ether of β-oxyconiferyl alcohol passes over into the phenolic methyl ether of 1-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone; the known absence of terminal methyl groups in spruce native lignin, and the newly discovered behavior of 1-acetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone on ethanolysis form a composite picture indicating clearly a common parent progenitor, namely, the lignin building unit, β-oxyconiferyl alcohol (β,γ-dioxyisoeugenol), or its keto form, as the source of all of the water-soluble, spruce lignin propyl phenol ethanolysis products.

Studies on Lignin and Related Compounds. LXXXI. Properties of 1-Bromo-1-(4-acetoxy-3-methoxyphenyl)-2-propanone and Relation to Lignin Structure[1]

BY LEONARD MITCHELL,[2] T. H. EVANS AND HAROLD HIBBERT

In the preceding communication[3] it was shown experimentally that 1-acetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (I), on ethanolysis under the identical conditions used for the extraction of spruce lignin from wood, gave a reaction product containing each of the four propyl phenol units found in the spruce wood ethanolysis mixture.

In the present paper additional confirmatory evidence for the β-oxyconiferyl alcohol theory of lignin structure is provided in the action of aqueous silver sulfate on 1-bromo-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (II). In aqueous solution at room temperature interaction takes place readily with precipitation of the theoretical quantity of silver bromide. The aqueous solution on analysis was shown to contain a distillable mixture (60% of original material) of 1-(4-acetoxy-3-methoxyphenyl)-1,2-propanedione (III) and 1-(4-acetoxy-3-methoxyphenyl)-2-propanone (IV) together with a non-distillable product (35%), presumably a polymer of 1-hydroxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (V). The amounts of III and IV present in the distillable mixture were found to be 44 and 27%, respectively, equivalent to 24 and 16% when calculated on the original bromo derivative (II). The low value for IV is to be regarded as a minimum due to the extensive losses involved in its isolation.

The formation of the theoretical quantity of silver bromide in this reaction indicates (1) absence of any secondary type of oxidation change; and (2) formation of 1-hydroxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (V) as the primary product of the reaction. Inasmuch as the veratryl analog[4] of V is stable to even *hot* dilute sulfuric acid, it is very improbable the formation of III and IV proceeds directly (intramolecularly) through V.

It is possible a bimolecular reaction takes place between the bromo product (II) and the hydroxy derivative (V) to give silver bromide, sulfuric

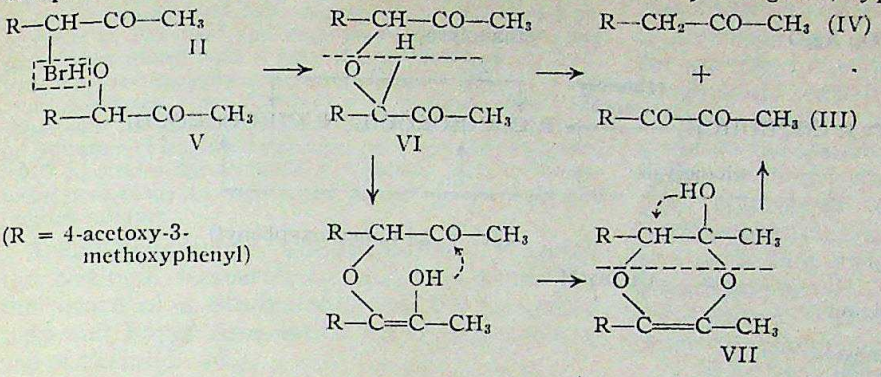
acid and an unstable ether (VI) which then decomposes into III and IV.



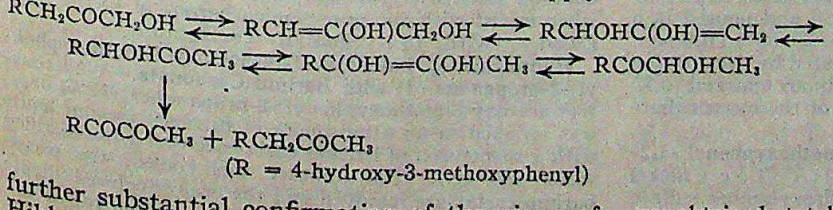
It is also conceivable that VI, by an intramolecular rearrangement could yield an unstable six-membered ring VII also capable, on decomposition, of giving III and IV in the manner indicated.

The fact that these changes take place under such mild conditions, *at room temperature*, may have considerable biological significance. The reaction is, in many ways, analogous to that found by Kohler[5] in the behavior of a series of aromatic α-bromoketones toward alkalies, whereby, in addition to the hydroxy substitution products, 1,2-diketones and desoxybenzoins were obtained.

In the present investigation it was found that small amounts of the 1,2-diketone, 1-(4-hydroxy-3-methoxyphenyl)-1,2-propanedione (VIII), are obtained both when the bromo derivative (II) is refluxed with 5% aqueous potassium acetate and when 1-acetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (I)[3] is refluxed with an aqueous suspension of barium carbonate. In both cases the principal product of hydrolysis is 2-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone (IX).

It has been shown previously[4] that a considerable amount of diketone, 1-(3,4-dimethoxyphenyl)-1,2-propanedione is obtained by the action of 5% aqueous potassium acetate on 3-chloro-1-(3,4-dimethoxyphenyl)-2-propanone, in addition to the main product, 1-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone, the latter being formed as the result of an allyl shift similar to that found more recently[6] with 3-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone.

These results, Chart I, considered in conjunction with those of the present research, Chart II, would seem to provide definite proof of the following interrelated mechanisms and in turn supply



further substantial confirmation of the views of Hibbert that spruce native lignin is derived from building-units of the β-oxyconiferyl alcohol (β,γ-dioxyisoeugenol) type.

Experimental

The synthesis of 1-bromo-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (II) was accomplished by a preliminary acetylation of the phenolic hydroxyl in 1-(4-hydroxy-3-methoxyphenyl)-2-propanone[7] and subsequent bromination in the presence of a trace of benzoyl peroxide.[8] The procedure for isolation of the free hydroxy hydrolysis products, 1-(4-hydroxy-3-methoxyphenyl)-1,2-propanedione (VIII) and 1-(4-hydroxy-3-methoxyphenyl)-2-propanone (X) was similar to that employed for the components of the bisulfite soluble fraction from the ethanolysis of wood.[7]

Synthesis of 1-(4-Acetoxy-3-methoxyphenyl)-2-propanone.—1-(4-Hydroxy-3-methoxyphenyl)-2-propanone[7] (20 g.) was dissolved in aqueous sodium hydroxide (65 cc. of 10% solution) and the solution cooled by the addition of cracked ice. Acetic anhydride (15 cc.) was added rapidly and the mixture shaken for five to ten minutes, sufficient ice being present to maintain the temperature at 0–10°. The heavy oil was separated and the aqueous layer extracted thoroughly with ether. The ether extracts were combined with the oil and the entire solution back-extracted once with dilute sodium hydroxide (1% solution), the ethereal solution washed with water and dried over sodium sulfate. Removal of solvent and vacuum distillation of the crude product at 150–160° (bath temperature) (0.075 mm.) yielded an almost colorless oil which crystallized rapidly; yield, 22.0 g. (98%). This distilled product was sufficiently pure for the succeeding step in the synthesis. When recrystallized from dilute ethanol it melted at 47–48°. *Anal.* Calcd. for $C_{12}H_{14}O_4$: C, 64.8; H, 6.30; OCH_3, 14.0. Found: C, 64.5; H, 6.35; OCH_3, 13.9. The semicarbazone, recrystallized from dilute ethanol, melted at 168–169°. *Anal.* Calcd.: OCH_3, 11.1. Found: OCH_3, 11.1.

Synthesis of 1-Bromo-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (II).—To a solution of 1-(4-acetoxy-3-methoxyphenyl)-2-propanone (15 g.) and benzoyl peroxide (0.15 g.) in anhydrous chloroform (100 cc.) contained in a three-necked flask, fitted with a dropping funnel, a thermometer and a stirrer was added a solution of bromine (12.5 g.) in chloroform (50 cc.) over a period of one hour. During the addition the solution was stirred vigorously and the temperature kept below 10° by means of an ice-bath. At the conclusion of the addition the stirring was continued for an additional one and one-half hours at room temperature. The solution was washed twice with water, once with 1% sodium bicarbonate and, finally, twice again with water. Remaining traces of water were removed by passage through a dry filter paper and the solution evaporated almost to dryness at room temperature under reduced pressure (15 mm.). Addition of ether to the residue precipitated a crude yellowish product which was filtered on a sintered glass funnel and washed with ether until most of the color had been removed. The crude product, only slightly soluble in ether, was dissolved in a large volume of the pure dry solvent, boiled with charcoal, filtered and the solution concentrated to a volume of 50 cc. On cooling, the almost pure compound (12.5 g.), m. p. 98–99°, separated out. From the mother liquors and washings an additional amount (2.5 g.), m. p. 98–99°, was obtained; total yield, 15.0 g. (73%). On recrystallization, alternately from ether and ether–petroleum ether

CHART I[4,6]

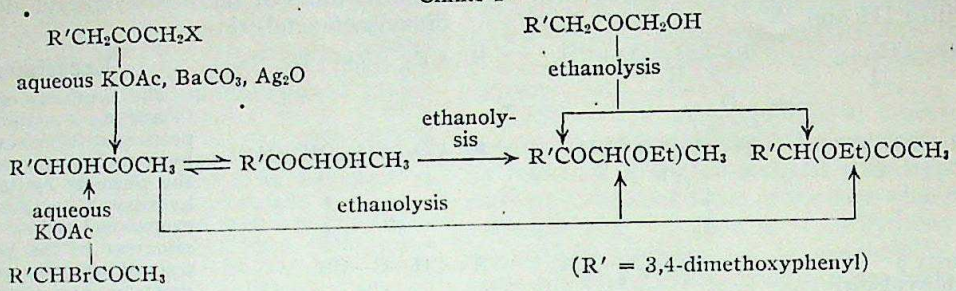

CHART II

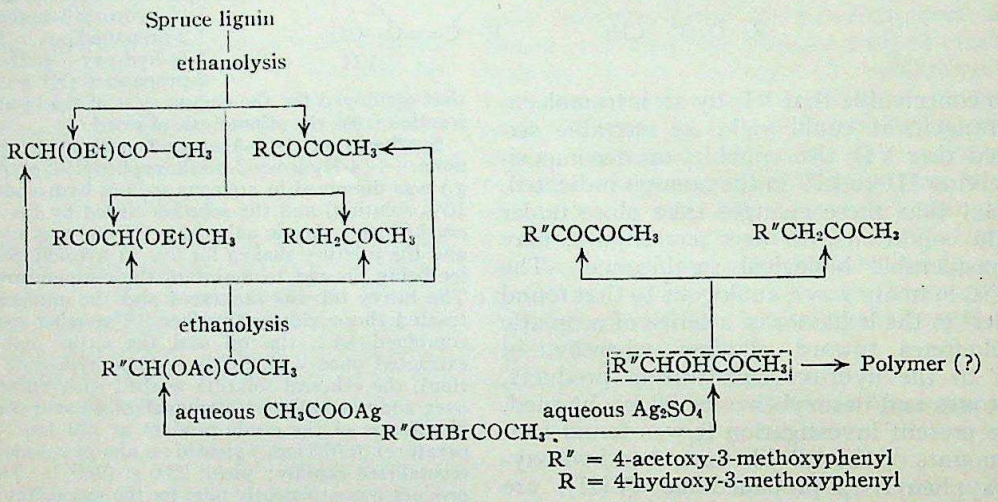

(b. p. 30–50°) the melting point was raised to 100–101°. *Anal.* Calcd.: OCH_3, 10.3; Br, 26.5. Found: OCH_3, 10.2; Br, 26.5. The semicarbazone, recrystallized from dilute methanol, melted at 180–181°. *Anal.* Calcd.: OCH_3, 8.65. Found: OCH_3, 8.5.

Action of Aqueous Silver Sulfate on 1-Bromo-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (II).—1-Bromo-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (3.5 g.) was dissolved in a mixture of dioxane (100 cc.) and water (50 cc.). Freshly precipitated silver sulfate (3.0 g.) and barium carbonate (3.0 g.) were added and the mixture stirred at room temperature in an atmosphere of nitrogen for five days. The insoluble salts were filtered off and the filtrate concentrated at room temperature (using a carbon dioxide bubbler under reduced pressure) to a volume of 25 cc. This solution was extracted thoroughly with chloroform, and the extract dried over sodium sulfate, filtered and the solvent removed under reduced pressure leaving a crude yellowish-orange oil (3.0 g.) which could not be crystallized. Vacuum distillation of this product at 150–180° (bath temperature) (0.10 mm.) yielded a mobile orange-colored distillate (A), 1.5 g. (60%) and a non-distillable residue (B), 0.90 g. (35%). The low methoxyl value of the distillate (A), 13.2%, as compared with that of 15.8% for IX and 17.2% for X indicated that the phenolic acetate group was still intact. The highly colored residue (B) was dissolved in chloroform (5 cc.) and poured in a fine stream into petroleum ether (b. p. 30–50°) (100 cc.), the dark-colored precipitated tar separated by decantation and dried *in vacuo* leaving a brittle resinous material (0.75 g.), probably a condensation polymer of the intermediate 1-hydroxy derivative.

(a) **Isolation of 1-(4-Hydroxy-3-methoxyphenyl)-1,2-propanedione (VIII) from (A).**—The oil (A) (1.5 g.), nickel chloride (15 cc. of 5% solution), hydroxylamine sulfate (1.0 g.) and sodium acetate (8 g.) were dissolved in water (400 cc.) and the nickel glyoxime salt (C) isolated and hydrolyzed as described previously[9]; yield of nickel salt (C), 0.82 g., equivalent to 0.66 g. diketone present in (A) (44%).

Distillation of the crude diketone obtained from the hydrolysis of the nickel glyoxime salt (C) yielded a yellow distillate which solidified rapidly on standing. Recrystallized once from dilute ethanol the product melted at 69–70° and gave no depression in melting point when mixed with an authentic sample of 1-(4-hydroxy-3-methoxyphenyl)-1,2-propanedione (VIII).

(b) **Isolation of 1-(4-Hydroxy-3-methoxyphenyl)-2-propanone (X) from (A).**—The aqueous solution remaining after separation of the nickel glyoxime salt (C) was concentrated to about 250 cc. and extracted continuously with benzene for thirty-six hours. The benzene extract was dried and the solvent removed under reduced pressure, leaving the crude oxime of the desoxybenzoin. After removal of the last traces of solvent this crystallized partially as a yellow solid, yield 0.63 g. Distillation of the crude product remaining after hydrolysis of the oxime yielded a mobile yellow oil analyzing correctly for 1-(4-hydroxy-3-methoxyphenyl)-2-propanone (X); yield, 0.33 g., equivalent to 0.40 g. (27%) of 1-(4-acetoxy-3-methoxyphenyl)-2-propanone (IV) in the oil (A). *Anal.* Calcd.: OCH_3, 17.2. Found: OCH_3, 17.1. The semicarbazone of this distilled product, after one recrystallization from ethanol, melted at 157–158° and showed no depression when mixed with the pure semicarbazone of (X). *Anal.* Calcd.: OCH_3, 13.1. Found: OCH_3, 13.1.

Hydrolysis of 1-Acetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (I) with Barium Carbonate.—1-Acetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone[3] (I) (1.0 g.) was refluxed in an atmosphere of nitrogen for ten hours with a suspension of barium carbonate (2.0 g.) in distilled water (50 cc.). The mixture was cooled, the excess barium carbonate removed and the orange-colored filtrate extracted thoroughly with chloroform. Removal of solvent and vacuum distillation of the residue at 150–180° (bath temperature) (0.075 mm.) gave a clear yellow oil which solidified on standing; yield, 0.50 g. (74%). The

crude product was washed with small portions of an ether–petroleum ether (b. p. 30–50°) mixture (1:1) until almost colorless. The product (0.28 g.) then melted at 101–102°, this value being raised, following one recrystallization from benzene, to 108–109° and gave no depression in melting point when mixed with a pure sample of 2-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone (IX). The ether–petroleum ether washings were evaporated and the presence of the diketone in the residual yellow oil shown by precipitation of its nickel glyoxime salt; yield of the latter, 0.075 g., equivalent to 0.058 g. diketone (VIII). No attempt was made to isolate the desoxybenzoin from the reaction mixture.

Acknowledgment.—The authors wish to thank the National Research Council of Canada for the award of a Studentship and the Canadian Pulp and Paper Association for financial aid to one of them (L. M.).

Summary

1. The synthesis of 1-bromo-1-(4-acetoxy-3-methoxyphenyl)-2-propanone has been carried out.

2. Aqueous silver sulfate reacts with this product at room temperature (*that is, under approximate biological conditions*) to give a mixture containing 1-(4-acetoxy-3-methoxyphenyl)-1,2-propanedione and 1-(4-acetoxy-3-methoxyphenyl)-2-propanone in a combined yield of 60% based on the starting material. The amounts of these two components present in the mixture were 44 and 27%, respectively, equivalent to 24 and 16% based on the starting material. A possible mechanism for their formation is suggested.

3. Hydrolysis of 1-acetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone with aqueous barium carbonate yielded 2-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone as the main product together with small quantities of 1-(4-hydroxy-3-methoxyphenyl)-1,2-propanedione.

4. The formation of these two products (the 1,2-diketone and desoxybenzoin), as indicated, supplies additional evidence in support of Hibbert's β-oxyconiferyl alcohol theory of spruce native lignin structure.

Studies on Lignin and Related Compounds. LXXXII. Synthesis and Properties of 1,3-Diacetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone and 1-Acetoxy-3-chloro-1-(4-acetoxy-3-methoxyphenyl)-2-propanone and their Relation to Lignin Structure[1]

BY J. A. F. GARDNER[2] AND HAROLD HIBBERT

In the two preceding communications[3,4] experimental evidence was presented showing the remarkable ease of formation of 1-(4-hydroxy-3-methoxyphenyl)-1,2-propanedione (I) from 1-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone (II) under very mild conditions. The latter product (as its phenolic methyl ether) is, in turn, readily formed[5] under the influence of mild reagents from 3-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone (III) (the keto form of methylated β-oxyconiferyl alcohol) through an allylic shift. The presence of the diketone (I) in the ethanolysis mixture from spruce wood is thus satisfactorily accounted for by Hibbert's theory of lignin structure[5,6,7] which assumes the presence, in the spruce native lignin complex, of a building unit of the β-oxyconiferyl alcohol (β-γ-dioxyisoeugenol) type.

Consideration of this new type of allyl transformation, involving a *mono*-hydroxylated allyl alcohol indicated the possibility of a similar type of reaction occurring with the analogous *dihydroxy* derivative, R—C(OH)=C(OH)—CH_2OH (IV) (R = 4-hydroxy-3-methoxyphenyl) since in this case the final product should also be the above diketone (I).

$$RC(OH)=C(OH)-CH_2OH \rightleftharpoons \underset{IV}{}$$

$$R-C(OH)_2-C(OH)=CH_2 \longrightarrow R-COCOCH_3 + H_2O \quad (I)$$

The product IV is the ene-diol intermediate of a dismutation system

$$R-COCHOHCH_2OH \rightleftharpoons (V)$$

$$R-C(OH)=C(OH)-CH_2OH \rightleftharpoons (IV)$$

$$R-CHOHCOCH_2OH \quad (VI)$$

and, by analogy, either V or VI (or their halides) might be expected to undergo an allyl shift in the presence of suitable mild chemical reagents.

Formation of a diketone has been observed by Bradley and Eaton[8] in the case of 1-acetoxy-1-phenyl-3-chloro-2-propanone, mild hydrolysis of the latter yielding 1-phenyl-1,2-propanedione. These authors made no comment concerning the mechanism of its formation. Based on the above

$$R''\text{—CHOAcCOOH} \xrightarrow[\text{XIV}]{\text{SOCl}_2,\ C_6H_6}$$

$$R''\text{—CHOAcCOCl} \xrightarrow[\text{XV}]{CH_2N_2} R''\text{—CHOAcCOCHN}_2 \xrightarrow[\text{XVI}]{\text{HCl}}$$

$$R''\text{—CHOAcCOCH}_2\text{Cl} \quad \text{VIII}$$

$$R''\text{—CHOAcCOCH}_2\text{OAc} \quad \text{VII}$$

(R = 4-hydroxy-3-methoxyphenyl
R″ = 4-acetoxy-3-methoxyphenyl)

The substituted mandelic ester (XII) has been prepared previously from vanillin through the cyanohydrin (X) and imino ether hydrochloride (XI) in 16% yield by Schwartz and McCarthy.[9] By utilizing the method of Hahn, Stiehl and Schulz,[10] for preparation of the cyanohydrin and carrying out the reactions at lower temperatures the yield was increased to 24%.

The 4-hydroxy-3-methoxymandelic acid (XIII), which readily resinified on heating or on exposure to air, was acetylated to prevent reaction of thionyl chloride with the phenolic and secondary hydroxyls. The resulting diacetate, 4-acetoxy-3-methoxy-acetylmandelic acid (XII), crystallized readily from aqueous solution as a monohydrate, readily dehydrated at room temperature *in vacuo*. Considerable difficulty was experienced in obtaining a good yield of the acid chloride (XV) but this was accomplished by using a solution of thionyl chloride in benzene and employing a much shorter period of reflux than in the case of mandelic acid.[11]

While the diazoketone (XVI) did not react with *cold* glacial acetic, at *reflux* temperature it yielded the desired triacetate (VII).

(9) Schwartz and McCarthy, *Can. J. Research*, **19B**, 150 (1941).
(10) Hahn, Stiehl and Schulz, *Ber.*, **72B**, 1296 (1939).
(11) Thayer, "Organic Syntheses," **4**, 1 (1925).

As anticipated, this triacetate, on ethanolysis, gave the 1,2-diketone (I) together with an amorphous resinous product, in yields of 8 and 66%, respectively. No work has been carried out on the nature of this resin. Hydrolysis of VII with dilute sulfuric acid (2%) gave a 9% yield of I. A much larger amount (75%) of the diketone was obtained on mild hydrolysis of the monochlor derivative (VIII) with acidified sodium acetate solution, little or no resinification taking place.

The 1,2-diketone (I) was determined by precipitation as the nickel glyoxime salt and identified by hydrolysis of this and preparation of the quinoxaline and semicarbazone[12,13] of the hydrolyzed product.

The formation of 1-(4-hydroxy-3-methoxyphenyl)-1,2-propanedione (I), from the intermediary dihydroxy ketone (VI), raises the question as to whether the latter product (VI) or its dismutation isomer (V), might not also be present, *to a limited extent*, as one of the building-stones of the spruce native lignin complex. If the dismutation reactions shown in the chart are capable of taking place under the conditions of spruce wood ethanolysis, then either V or VI could serve as the source of origin of a portion of the 1,2-diketone (I) but neither could account for the presence in the ethanolysis mixture of the remaining ethanolysis products, R—CH(OC$_2$H$_5$)—CO—CH$_3$, R—CO—CH(OC$_2$H$_5$)—CH$_3$ and R—CH$_2$—CO—CH$_3$ (R = 4-hydroxy-3-methoxyphenyl). It is significant, however, that spruce ethanolysis products contain only *small amounts* (3–5%) of monomolecular units and very large amounts of amorphous ethanol lignins. Conceivably VI could be synthesized in the plant by condensation of guaiacol with hydroxypyruvic aldehyde. No *direct* experimental evidence, however, regarding its presence in spruce native lignin has been obtained, as yet.

Experimental

Synthesis of 1-Acetoxy-3-chloro-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (VIII)

Preparation of Ethyl 4-Hydroxy-3-methoxymandelate (XII).—An ethereal solution (200 cc.) of vanillin cyanohydrin, prepared from vanillin (50 g.) by the method of Hahn, Stiehl and Schulz,[10] was dried for twelve hours at −10° over sodium sulfate and drierite and then filtered. Absolute ethanol (20 cc.) was added and dry hydrogen chloride (10 g.) bubbled in at −10°. After forty-eight hours at this temperature the crude imino ether hydrochloride was hydrolyzed by the procedure of Schwartz and McCarthy.[9] The crude ester (21 g.) on distillation (140–160° (0.4 mm.)) gave a light yellow oil (17.8 g.) which crystallized to a white solid; m. p. 75–77°; yield, 24%. One recrystallization from benzene–petroleum ether (b. p. 30–50°) gave colorless crystals, m. p. 77°. *Anal.* Calcd. for C$_{11}$H$_{14}$O$_5$: OR, 27.4. Found: OR, 27.3.

4-Hydroxy-3-methoxymandelic Acid (XIII).—The ester (XII) (17 g.) was refluxed one hour with sodium hydroxide (600 cc., 2%) under a nitrogen atmosphere, the mixture then extracted with benzene (2 × 50 cc.), acidified with hydrochloric acid, saturated with sodium chloride and continuously extracted with ether. Drying of the ethereal extract

over sodium sulfate and removal of the solvent left a light yellow oil (15.2 g.) which crystallized after washing with a small quantity of benzene. Recrystallization from an acetone–petroleum ether (b. p. 30–50°) mixture gave colorless crystals; m. p. 129–131°; yield, 12.2 g. (80%). Repeated recrystallization from ether–benzene raised the melting point to 133°. The product was very soluble in water and acetone, moderately soluble in ether, and almost insoluble in benzene. *Anal.* Calcd. for $C_9H_{10}O_5$: C, 54.5; H, 5.05; OCH_3, 15.6. Found: C, 54.7; H, 5.15; OCH_3, 15.4.

4-Acetoxy-3-methoxyacetylmandelic Acid (XIV).—Pure 4-hydroxy-3-methoxymandelic acid (XIII) (m. p. 133°) (3.6 g.) was dissolved in a mixture of pyridine (27 cc.) and acetic anhydride (22 cc.), refluxed for twenty-five minutes, and the excess pyridine and acetic anhydride removed under reduced pressure. The residual oil was dissolved in hot water, and the solution decolorized with charcoal and filtered. Crystals of the monohydrate (m. p. 112–113°) separated on cooling. On addition of 6 *N* hydrochloric acid (3 cc.) a further quantity was obtained. The combined products were dehydrated by standing for forty-eight hours in a vacuum desiccator; m. p. 142°; yield, 4.15 g. (81%). Recrystallization from benzene did not raise the melting point. *Anal.* Calcd. for $C_{13}H_{14}O_7 \cdot H_2O$: H_2O, 6.0. Found: H_2O, 5.9. Calcd. for $C_{13}H_{14}O_7$: C, 55.3; H, 5.0; OCH_3, 11.0; neut. equiv., 282. Found: C, 55.5; H, 4.9; OCH_3, 10.9; neut. equiv., 281.

4-Acetoxy-3-methoxy-acetylmandelyl Chloride (XV).—The above diacetate (XIV, 0.8 g.) was dissolved in a mixture of anhydrous benzene (8 cc.) and carefully purified thionyl chloride (3.2 cc.) and then refluxed one and three-quarters hours. The excess thionyl chloride was distilled off (reduced pressure) and the last traces removed by successive addition and distillation (reduced pressure) of two portions (5 cc.) of anhydrous benzene. The residual light yellow oil solidified completely on cooling and was recrystallized from an anhydrous benzene–petroleum ether (b. p. 30–50°) mixture; m. p. 71–72°; yield, 0.804 g. (94%). On repeated recrystallization from petroleum ether (b. p. 30–50°) the m. p. was raised to 72°. *Anal.* Calcd. for $C_{13}H_{13}O_6Cl$: OCH_3, 10.3; Cl, 11.8. Found: OCH_3, 10.2; Cl, 11.8.

1-Acetoxy-3-diazo-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (XVI).—Crude acid chloride (XV) prepared from the acid (XIV) (1.07 g.), was dissolved in benzene (5 cc.) and poured in a fine stream into a well-stirred dry ethereal solution of diazomethane (from 4 g. of nitrosomethylurea) cooled previously to 0° and the mixture allowed to stand at this temperature for twelve hours. The ether solution was decanted from the first crop of crystals, filtered, and evaporated in a stream of dry air. Scratching caused the light yellow residual oil to crystallize. The two crops of crystals were washed with cold ether and combined; yield, 0.96 g. (88%). Recrystallization from benzene gave light yellow crystals, m. p. 129–130°. *Anal.* Calcd. for $C_{14}H_{14}O_6N_2$: C, 55.0; H, 4.61; OCH_3, 10.10. Found: C, 55.2; H, 4.58; OCH_3, 10.05.

1-Acetoxy-3-chloro-1-(4-acetoxy-3-methoxyphenyl)-2-propanone.—The diazoketone (XVI) (0.38 g.), dissolved in anhydrous benzene (10 cc.), was treated with anhydrous ethereal hydrogen chloride (1.6 cc., 0.89 *N*) and the mixture allowed to stand at 0° for three hours. It was washed with 1% sodium bicarbonate solution, then with water, dried over sodium sulfate and the solvent removed. Colorless crystals, m. p. 109–110°; yield, 0.316 g. (81%). Recrystallization from ether or ether–benzene raised the melting point to 110–111°. *Anal.* Calcd. for $C_{14}H_{15}O_6Cl$: C, 53.4; H, 4.81; OCH_3, 9.85; Cl, 11.3. Found: C, 53.09; H, 4.94; OCH_3, 9.80; Cl, 11.2.

Hydrolysis of 1-Acetoxy-3-chloro-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (VIII) and Isolation of the Diketone (I)

Action of Acidified Sodium Acetate Solution.—The above chloro derivative (VIII) (0.31 g.) was suspended in an aqueous solution of sodium acetate (0.4 g. in 50 cc.) and acetic acid (0.5 cc.) and the mixture refluxed for six hours under an atmosphere of carbon dioxide. The deep yellow colored solution was filtered, sodium acetate (0.4 g.), hydroxylamine sulfate (0.2 g.) and 5% nickel chloride solu-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

tion (1 cc.) added and the mixture refluxed gently under a carbon dioxide atmosphere for twenty-four hours. The precipitated nickel salt was separated, more hydroxylamine sulfate (0.05 g.) and nickel chloride (0.5 cc., 5%) added to the filtrate and the refluxing continued until precipitation was complete. The combined precipitated salts were washed with cold water and dried at 100°; yield, 0.171 g. (equivalent to 0.142 g. of diketone on the basis of the customary 90% precipitation or 75% calculated on the chloroketone).

The nickel salt (0.171 g.) was hydrolyzed with 12 *N* sulfuric acid (70 cc.) at room temperature[12] and gave a yellow oil (0.119 g.) which crystallized on standing. The quinoxaline of the product was prepared and recrystallized from ethanol–water; m. p. 161–162°. It showed no melting point depression when mixed with an authentic sample of the quinoxaline of 1-(4-hydroxy-3-methoxyphenyl)-1,2-propanedione (I). The semicarbazone, m. p. 213°, was prepared and also showed no mixed melting point depression with the corresponding derivative of I.

Synthesis of 1,3-Diacetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (VII)

1 - Acetoxy - 3 - diazo - 1 - (4 - acetoxy - 3 - methoxyphenyl)-2-propanone (XVI) (2.89 g.) was dissolved in glacial acetic acid (60 cc.), acetic anhydride (1.5 cc.) added, and the solution refluxed until nitrogen evolution had ceased (thirty minutes). The excess acetic acid was removed (reduced pressure) and the residual oil dissolved in benzene (75 cc.). The resulting solution was extracted successively with aqueous sodium bicarbonate (5%) and sodium bisulfite (20%), then washed with water, dried over sodium sulfate, treated with charcoal and filtered. Evaporation of the solvent (reduced pressure) left a yellow viscous oil (2.85 g., OCH_3 8.9) which underwent marked decomposition on vacuum distillation. Purification of the product was achieved by solution in acetone (95 cc.) and addition of this in a fine stream to vigorously-stirred petroleum ether (b. p. 30–50°, 950 cc.). The solvent was removed (the last traces under reduced pressure, two hours at 65–70° (0.025 mm.)), leaving a homogeneous light yellow oil ($n^{50}D$ 1.5028); yield, 2.46 g. (77%). *Anal.* Calcd. for $C_{16}H_{18}O_8$: C, 56.8; H, 5.34; OCH_3, 9.17. Found: C, 56.9; H, 5.48; OCH_3, 9.13.

Hydrolysis of 1,3-Diacetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (VII)

Action of Ethanolic Hydrogen Chloride.—1,3-Diacetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (VII) (1.35 g.) was refluxed with 2% ethanolic hydrogen chloride (130 cc.) for thirty-six hours in an atmosphere of carbon dioxide. The reaction mixture was neutralized with freshly precipitated calcium carbonate, filtered, and evaporated to dryness (reduced pressure) in a stream of carbon dioxide. The residual reddish-brown tar was extracted thoroughly with hot benzene (50 cc.) and then washed with hot water (to remove calcium acetate), leaving an amorphous black powder (0.56 g., 66%). The benzene solution was extracted with sodium bisulfite solution (20%, 50 cc.), the extract acidified with sulfuric acid and sulfur dioxide removed in a stream of carbon dioxide (reduced pressure). The acid solution was extracted with benzene (30 cc.), the benzene extract dried, and the solvent removed leaving a yellow oil (0.086 g.) which crystallized on cooling. This product, in aqueous solution, gave the nickel glyoxime salt of the diketone (I); yield, 0.073 g. (equivalent to an 8% yield of diketone). The quinoxaline of the free diketone, obtained by hydrolysis of the nickel salt, melted at 161–162° and showed no mixed melting point depression with an authentic sample of the quinoxaline of I.

Action of Dilute Sulfuric Acid (2%).—1,3-Diacetoxy-(4-acetoxy-3-methoxyphenyl)-2-propanone (VII) (0.47 g.) was suspended in 2% sulfuric acid (100 cc.) and the mixture refluxed for two hours, cooled, filtered and extracted with benzene (50 cc.). The bisulfite soluble extract of the benzene solution yielded the same diketone as above, identified in similar manner; yield of nickel glyoxime salt, 0.027 g., equivalent to 8.6% yield of the diketone.

Action of Strong Sulfuric Acid (72%).—1,3-Diacetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (VII) (0.66 g.) when subjected to the customary treatment employed in a Klason lignin determination gave an amorphous, dark-colored, lignin-like product in high yield (0.28 g., equivalent to 68% based on the deacetylated product). *Anal.* Found C, 61.1; H, 5.32; OCH_3, 14.8.

Acknowledgment.—The authors wish to thank the National Research Council of Canada for the award of a Studentship and the Canadian Pulp and Paper Association for financial aid to one of them (J. A. F. G.).

Summary

1. The triacetate, 1,3-diacetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (VII) and the chloroketone, 1-acetoxy-3-chloro-1-(4-acetoxy-3-methoxyphenyl)-2-propanone (VIII) have been synthesized.

2. Under the influence of mild hydrolytic agents, both the triacetate and chloro derivative are converted into 1-(4-hydroxy-3-methoxyphenyl)-1,2-propanedione (I) (found in the ethanolysis products of spruce wood) in yields of 8 and 75%, respectively.

3. It is concluded that the 1,2-diketone is formed as the result of an allyl shift in a dismutation ene-diol product arising from the hydrolysis intermediate, 1,3-dihydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone. The allyl shift is thus indicated as taking place with a dihydroxy substituted allyl alcohol.

4. Attention is drawn to the possibility that a dihydroxy ketone of the type R—CO—CHOH—CH_2OH or R—CHOH—CO—CH_2OH (R = 4-hydroxy-3-methoxyphenyl) may function to a limited extent as a lignin progenitor.

4-Hydroxylaminobenzenesulfonamide, its Acetyl Derivatives and Diazotization Reaction

BY HUGO BAUER AND SANFORD M. ROSENTHAL

As a result of the work of Mayer,[1] who proposed that products formed by oxidation of the amino group were responsible for the mechanism of action of sulfanilamide, considerable study has been devoted to 4-hydroxylaminobenzenesulfonamide.[2] An attempt was made[2a] to develop a colorimetric method for the detection of 4-hydroxylaminobenzenesulfonamide based upon its unusual behavior to diazotization following acetylation. It was found that a diazo reaction could be obtained under certain conditions even after acetylation. In this respect it could be differentiated from sulfanilamide, although later work showed that this procedure was not specific.[3] In this paper the isolation and the properties of the substance responsible for the diazo reaction are described.

The action of nitrite upon hydroxylamines in acid solution was investigated by Bamberger,[4] who showed that the action of one mole of nitrite upon phenylhydroxylamine produces N-nitrosophenylhydroxylamine. This compound decomposes easily either in dry state or in solution with formation of various products, one of them being diazobenzene nitrate. The diazo compound was formed more readily by action of sodium nitrite upon nitrosophenylhydroxylamine in glacial acetic acid solution[4b]

$$C_6H_5NHOH + HNO_2 \longrightarrow C_6H_5N(NO)OH + H_2O \quad (1)$$

$$C_6H_5N(NO)OH + HNO_2 \longrightarrow C_6H_5{-}N_2{-}NO_3 + H_2O \quad (2)$$

The N-nitroso derivative of 2-hydroxylaminobenzoic acid which was obtained only in solution,[5] gave the diazo reaction with an excess of nitrite.

Our study of the 4-hydroxylaminobenzenesulfonamide and of the 4-hydroxylaminobenzoic acid confirms and supplements the observations of Bamberger.

By action of nitrous acid on 4-hydroxylaminobenzenesulfonamide, the N-nitroso-4-hydroxylaminobenzenesulfonamide, $H_2NSO_2C_6H_4N(NO)$-OH, is formed as a white crystalline, sparingly soluble precipitate, while diazotization occurs to a small extent only. The nitrosohydroxylaminobenzenesulfonamide is fairly stable in dry state and can be recrystallized by dissolving in ethyl acetate with subsequent addition of petroleum ether. However, it behaves differently in glacial acetic acid solution. This solution, without showing any sign of decomposition, contains diazobenzenesulfonamide which can readily be detected by coupling with N-(1-naphthyl)-ethylenediamine.[6] Colorimetric determinations of the purple dye, using sulfanilamide as a standard, showed that about 34% of the nitrosohydroxylamine was changed to the diazo compound.

For comparison, 4-hydroxylaminobenzoic acid,[7] which has not hitherto been isolated, and its N-nitroso derivative were prepared. The latter, when dissolved in glacial acetic acid and compared with an equivalent solution of 4-aminobenzoic acid, formed about 15% of diazo compound.

N-Nitrosophenylhydroxylamine behaved in the same way. About 18% of diazo compound was found, using aniline for comparison.

With all three nitrosohydroxylamines, the amount of diazo compound spontaneously formed in glacial acetic acid solution was only slightly changed by addition of nitrite or acetic anhydride (see below).

The spontaneous formation of a diazo compound from a nitrosohydroxylaminobenzene derivative requires the simultaneous formation of oxidation products. If we assume that a nitrosobenzene derivative is the main oxidation product, the following equation shows that three moles of nitrosohydroxylamine form two moles of diazo compound

$$3R{-}N\begin{matrix}NO\\OH\end{matrix} \longrightarrow 2R{-}N{=}N{-}OH + RNO + HNO_3 \quad (3)$$

The amount of diazo compound actually found was less than required by this equation.

To a small extent, formation of a diazo compound occurs also, as previously mentioned, with the preparation of the nitrosohydroxylaminobenzene sulfonamide. A larger amount of the diazo compound is formed by treating hydroxylaminobenzenesulfonamide in dilute acid solution with an excess of nitrite. The yield of diazo compound was considerably increased by treating the hydroxylaminobenzenesulfonamide with acetic an-

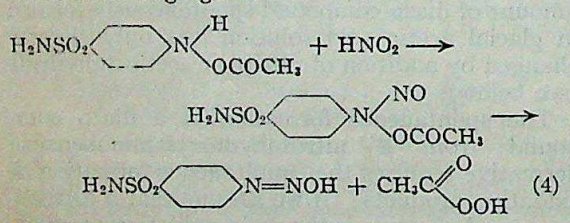
hydride before adding sodium nitrite. The amount of diazo compound formed was increased from 23 to 48% with 4-hydroxylaminobenzenesulfonamide, from 45 to 63% with 4-hydroxylaminobenzoic acid, from a trace to 10% with phenylhydroxylamine.

It was found that acetylation of 4-hydroxylaminobenzenesulfonamide in dilute aqueous solution yields two derivatives, one of which can be diazotized, the other cannot. As already pointed out by Bamberger,[8] for the 2-hydroxylaminobenzoic acid, the non-diazotizable product contains the acetyl group linked to the nitrogen. If acetylation is carried out in very dilute aqueous solution, little of the N-acetyl derivative is formed. The mother liquor contains the diazotizable product which can be extracted with ether or ethyl acetate. This isomer, which was not obtained in a pure state, apparently contains the acetyl group linked to the oxygen of the hydroxylamino group. Upon diazotization, about 65% was converted to the diazo compound; not more than 66.7% could be expected, according to equation 3.

The presence of the oxygen-bound acetyl group facilitates the formation of the diazo compound. It may be assumed that, in the first stage of reaction, an acetylated nitrosohydroxylamine is formed which is easily hydrolyzed in dilute aqueous solution with formation of peracetic acid (see equation 4). The latter could not be detected inasmuch as it is consumed immediately as an oxidizing agent.



(4)

As mentioned above, the diazotization reaction of the acetylated 4-hydroxylaminobenzenesulfonamide can be applied to the detection of this compound in body fluids in presence of sulfanilamide,[2a] although positive results must be confirmed by other methods because of the lack of specificity of this reaction. Other conjugation products of sulfanilamide which give a diazo reaction similar to 4-hydroxylaminobenzenesulfonamide may possibly be formed in the body. While acetylsulfanilamide cannot be diazotized, those conjugation products which are split by nitrous acid with formation of the diazo compound cannot be differentiated from the hydroxylamine. For example, a glucoside of sulfanilamide, tested with the acetylation–diazotization reaction, gave a positive result.[3]

Experimental

4-Hydroxylaminobenzenesulfonamide, $H_2NSO_2C_6H_4NHOH$.—The procedure for the preparation of 4-hydroxylaminobenzenesulfonamide differs in details from the method used by Bratton, White and Marshall,[2b] and in the present work the mother liquor was employed for the preparation of nitrosobenzenesulfonamide.

To a warm solution of 6 g. of 4-nitrobenzenesulfonamide[9] in 200 cc. of alcohol a solution of 10 g. of ammonium chloride in 100 cc. of water was added. With vigorous stirring, 8 g. of zinc dust was added gradually while the temperature was kept between 45 and 52°. After fifteen minutes stirring, the reaction mixture was kept in ice, for ninety minutes. The zinc sludge was filtered by suction and washed with alcohol. The yellow filtrate was concentrated under diminished pressure at 35°, while passing through a stream of nitrogen. When crystals separated, the distillation flask was cooled in an ice–salt mixture for two hours. The yellowish crystals of the hydroxylamine which separated, were filtered and washed twice with ice water. The yield varied between 3.5 (63% of the calcd.) and 4.95 g. (88.5% of the calcd.), the melting point of the crude product varied between 135 and 140°.

For further purification, the substance was dissolved in ethyl acetate, and petroleum ether was added. The colorless crystals thus obtained melted at 143–144° to a liquid which, on further heating, became yellow and decomposed between 148–158° to an orange solid.

Anal. Calcd. for $C_6H_8O_3N_2S$: C, 38.27; H, 4.29; S, 17.04. Found: C, 38.56; H, 4.40; S, 17.20.

Bratton, *et al.*,[2b] give the m. p. 139.5–140.5°. Formation of a substance of m. p. 163–164°, as obtained by Burton,[2g] consisting of a complex of two molecules of the hydroxylamine and one molecule of sulfanilamide, according to Sevag,[2i] was not observed when using the method described above.

4-Hydroxylaminobenzenesulfonamide is soluble in water, alcohol, ether, ethyl acetate, sparingly soluble in benzene, insoluble in petroleum ether. A water solution, saturated at 22.5°, contained 2.7 g. in 100 cc. Fehling solution and silver nitrate solution are immediately reduced at room temperature.

When titrated with 0.1 *N* sodium nitrite in dilute acetic acid solution, one mole of nitrite was used for one mole of 4-hydroxylaminobenzenesulfonamide, forming the nitroso derivative. The assay varied between 98 and 102%.

Reduction of the hydroxylamine with stannous chloride, following the procedure of Limpricht,[10] gave an assay of 94%.

N-Nitroso-4-hydroxylaminobenzenesulfonamide, $H_2NSO_2C_6H_4N(NO)OH$.—To an ice-cold solution of 1.2 g. of 4-hydroxylaminobenzenesulfonamide in 60 cc. of water and 7 cc. of 2 *N* hydrochloric acid, 6 cc. of *N* sodium nitrite solution were added at once. The colorless needles of the nitroso derivative which separated immediately, were filtered after half an hour standing and washed with ice water; 1.04 g. of the nitroso compound (75% of the calcd. amount) was obtained which melted with violent decomposition at 117°. It is soluble in alcohol or ethyl acetate, slightly soluble in water, not soluble in ether, benzene and petroleum ether. When recrystallized by dissolving in cold ethyl acetate and adding petroleum ether, the substance melted at 120°. It gives a beautiful Liebermann nitroso reaction; an intense blue color is formed with diphenylamine sulfuric acid reagent, a red color with ferric chloride. When dissolved in glacial acetic acid, the nitroso compound immediately forms diazobenzenesulfonamide; about 34% were found by coupling with N-(naphthyl)-ethylenediamine[6] (Table II).

Analysis. For nitrogen determination, the Kjeldahl method was modified in the following way: about 120 to 150 mg. of substance was dissolved in 10 cc. of water with addition of 3 drops of 10 *N* sodium hydroxide. 1 g. of sodium dithionite was added and the mixture was gently heated for one-half hour. After addition of 10 cc. of 2 *N* sulfuric acid the heating was continued for one more hour. Then 10 cc. of concentrated sulfuric acid was added, the water was evaporated and the digestion finished in the

usual manner. The results obtained were about one per cent. low.

Anal. Calcd. for $C_6H_7O_4N_3S$: N, 19.35; S, 14.76. Found: N, 18.46; S, 15.04.

N-Acetyl-4-hydroxylaminobenzenesulfonamide.—To 1 g. of 4-hydroxylaminobenzenesulfonamide 10 cc. of acetic anhydride was added. The substance changed its appearance but did not dissolve, while the mixture became warm. After standing for several hours, the mixture was diluted with ethyl acetate. The crystalline substance was filtered and washed with ethyl acetate. It melted at 228°, showed no diazo reaction, and gave a red color with ferric chloride.[8] No diacetyl derivative was formed, as is the case with phenylhydroxylamine.[8]

Anal. Calcd. for $C_8H_{10}N_2O_4S$: S, 13.93. Found: S, 14.21.

O-Acetyl-4-hydroxylaminobenzenesulfonamide, $H_2N\text{-}SO_2C_6H_4NH(OCOCH_3)$.—A 1% aqueous solution of the hydroxylamine was shaken with acetic anhydride and repeatedly extracted with ethyl acetate. The combined extracts were concentrated under diminished pressure and petroleum ether was added. The precipitate thus formed was washed with alcohol and further purified by dissolving in a little methyl alcohol and mixing with petroleum ether. The latter was separated from the alcoholic layer and yielded yellowish crystals of m. p. 138°.

Anal. Calcd. for $C_8H_{10}O_4N_2S$: S, 13.93. Found: S, 13.40.

A solution in aqueous acetic acid is readily diazotized by addition of sodium nitrite; 63–67% was converted to the diazo compound. The calculated value according to equation 3 is 66.7%.

4-Nitrosobenzenesulfonamide.—After separation of the 4-hydroxylaminobenzenesulfonamide a considerable amount of this compound remained in the mother liquor. It was oxidized by addition of an excess of 10% ferric chloride solution. The white precipitate of the nitroso compound thus produced was filtered and crystallized from alcohol; the alcoholic solution was green. The compound did not show a melting point; decomposition started at 155° and was complete at 268°. With diphenylamine–sulfuric acid reagent a vivid red color was formed.

Anal. Calcd. for $C_6H_6O_3N_2S$: S, 17.23. Found: S, 17.45.

4-Hydroxylaminobenzoic Acid.—Seventeen grams of 4-nitrobenzoic acid was dissolved in 350 cc. of water and 10 cc. of 10 *N* sodium hydroxide. After addition of 20 g. of ammonium chloride, the mixture was cooled to 15°, and 15 g. of zinc dust was added gradually with stirring. The temperature rose to 20°. After one-half hour stirring, the zinc sludge was filtered off. To the filtrate hydrochloric acid (sp. gr. 1.12) was added slowly. Amorphous flakes, which separated while the reaction was still neutral, were removed by filtration. Upon addition of more hydrochloric acid to the filtrate, white needles separated; yield 4.8 g. (31% of the calculated amount). The substance did not melt up to 300°, became dark at about 240°; sparingly soluble in cold water; readily in hot water; soluble in alcohol, ether, and ethyl acetate; not soluble in petroleum ether. Fehling solution is reduced immediately at room temperature.

Anal. Calcd. for $C_7H_7NO_3$: N, 9.15. Found: N, 9.15.

N-Acetyl-4-hydroxylaminobenzoic Acid.—To a solution of 1 g. of 4-hydroxylaminobenzoic acid in ether, acetic anhydride was added: colorless crystals separated, 0.6 g.: melted at 210° with darkening and decomposition; gave an intense red color with ferric chloride.

Anal. Calcd. for $C_9H_9O_4N$: N, 7.18. Found: N, 7.11.

N-Nitroso-4-hydroxylaminobenzoic Acid.—To an ice-cold solution of 1.5 g. of 4-hydroxylaminobenzoic acid in 400 cc. of water, 10.5 cc. of 2 *N* hydrochloric acid and 9 cc. of *N* sodium nitrite solution were added. A white, amorphous precipitate separated, 1.3 g. It did not melt up to 270°, but decomposed gradually with blackening. With ferric chloride solution a red color was produced. When dissolved in glacial acetic acid and coupled with Marshall's reagent,[6] about 15% of diazo compound was formed (Table II).

Coupling of Hydroxylamines.—For colorimetric determination of diazo compound formed by diazotization of hydroxylamines, the procedure of Bratton and Marshall[6] was used with slight modifications. Treatment of hydroxylamines with acetic anhydride before diazotizing increases the amount of diazo compound formed (Table I). N-Nitrosohydroxylamines, when dissolved in glacial acetic acid, spontaneously form diazo compounds (Table II).

Summary

Nitrous acid acts upon 4-hydroxylaminobenzenesulfonamide with formation of N-nitroso-4-hydroxylaminobenzenesulfonamide. The latter, when dissolved in glacial acetic acid, is partly transformed to diazobenzenesulfonamide. 4-Hydroxylaminobenzoic acid and phenylhydroxylamine behave the same way. To some degree, dilute solutions of hydroxylamines form the corresponding diazo derivative with nitrous acid. By treating dilute solutions of hydroxylamines with acetic anhydride before diazotization, an increase of diazo compound was obtained. It was found that acetylation yields two derivatives. The

derivative which gives the diazo reaction was isolated. It contains the acetyl group presumably linked to the oxygen of the hydroxylamino group. The other derivative is acetylated on the nitrogen and cannot be diazotized. The application of this reaction to the detection of hydroxylaminobenzenesulfonamide in body fluids is discussed. The preparation of 4-nitrosobenzenesulfonamide is described.

Gliotoxin, the Antibiotic Principle of *Gliocladium fimbriatum*. II. General Chemical Behavior and Crystalline Derivatives[1]

BY WILLIAM F. BRUCE, JAMES D. DUTCHER,[2] JOHN R. JOHNSON AND LEON L. MILLER[3]

In a preliminary examination of the chemical behavior of gliotoxin, Weindling[4] has observed that in spite of its nitrogen content, gliotoxin has no basic properties. By prolonged heating with acid, it was slowly converted to a gum from which none of the original material could be recovered. In a partition between ether and 1% potassium hydroxide, practically none of the gliotoxin was dissolved in the alkaline layer. This showed the non-acidic nature of the material. It was, however, rapidly altered by treatment with alkali. Boiling with 5% potassium hydroxide rapidly eliminated sulfur and, even in the ether partition, a large proportion of the material was altered. Gliotoxin was found strongly reducing toward permanganate.

To extend these observations, a quantitative study of the effect of alkali on gliotoxin seemed desirable. By connecting a trap containing 0.1 *N* hydrochloric acid with a refluxing alkaline suspension of gliotoxin, evolution of a volatile base was readily demonstrated. On evaporation of the acid solution, a hydrochloride and from it a chloroplatinate were prepared which showed that the volatile base was methylamine, and in an amount which accounted for about half the nitrogen in the sample. The amount of sulfur liberated as sulfide by the action of alkali was then determined by acidification and steam distillation of the solution which remained. From 40–60% of the total sulfur was liberated as hydrogen sulfide, and some as elementary sulfur. In the non-volatile portion, a red amorphous solid remained, insoluble in acid, but soluble in alkali, containing nitrogen and sulfur. By using barium hydroxide in place of sodium hydroxide, the same volatile products were observed, but the residue was not as highly colored. On purification by sublimation *in vacuo*, it yielded a small amount of crystalline solid. This solid, slightly soluble in water, dissolved readily in sodium bicarbonate solution, and formed a silver salt, methyl and ethyl esters through which it was identified as indole-2-carboxylic acid.

Gliotoxin proved inert toward phenyl isocyanate, either when refluxed in benzene solution or on long standing at ordinary temperature: the original material was recovered unchanged. With diazomethane, methyl iodide and dimethyl sulfate, some reaction may have occurred since none of the original material was recovered; only gums and sirups were obtained.

A Zeisel determination showed the absence of methoxyl or ethoxyl groups. The N-methyl determination[5] was positive in agreement with the isolation of methylamine. No reaction occurred with the carbonyl reagents hydroxylamine, semicarbazide or 2,4-dinitrophenylhydrazine. The Ehrlich reaction, pine splint test, Keller's indole reaction and the ninhydrin reaction were all negative. Clowes' test for $CH_2\begin{matrix}O\\O\end{matrix}$ or $CH_2\begin{matrix}S\\S\end{matrix}$, using phloroglucinol and 50% sulfuric acid,[6] was also negative. Ammoniacal silver nitrate (Tollens reagent) and phosphotungstic acid (Folin reagent) in the presence of sulfite were reduced. These reactions and a positive nitroprusside reaction could be attributed to the products, particularly sulfide, formed as a result of the lability of gliotoxin in alkaline media.

Oxidizing agents such as permanganate, bromine water and sodium hypochlorite rapidly converted the sulfur of gliotoxin to sulfate. Reducing agents, including sodium sulfite, stannous chloride, hydriodic acid, aluminum amalgam, zinc or tin and acid, reduced the sulfur in gliotoxin to hydrogen sulfide. Certain of these procedures will be considered in detail in later papers. By treatment of gliotoxin with mercuric acetate or silver nitrate, *one* sulfur atom was removed. Cupric sulfate, lead acetate, and barium chloride gave no reaction.

A Zerewitinoff determination of active hydrogen in gliotoxin dissolved in pyridine gave somewhat uncertain results, for a rather large blank from the pyridine was observed, and while the blank was constant under given conditions, it was variable with time. It was necessary to use pyridine because gliotoxin is insoluble in the isoamyl ether

used for preparing the Grignard reagent. Our conclusion from this determination is that gliotoxin has two, or perhaps three, active hydrogens.

In attempts to replace these active hydrogens by acyl groups, a solution of gliotoxin in pyridine was boiled with acetic anhydride and with benzoyl chloride, but only gums resulted. By conducting the reaction at room temperature, however, and adding water cautiously, a crystalline dibenzoate was secured. A di-*p*-bromobenzoate and a di-*p*-nitrobenzoate were similarly prepared in crystalline form. No crystalline acetyl derivative was obtained; but by a quantitative acetylation following the method of Shriner,[7] the introduction of one acetyl radical into gliotoxin was established. No reaction with *p*-toluenesulfonyl chloride could be discovered; neither did phthalic anhydride in pyridine or on fusion react with gliotoxin.

From this examination of the chemistry of gliotoxin, the presence of an indole structure appears probable in the original substance, although the yield of indole derivative was low. The ultraviolet absorption spectrum[1] supports this conception, and the consistent isolation of indole-2-carboxylic acid under different conditions of reaction makes it difficult to believe that this product is the result of a secondary reaction. A further study of the alkaline hydrolysis to determine whether the yield of indole derivative can be improved is desirable in order to help remove any doubt on this point. It is worth noting that the benzene ring in the indole nucleus is unsubstituted. This greatly reduces the number of possible locations of the other atoms in gliotoxin. Of the thirteen carbon atoms in the gliotoxin molecule, the indole-2-carboxylic acid fragment accounts for nine. One more is known to be present as a methyl radical attached to nitrogen. The disposition of the remaining three carbons, of two, possibly three, active hydrogens is still unknown; and the relation of the one other nitrogen and of the two sulfur atoms to the portion of the molecule thus far outlined also remains to be elucidated. In the following paper of this series, the position of these three carbon atoms is elucidated by means of a study of the reduction of gliotoxin by hydriodic acid. The arrangement of the functional groups and the nature of the sulfur atoms in gliotoxin will be the subject of subsequent papers.

We wish to thank the Cornell Research Foundation and E. I. du Pont de Nemours and Co. for generous support of this work.

Experimental Part

Alkaline Degradation of Gliotoxin.—To a 10% solution of sodium hydroxide in a Kjeldahl distillation apparatus equipped with a separatory funnel and spray trap was added a weighed sample of gliotoxin. The solution was boiled for an hour and the volatile base collected in standard 0.1 *N* hydrochloric acid. The unused acid was determined by standard 0.1 *N* sodium hydroxide using methyl red as indicator. A receiver containing ammoniacal zinc sulfate was then substituted for that containing the standard acid. After addition of excess 15% sulfuric acid through the funnel, the liberated hydrogen sulfide was distilled into the zinc sulfate solution, the precipitated sulfide was treated with hydrochloric acid and determined iodometrically. The results are presented in Table I.

TABLE I

ALKALINE HYDROLYSIS OF GLIOTOXIN

Sample, mg.	% N volatile with base	% N by analysis[1]	% S volatile with acid	% S by analysis[1]
236.9	3.02	8.27	9.0	19.38
236.1	3.31	8.27	7.7	19.38
146.5	..	8.27	11.6	19.38
210.3	3.25[a]	8.27	..	19.38

[a] Hydrolysis by barium hydroxide.

A small amount of free sulfur steam distilled during the distillation of hydrogen sulfide and was identified by mixed melting point, 118°, with an authentic sample. From 450 mg. of gliotoxin, 130 mg. of a brick red residue insoluble in water or mineral acid remained. It was soluble in sodium hydroxide, contained nitrogen and sulfur, and did not melt, but merely charred gradually.

Concentration of a solution of the volatile base in dilute hydrochloric acid gave a white deliquescent solid melting at 222–225°. This was compared with an authentic sample of methylamine hydrochloride melting at 223–227°; no depression was observed on determination of the mixed melting point. Conversion to the chloroplatinate gave a yellow solid which was analyzed.

Anal. Calcd. for $C_2H_{12}Cl_6N_2Pt$: C, 6.4; H, 3.2; Pt, 41.3. Found: C, 6.12, 6.67; H, 2.96, 3.11; Pt, 41.2, 41.3.

By boiling 500 mg. of gliotoxin with 70 ml. of a 15% solution of barium hydroxide for one and one-half hours, followed by removal of the barium as sulfate, a clear yellow faintly acid solution was obtained. On evaporation to dryness, this yielded 80 mg. of a red-brown but crystalline residue. By subliming this material at 110–120° at 1 mm., 25 mg. of a white crystalline sublimate was secured. This substance melted at 201–202°, reacted with potassium permanganate and bromine water and contained nitrogen but not sulfur.

Anal. Calcd. for $C_9H_7NO_2$: C, 66.1; H, 4.35, N, 8.70. Found: C, 66.5; H, 4.26; N, 8.6.

By adding 5% silver nitrate to a solution of 5 mg. of the substance in water, a flocculent precipitate was obtained.

Anal. Calcd. for $C_9H_6AgNO_2$: Ag, 41.1. Found: Ag, 40.6.

These data give $C_9H_7NO_2$ as the best molecular formula.

The methyl and ethyl esters, each made from 5 mg. of sublimate by the action of the alcohol saturated with hydrogen chloride, melted at 149.5–151.5° and 121–123°, respectively. These data agree with those reported for indole-2-carboxylic acid and its esters,[8] and each of the three substances melted without depression on admixture with the corresponding authentic samples.

Oxidation by Bromine Water.—Into a 1% solution of gliotoxin in acetic acid bromine vapor was aspirated until a definite yellow orange color persisted. After two hours, a slight excess of barium chloride solution was added and the precipitate was digested at 50°, filtered, washed, ignited and weighed. The data are given in Table II.

Reaction of Gliotoxin with Mercuric Acetate and with Silver Nitrate.—To a solution of 50 mg. of gliotoxin in 25 ml. of absolute alcohol was added a solution of 200 mg. of

The ethyl ester reported by Oddo and Sessa, *Gazz. chim. ital.*, **41**, 247 (1911), melting at 107° is not in agreement with an authentic sample prepared from indole-2-carboxylic acid synthesized by the method of Reissert. Our authentic ethyl ester melts at 121–122° and the methyl ester at 150–151°. These values agree with those reported by Grānacher.

OXIDATION BY GLIOTOXIN BY BROMINE WATER

Sample, mg.	$BaSO_4$, mg.	% S	% S (Carius)
97.8	138.5	19.46	19.37
133.7	190.9	19.60	19.37

mercuric acetate in 10 ml. of alcohol to which 10 drops of acetic acid was added to decrease hydrolysis. After standing in the dark for twenty-four hours, the amorphous, slowly-deposited white complex containing mercuric acetate and mercuric sulfide, when filtered, washed and dried, weighed 90 mg. corresponding to 5.22 mg. of sulfur or 53% of the total sulfur. The filtrate was treated with hydrogen sulfide to remove excess mercury, filtered and evaporated. A resinous sulfur-containing solid remained.

A solution of 100 mg. of gliotoxin in 25 ml. of absolute alcohol was treated with a solution of 350 mg. of silver nitrate in 25 ml. of 95% alcohol. A black precipitate of silver sulfide soon settled out, and a slight silver mirror formed. After an hour, the precipitate was collected on a filter. It weighed 80 mg., corresponding to 10.3 mg. of sulfur, or 53% of the total sulfur in the sample.

Determination of Active Hydrogen.—The sample, dissolved in 10 ml. of anhydrous pyridine, after standing an hour to ensure complete solution and temperature equilibrium, was treated with ethylmagnesium bromide in an apparatus similar to that of Soltys.[9] Gas was at once evolved. After fifteen to twenty minutes the gas evolution subsided and the reaction vessel was warmed at 50° with shaking for five minutes. After the original temperature was established, the volume increase was determined. The data in Table III show that the pyridine gave a high blank. The pyridine was dried over solid potassium hydroxide, kept over barium oxide for a week, and redistilled.[10] The constancy of the blank, determined on the same sample, permitted a reasonably satisfactory estimation of active hydrogen.

TABLE III

DETERMINATION OF ACTIVE HYDROGEN IN GLIOTOXIN BY REACTION WITH ETHYLMAGNESIUM BROMIDE

Sample, mg.	Volume increase, ml.	Active hydrogens
86.6	30.2 (28°, 733 mm. cor.)	2.2
109.7	38.0 (29°, 730 mm. cor.)	3.2
105.5	32.7 (29°, 730 mm. cor.)	2.2
0	15.4 (31°, 730 mm. cor.)	Blank
0	15.3 (29°, 730 mm. cor.)	Blank

The quantitative acetylation method of Shriner[7] was used to determine how many acetyl groups can be introduced into gliotoxin. Two samples of 100 mg. each were dissolved in 1.0 ml. of dry pyridine and 5 ml. of the acetyl chloride–toluene reagent was added. After twelve hours at room temperature water was added and the mixture titrated with 0.1 *N* sodium hydroxide. The two samples showed acetylation equivalent to 3.3 and 3.1 ml. of 0.1 *N* sodium hydroxide, respectively. The average equivalent weight from these data is 312. If the molecular weight is taken to be 326,[1] this represents 1.05 acetyl groups introduced per molecule. No crystalline acetate could be secured from these reactions.

A sample of 55 mg. of gliotoxin was treated with 2.0 ml. of 20% acetic anhydride in pyridine. Water was added after half an hour and the residual acetic acid determined by titration. The combined acetic acid, obtained by difference, was equivalent to 1.5 ml. of 0.1 *N* sodium hydroxide. The equivalent weight per acetyl group is then 366, representing 0.9 acetyl groups on the basis of a molecular weight of 326.

Crystalline Acylation Products of Gliotoxin.—A solution of 1 g. (3.07 millimoles) of gliotoxin in 10 ml. of dry pyridine was cooled in an ice-bath. During an hour 1.4 g. (10 millimoles) of benzoyl chloride was added with stirring. After standing for twelve hours at room temperature, the solution was red-brown and contained a deposit of pyridine hydrochloride. After cooling in an ice-bath, water was added dropwise with stirring. Crystallization was initiated by scratching. After one volume of water was added, the precipitate which formed was allowed to stand for an hour, filtered, washed with alcohol and dried to give 1.5 g. of product. Digestion with hot alcohol removed a yellow impurity. The product was recrystallized from hot chloroform by the addition of methanol, yielding nearly colorless glistening plates melting at 192–193° with decomposition; $[\alpha]^{22}D$ −20° (1% in $CHCl_3$).

Anal. Calcd. for $C_{27}H_{22}N_2O_6S_2$ (dibenzoate): C, 60.70; H, 4.12; N, 12.00; S, 5.25. Found: C, 60.02; H, 3.95; N, 12.26; S, 5.22.

The substance is sparingly soluble in acetone and alcohol, but soluble in pyridine and dioxane. In the latter solvent it appeared to undergo alteration since the specific rotation varied. Recrystallization from acetic acid also caused alteration since the melting point was lowered to 186–188°. The dibenzoate gave no reaction with acetyl chloride in pyridine.

The di-*p*-bromobenzoate of gliotoxin was prepared by a similar procedure from 1 g. of gliotoxin in pyridine and 1.5 g. of *p*-bromobenzoyl chloride. The product crystallized from dioxane solution on addition of water to give 1.8 g. of colorless needles melting at 193° with decomposition; $[\alpha]D$ +20° (1% in $CHCl_3$).[11]

Anal. Calcd. for $C_{27}H_{20}Br_2N_2O_6S_2$ (di-*p*-brombenzoate): C, 46.80; H, 2.90; Br, 23.10. Found: C, 46.50; H, 2.72; Br, 24.17.

The di-*p*-nitrobenzoate was prepared from 326 mg. (1 millimole) of gliotoxin dissolved in pyridine and 930 mg. (5 millimoles) of *p*-nitrobenzoyl chloride in the manner previously described. The product was insoluble in alcohol, ether, or acetone. It crystallized from chloroform, on addition of methanol, in pale yellow prismatic rods which melted with decomposition at 189°; $[\alpha]^{22}D$ +13° (1% in $CHCl_3$).

Anal. Calcd. for $C_{27}H_{20}N_4O_{10}S_2$ (di-*p*-nitrobenzoate): N, 9.0; S, 10.25. Found: N, 9.2; S, 9.84. Calcd. for $C_{34}H_{23}N_5O_{13}S_2$ (tri-*p*-nitrobenzoate): N, 9.05; S, 8.28.

Summary

An investigation of the chemical behavior of gliotoxin has shown that a part of the carbon skeleton probably includes that of indole-2-carboxylic acid. The presence of an N-methyl grouping has been demonstrated. The lability of the sulfur atoms in gliotoxin makes it difficult to secure crystalline reaction products. A number of reactions by which sulfur can be removed have been discovered, including oxidation by bromine water, reaction with mercuric acetate and silver nitrate, and reduction by various acidic and neutral reducing agents. Three crystalline derivatives of gliotoxin have been prepared: the dibenzoate, the di-*p*-bromobenzoate and the di-*p*-nitrobenzoate. In each case the formulation of the product agrees with the formulation of gliotoxin previously proposed.

(10) MacArdle, "Solvents in Organic Chemistry," D. Van Nostrand Co., New York, N. Y., 1925, p. 108.

(11) In a preliminary experiment, a smaller sample of a product was obtained for which the melting point, 189–191°, and specific rotation, $[\alpha]D$ +20° (1% in dioxane), agree with those given above. The analytical values, however, indicated that the substance was a tri-*p*-bromobenzoate. *Anal.* Calcd. for $C_{34}H_{23}Br_3N_5O_{13}S_2$ (tri-*p*-bromobenzoate): C, 46.60; H, 2.63; Br, 27.40; N, 3.20; S, 7.32. Found: C, 46.00; H, 2.62; Br, 27.17; N, 3.07, 3.65; S, 7.91. All subsequent preparations, regardless of the amount of *p*-bromobenzoyl chloride employed, afforded the di-*p*-bromobenzoate.

Gliotoxin, The Antibiotic Principle of *Gliocladium fimbriatum*. III. The Structure of Gliotoxin: Degradation by Hydriodic Acid[1]

BY JAMES D. DUTCHER,[2] JOHN R. JOHNSON AND WILLIAM F. BRUCE

The isolation and general physical properties of gliotoxin, as well as a preliminary study of the nature of the functional groups have been previously described.[1,3] In an effort to elucidate the chemical structure of gliotoxin, it was early observed that the sulfur atoms possess marked lability; this lability made the degradation of gliotoxin to a discrete product very difficult. A reaction was therefore sought which would eliminate the sulfur atoms and leave a more tractable compound with which to work. The reactions which were known to remove sulfur were accordingly examined more closely in order to determine the nature of the organic residue. While the majority of these procedures gave organic products which could not be crystallized, they gave some indication of the nature of the combination of sulfur in gliotoxin and will therefore be described in a later paper. By reduction with hydriodic acid and red phosphorus in glacial acetic acid, a crystalline, neutral, optically inactive organic product (I) was secured. By analysis its empirical formula was found to be $C_{13}H_{12}N_2O_2$. This substance was therefore derived from gliotoxin simply by the apparent loss of two molecules of water and two of hydrogen sulfide, as equation 1 shows

(1) $C_{13}H_{14}N_2O_4S_2 + 6H\ (HI \text{ and } P) \longrightarrow C_{13}H_{12}N_2O_2 + 2H_2S + 2H_2O$

It may be seen from this formulation that both of the sulfur atoms and two of the four oxygen atoms in gliotoxin were eliminated without the loss of any carbon or nitrogen.

The determination of the chemical nature of this reduction product was achieved in the following manner: Treatment with 0.5 *N methanolic* potassium hydroxide at room temperature resulted in reaction with one mole of alkali to yield the salt of a 13-carbon acid of formula $C_{13}H_{14}N_2O_3$, which was characterized by the preparation of the ethyl ester. The equation for this hydrolysis may be written

(2) $C_{13}H_{12}N_2O_2 + H_2O \xrightarrow[KOH]{0.5\ N \text{ methanolic}} C_{12}H_{13}N_2OCO_2H$

The formation from the original neutral product of an acid with the same number of carbon atoms is indicative of the presence of a lactam or lactone linkage. Further cleavage of this acid was accomplished by refluxing with 20% *aqueous* potassium hydroxide solution. One mole of alkali was consumed beyond that required for neutralization and from this hydrolysis mixture was isolated in good yield an acid of the composition $C_9H_7NO_2$. The equation for this hydrolysis may be written

(3) $C_{13}H_{14}N_2O_3 + H_2O \xrightarrow[KOH]{20\%\ \text{aqueous}} C_8H_6NCO_2H + C_4H_9NO_2$

This acid was identified as indole-2-carboxylic acid by comparison with an authentic specimen of the free acid. The methyl and ethyl esters of indole-2-carboxylic acid also proved identical with the corresponding derivatives of the hydrolysis product. The isolation of this acid confirmed the presence in gliotoxin of an indole nucleus substituted in the 2-(or α) position.[1]

An examination of the equation 3 shows that a 4-carbon fragment and a nitrogen atom were split off. It was known that one of the nitrogen atoms of gliotoxin bore a methyl group[1] (Herzig–Meyer determination of N-methyl groups) and since indole-2-carboxylic acid which was isolated has an unsubstituted nitrogen atom it could be assumed as a working hypothesis that the four carbon fragment represented an α- or β-methyl-aminopropionic acid residue. Because of the small amount of material available it was not possible to isolate this product from the hydrolysis mixture but verification of the hypothesis was obtained by the synthesis of the ethyl ester of the 13-carbon acid previously mentioned (equation 2) from indole-2-carboxylic acid chloride and *dl*-α-N-methylalanine ethyl ester.

(4) 
Furthermore, it was observed that under suitable conditions this ester of the 13-carbon acid could be cyclized by the elimination of a mole of ethyl alcohol to yield a product identical with I, the neutral product obtained by the hydriodic acid reduction of gliotoxin. In view of both the ready hydrolysis and ease of cyclization of this product there seems little doubt that this cyclization takes place through the imide hydrogen of the indole nitrogen atom.

A compound with a similar ring system has been prepared by Kermack, Perkin and Robinson,[4] who found that indole-2-carboxyacetalyl amide cyclized readily to give a compound of formula II.

According to the Ring Index such a system is called pyrazino-[1.2-a]-indole (No. 1630). Employing the preferred numbering of the Ring Index, the compound obtained from gliotoxin is named 2,3-dimethyl-1,4-diketotetrahydropyrazino-[1.2-a]-indole (equation 5). In a later report dealing with the synthesis of various homologs of this neutral degradation product it will be shown more conclusively that the alternative formulation involving cyclization through the 3-(or β)-carbon atom of the indole nucleus to form a carboline derivative corresponding to formula III does not represent the structure of the product (I) derived from gliotoxin.

The elucidation by this means of the complete carbon and nitrogen skeleton of gliotoxin leaves undetermined only the position and function of two oxygen and two sulfur atoms. These matters will be the subject of subsequent reports.

Experimental

Hydriodic Acid Reduction of Gliotoxin.—One gram of gliotoxin was refluxed in 25 ml. of glacial acetic acid with 1.0 g. of red phosphorus and 1.0 ml. of hydriodic acid, sp. gr. 1.7, until no more hydrogen sulfide was evolved. This required approximately four hours. The hydrogen sulfide which was formed was trapped in alkaline plumbite solution. An amount of lead sulfide equivalent to 96% of the sulfur in the gliotoxin was obtained. The warm acetic acid solution was filtered from excess phosphorus and the filtrate and washings poured into 200 ml. of cold water containing 2.0 g. of sodium bisulfite. The solution was thoroughly extracted with ether and the ether washed free of acetic acid with dilute sodium carbonate solution. After drying over anhydrous sodium sulfate the ether solution was evaporated in vacuum and yielded a pale yellow sirup which weighed 380 mg. After addition of a few drops of ethanol and storage in the ice-chest for several days the sirup crystallized. The crystalline material was washed free of pigmented mother liquor and then recrystallized from ethanol. It was obtained as large, dense, rhombic crystals which melted at 122°.[5] It was optically inactive. This compound was slightly soluble in hot water but insoluble in cold water or dilute acid or alkali solution. It was moderately soluble in most organic solvents. It was readily oxidized by potassium permanganate solution, gave a negative Ehrlich reaction (an alcoholic solution treated with *p*-dimethylaminobenzaldehyde and concentrated hydrochloric acid) and coupled immediately in 1% sodium carbonate solution with diazotized sulfanilic acid to yield a deep orange-red solution.

Anal. Calcd. for $C_{13}H_{12}N_2O_2$: C, 68.40; H, 5.26; N, 12.30. Found: C, 68.25; H, 5.24; N, 12.69.

Hydrolysis of Hydriodic Acid Reduction Product.—A methanol solution of 480 mg. of the compound m. p. 122° was treated with 5.0 ml. of 0.5 *N* methanolic potassium hydroxide at room temperature for four hours. Titration with standard acid showed the consumption of 4.2 ml. of the 0.5 *N* alkali, corresponding to a saponification equivalent of 228. With the assumption that one mole of alkali per mole of compound was consumed, the formula of the substance was $C_{13}H_{12}N_2O_2$, molecular weight 228. The methanolic solution was strongly acidified and concentrated in vacuu to a small volume from which a crystalline precipitate separated. This precipitate, which weighed 320 mg., was recrystallized from acetic acid and was obtained as rosets of colorless needles, m. p. 187°. This compound was shown to be an acid by titration with standard alkali using phenolphthalein as indicator. Neutral equivalents of 247, 250 and 245 were obtained. The formula $C_{12}H_{13}N_2O\cdot CO_2H$ requires a molecular weight of 246.

Anal. Calcd. for $C_{13}H_{14}N_2O_3$: C, 63.40; H, 5.70; N, 11.40. Found: C, 63.23; H, 5.98; N, 11.32, 11.63.

The *ethyl ester* was prepared by refluxing the acid in absolute alcohol with a trace of sulfuric acid. Addition of water to the hot solution caused the precipitation, on cooling, of long shining needles. The ester was recrystallized from aqueous alcohol and from benzene–petroleum ether mixture. It melted at 127°.

Anal. Calcd. for $C_{15}H_{18}N_2O_3$: C, 65.70; H, 6.57; N, 10.22. Found: C, 66.10; H, 6.85; N, 10.51.

The yield of ester was good and there was no evidence of any cyclization under these conditions to yield the neutral product $C_{13}H_{12}O_2N_2$, m. p. 122°. This product was obtained from the same ester, as shown below, under other reaction conditions.

Further Hydrolysis of the Acid $C_{13}H_{14}N_2O_3$.—Two hundred and thirty-three mg. of this acid was dissolved in 5.0 ml. of 20% aqueous potassium hydroxide and refluxed for four hours. A stream of nitrogen was passed through the flask during refluxing and then passed into standard acid solution. It was found that *no* volatile amine was produced during hydrolysis. The cooled solution was made up to 50 ml. in a volumetric flask and 5.0-ml. aliquots titrated. A blank on the alkali was run in the same manner. By subtracting one equivalent of alkali for the neutralization of the original carboxyl group, a saponification equivalent of 233 was obtained, in good agreement with the molecular weight of the acid, 246. After acidification of the entire solution, the material was concentrated in

vacuum. At a small volume a colorless product crystallized out. This product was filtered off, washed with water and recrystallized from acetic acid. The melting point was 204° with sublimation and decomposition; 150 mg. was obtained.

Anal. Calcd. for $C_9H_7NO_2$: N, 8.70; neut. equiv., 161. Found: N, 8.67; neut. equiv., 160, 165.

The **methyl ester** was prepared by refluxing for one hour with methanol and a trace of sulfuric acid. It crystallized from aqueous acetone as platelets; m. p. 151°.

Anal. Calcd. for $C_{10}H_9NO_2$: N, 8.00. Found: N, 8.02.

The **ethyl ester** was prepared in a similar way with ethanol and sulfuric acid. Needles were obtained on recrystallization from aqueous ethanol or benzene–petroleum ether; m. p. 121°.

Anal. Calcd. for $C_{11}H_{11}NO_2$: N, 7.40. Found: N, 7.36.

These compounds were proved to be identical with indole-2-carboxylic acid, m. p. 204°, indole-2-carboxylic acid methyl ester, m. p. 151°, and indole-2-carboxylic acid ethyl ester, m. p. 122°, by mixed melting point determinations with synthetic samples.

Synthesis of the Hydriodic Acid Reduction Product of Gliotoxin.—After the isolation of indole-2-carboxylic acid from the strong aqueous alkaline hydrolysis of the 13-carbon acid it was found impossible to obtain any further crystalline material. In view of the possibility that the remainder of the molecule might be either α- or β-N-methylalanine the following synthesis was carried out. Indole-2-carboxylic acid was synthesized by the method of Reissert[6] and converted to the acid chloride by the action of thionyl chloride. To 25 ml. of dry ether containing 1.0 g. of thionyl chloride, 175 mg. of finely powdered indole-2-carboxylic acid was slowly added. Solution occurred readily and after all the acid had been added the mixture was allowed to stand at room temperature for forty minutes before the ether and excess thionyl chloride were removed in vacuum. The slightly pigmented semi-crystalline residue was redissolved in dry ether and used without further purification since it decomposed readily. Since the 13-carbon acid obtained from gliotoxin possessed no optical activity, inactive α-N-methyl alanine ethyl ester, prepared by the method of Zelinsky, *et al.*,[7] was used. An ethereal solution of 175 mg. of this ester was added to the solution of indole-2-carboxylic acid chloride. The mixture warmed slightly and became cloudy. It was allowed to stand at room temperature for one hour after which the ether and excess amino acid ester were removed in vacuum. The crystalline residue was taken up in absolute alcohol and recrystallized by the addition of water to the warm solution. Colorless needles melting at 126° were obtained. The yield was 148 mg. and represented 55% of the theoretical yield on the basis of the indole-2-carboxylic acid used.

This synthetic ester agreed exactly in all properties with the ester of the 13-carbon acid and showed no depression in a mixed melting point determination. On saponification it yielded the identical 13-carbon acid; m. p. 187°.

It was observed in a second preparation of this ester that if the alcoholic solution of the initial condensation product of the indole-2-carboxylic acid chloride and *dl*-α-N-methyl alanine ester was allowed to stand for thirty-five hours, instead of obtaining the open chain ester of the 13-carbon acid, a product melting at 122° and identical with the hydriodic acid reduction product of gliotoxin was obtained. The presence of a small amount of hydrochloric acid was apparently responsible for this cyclization since the addition of solid sodium carbonate to the ethereal solution, after condensation, to remove all traces of hydrochloric acid prevented the cyclization. The neutral, cyclized product was then obtained from the ester by allowing an alcoholic solution containing 1% hydrochloric acid to stand for forty-eight hours. From 750 mg. of indole-2-carboxylic acid, 525 mg. of the cyclized product was obtained; this represents 50% of the theoretical yield.

(7) Zelinsky, Annenkoff and Kulikoff, *Z. physiol. Chem.*, **73**, 468 (1911).

Summary

Treatment of gliotoxin with phosphorus and hydriodic acid in acetic acid gave a crystalline product in which analysis showed that no sulfur and two less oxygen atoms were present; but the same number of carbons as in gliotoxin were found. This product was degraded stepwise to N-(indole-2-carboxoyl)-N-methyl-α-alanine and to indole-2-carboxylic acid. The crystalline reduction product, 2,3-dimethyl-1,4-diketotetrahydropyrazino-[1,2-a]-indole (I) and the several degradation products have been identified by synthesis.

Gliotoxin, the Antibiotic Principle of *Gliocladium fimbriatum*. IV. The Structure of Gliotoxin: The Action of Selenium

BY JAMES D. DUTCHER,[1] JOHN R. JOHNSON AND WILLIAM F. BRUCE

In seeking to establish the structure of gliotoxin, the antibiotic substance produced by the fungus *Gliocladium fimbriatum*,[2] a distillation with selenium was carried out. A curious but informative reaction occurred which yielded a product that shed considerable light upon the structure of the gliotoxin molecule and served to verify the observations previously reported for the hydriodic acid reduction of gliotoxin.[3]

When an intimate mixture of selenium and gliotoxin was heated at 230 to 250° a crystalline sublimate was obtained which analysis showed to have the formula $C_{12}H_8N_2O_3$. Sulfur, hydrogen sulfide and water were the only other products of the reaction which were observed, but under the conditions of the reaction carbon dioxide formaldehyde or methane might have been overlooked. Expressed in the form of an equation the reaction was

$$C_{13}H_{14}N_2O_4S_2 \xrightarrow[250°]{Se} C_{12}H_8N_2O_3\ (II) + 2H_2S + [C] + H_2O$$

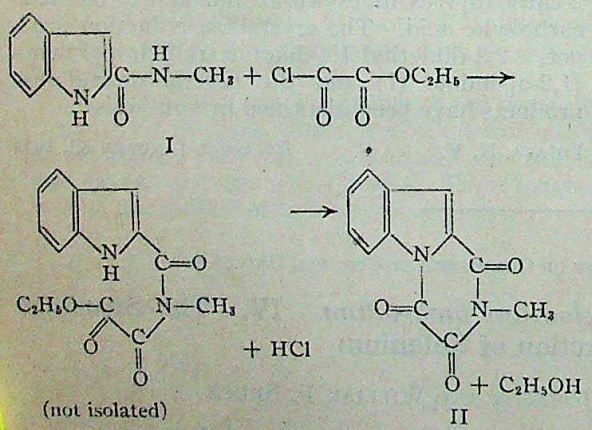
Digitized by Arya Samaj Foundation Chennai and eGangotri

The structure of this product, II, was determined by means of alkaline hydrolysis. It was found to be split rapidly by methanolic potassium hydroxide at room temperature; approximately two moles of alkali were consumed. The product isolated from this hydrolysis was a neutral compound (I) possessing the formula $C_{10}H_{10}N_2O$. The equation for this reaction is

$$C_{12}H_8N_2O_3 + 2H_2O \xrightarrow[\text{methanol}]{KOH} C_{10}H_{10}N_2O(I) + H_2C_2O_4$$

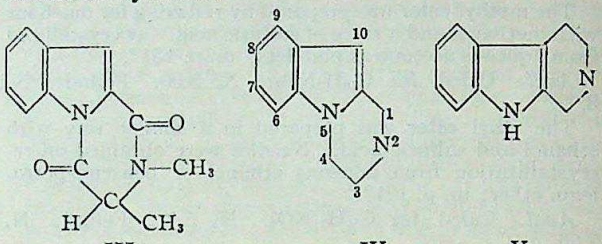
The neutral 10-carbon compound yielded indole-2-carboxylic acid and methylamine on vigorous hydrolysis with 25% aqueous potassium hydroxide. That I was the methyl amide of indole-2-carboxylic acid was shown by comparison with a synthetic sample. The other product of the original hydrolysis appeared from the equation to be oxalic acid although it was not isolated.

The structure assigned to the selenium degradation product is shown in formula II. This structure was proved by the synthesis of II from the methyl amide of indole-2-carboxylic acid and ethyl oxalochloride. When these two compounds were condensed in the presence of pyridine the product which was obtained was identical in all respects with the material obtained from gliotoxin by distillation with selenium. This synthesis is similar to that by which the hydriodic acid reduction product of gliotoxin, 2,3-dimethyl-1,4-diketotetrahydropyrazino[1,2-a]-indole (III), was prepared[3] and the reaction may be represented as follows



It has thus been possible to obtain by two different procedures degradation products of gliotoxin whose structures have been proved by synthesis. Both of these products contain the same tricyclic nucleus, IV, which according to the Ring Index No. 1630 is called pyrazino-[1.2-a]-indole. The selenium degradation product is therefore named 2-methyl-1,3,4-triketotetrahydropyrazino-[1.2-a]-indole. As in the synthesis of III,[3] the readiness with which the ring is opened and closed makes improbable the alternative mode of cyclization (V).

The action of selenium in splitting off a carbon atom from C_3 is difficult to explain in this particular case although it is well known that methyl groups are split off by this reagent in the dehydrogenation of sterols and polyterpenes to yield aromatic systems.[4]



We wish to thank the Cornell Research Foundation and E. I. du Pont de Nemours and Co. for generous support of this work.

Experimental

Selenium Distillation of Gliotoxin.—One gram of powdered gliotoxin was intimately ground with 5.0 g. of powdered black selenium. The gray mixture was placed in the bottom of a 50-ml. Erlenmeyer flask equipped with a short air condenser and heated in a metal bath. At approximately 200° water vapor and a yellow sublimate, apparently sulfur, began to come off. The mix was held at this temperature until all the water was off. The temperature was then allowed to rise gradually; at 230° a yellow, crystalline sublimate began to appear on the walls of the flask just above the surface of the melt. This product was collected over a period of one hour. When no more formed the temperature was raised to 250° but without further yield of product. About 50 mg. of crude sublimate was obtained. An additional 50 mg. of this compound was obtained by pulverizing the cooled melt in an iron mortar, extracting the powder in a Soxhlet with benzene and resubliming the benzene residue. Recrystallization of the combined sublimate from acetic acid gave rhombic plates with a pale yellow color, m. p. 253–255° with sublimation.[5]

Anal. Calcd. for $C_{12}H_8N_2O_3$: C, 63.20; H, 3.51; N, 12.30. Found: C, 63.40; H, 3.57; N, 12.38.

This product (II) was insoluble in water or dilute aqueous acid or alkali. It was insoluble in cold ethanol, methanol or ether and only slightly soluble in a large volume of hot ethanol. It was somewhat more soluble in acetone, benzene and chloroform, and dissolved readily in pyridine or dioxane. It was insoluble in concentrated hydrochloric acid but dissolved unchanged in concentrated sulfuric acid from which it was precipitated by the addition of water.

Alkaline Hydrolysis of the Selenium Sublimate.—A suspension of 75 mg. of the yellow crystals in 2.0 ml. of methanol was treated with 5.0 ml. of 1 *N* methanolic potassium hydroxide. The crystalline material dissolved on gentle warming. After standing for half an hour at room temperature the excess alkali was back-titrated with standard acid; 0.65 ml. of 1 *N* alkali had been consumed. Saponification equivalent found, 115; since the molecular weight for $C_{12}H_8N_2O_3$ is 228, two moles of alkali per mole of sublimate were used. The neutral solution was then concentrated in vacuum until all of the methanol had been removed. The colorless, crystalline precipitate (I) which had separated from the aqueous solution was filtered off, dried and recrystallized from benzene. Long, glistening

needles were obtained which melted at 220° with sublimation. The yield was 55 mg. corresponding to 96% of the theoretical.

Anal. Calcd. for $C_{10}H_{10}N_2O$: C, 69.00; H, 5.75; N, 16.10. Found: C, 69.19; H, 5.89; N, 16.40.

Picrate.—The picrate of this neutral hydrolysis product was obtained by adding a solution of picric acid in benzene to a hot benzene solution of the compound. The picrate separated on cooling as long, deep red needles which melted at 168–170° with decomposition.

Anal. Calcd. for $C_{16}H_{13}N_5O_7$: N, 17.35. Found: N, 17.36.

Iodo Derivative.—The iodo derivative was easily prepared by adding a solution of iodine in potassium iodide to a dilute solution of the compound in 5% aqueous sodium hydroxide. It crystallized in clusters of long colorless needles, m. p. 186°. It was soluble in alcohol and acetone, insoluble in water, and quite stable under ordinary conditions.

Anal. Calcd. for $C_{10}H_9IN_2O$: I, 42.30. Found: I, 42.31.

Hydrolysis of Compound $C_{10}H_{10}N_2O$.—Forty mg. of the product of methanolic alkaline hydrolysis, $C_{10}H_{10}N_2O$ (I), was refluxed for two hours with a 25% aqueous solution of potassium hydroxide. Nitrogen was passed through the solution during the hydrolysis and the volatile base trapped in hydrochloric acid. This base was identified as monomethylamine by preparation of the hydrochloride and the chloroplatinate. From the alkaline solution indole-2-carboxylic acid was isolated in good yield. It melted at 204° and did not depress the melting point of an authentic sample.

Synthesis of Indole-2-carboxylic Acid Methyl Amide (I).—To confirm the identity of the neutral $C_{10}H_{10}N_2O$ product with indole-2-carboxylic acid N-methyl amide this compound was synthesized by the following two methods. 1. Indole-2-carboxylic acid chloride was prepared in the manner previously described[3] and was condensed in benzene solution with methylamine. Long, lustrous needles were obtained on recrystallization from benzene and melted at 219° with sublimation. No depression was observed in a mixed m. p. determination with the neutral product derived from gliotoxin. 2. The methyl amide was also obtained in good yield when indole-2-carboxylic acid ethyl ester reacted with a concentrated alcoholic solution of methylamine. The monomethyl amide of indole-2-carboxylic acid was readily soluble in ethanol, methanol and acetone; less soluble in cold benzene but soluble in hot benzene; it dissolved in hot water and crystallized out on cooling as lustrous, hexagonal platelets. It absorbed bromine in acetic acid solution to yield a crystalline bromo derivative, m. p. 185°. The iodo derivative was described above. The methyl amide coupled in alkaline solution with diazotized sulfanilic acid to form a deep orange-red solution; it gave a positive Ehrlich reaction (*p*-dimethylaminobenzaldehyde and concentrated hydrochloric acid).

Synthesis of the Selenium Degradation Product, $C_{12}H_8N_2O_2$ (II).—Although oxalic acid was not isolated from the hydrolysis products of the selenium sublimate, in view of the structure established for the remainder of the molecule, there was little doubt but that this dicarboxylic acid represented the missing fragment. This assumption was fully justified by the synthesis of the selenium degradation product (II) in the following manner.

Six hundred mg. of indole-2-carboxylic acid methyl amide (I) was dissolved in 10 ml. of dry pyridine and 25 ml. of dry ether added; to this solution was added slowly and with cooling a solution of 600 mg. of ethyl oxalochloride in 25 ml. of anhydrous ether. As the two solutions were mixed, a crystalline precipitate was formed which consisted partially of unchanged amide and partially of pyridine hydrochloride. The mixture was allowed to stand at room temperature for fifteen hours. The crystalline material was removed by filtration and the filtrate evaporated in vacuum. The sirupy residue crystallized upon the addition of ethanol; 115 mg. of pale yellow rhombs was obtained, m. p. 255°. The mother liquors contained some unchanged amide which was recovered and some non-crystalline oil, which probably represented uncyclized condensation products. The synthetic compound was identical in every respect with that isolated from gliotoxin. A mixed m. p. determination showed no depression.

Summary

The degradation of gliotoxin by selenium has been shown to yield 2-methyl-1,3,4-triketotetrahydropyrazino-[1.2-a]-indole. The structure of this substance has been determined by degradation and by synthesis. This formulation is in agreement with the structure of the product of the hydriodic acid reduction of gliotoxin previously published.

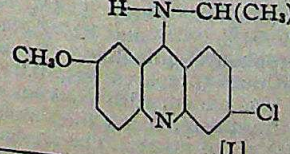
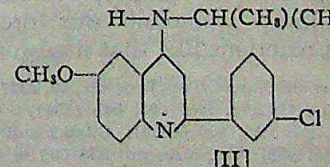
Some Quinolines Patterned as "Open Models" of Atabrine

BY HENRY GILMAN AND SYDNEY M. SPATZ[1]

It seemed of interest to prepare some so-called open models of atabrine [I] in connection with studies on attempted correlations of constitution with antimalarial action. One of these models is 6-methoxy-2-(3′-chlorophenyl)-4-[(α-methyl-δ-diethylaminobutyl)-amino]-quinoline [II]. This compound has a chlorophenyl group in place of the fused chlorobenzo group in atabrine.



[I]



[II]

Compound [II] was synthesized by the sequence of reactions shown beyond.

The over-all yield is quite satisfactory. *m*-Chlorophenyllithium was prepared in 70% yield

(1) Present address: National Aniline Division, Allied Chemical and Dye Corporation, Buffalo, New York.

by the following halogen-metal interconversion reaction, which recent[2] related studies show to be of broad applicability for the preparation of a wide variety of substituted aryllithium compounds.

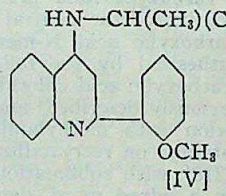
$$m\text{-ClC}_6\text{H}_4\text{Br} + n\text{-C}_4\text{H}_9\text{Li} \longrightarrow m\text{-ClC}_6\text{H}_4\text{Li} + n\text{-C}_4\text{H}_9\text{Br}$$

4 - Chloro - 6 - methoxy - 2 - (3′ - chlorophenyl)-quinoline [III] was also prepared from 4-chloro-6-methoxyquinoline and *m*-chlorophenyllithium, thereby establishing the position of N-oxide halogenation. It is interesting to note in connection with this reaction that the γ-quinolyl chlorine which is sufficiently reactive to undergo condensation with 1-diethylamino-4-aminopentane, but relatively unreactive toward the RLi compound, does not show any deactivating effect on the anil linkage.[3] The use of substituted RLi compounds provides, in general, a better approach than other more involved procedures hitherto used for the preparation of variously substituted aryl-quinolines.

Although a shift of the chlorine from the 6-position to the 7-position in atabrine extinguishes the antimalarial action,[4a] there was no basis for predicting the effect of a compound in which the *m*-chlorophenyl group of [II] was replaced by a *p*-chlorophenyl group. It is known that 6-chloro-8-dialkylaminoalkylaminoquinolines are weakly active in avian malaria, but a shift of the chlorine atom to the 7-position confers increased activity upon the molecule. Accordingly, 6-methoxy-2-(4′-chlorophenyl) - 4 - [(α - methyl - δ - diethylaminobutyl) - amino] - quinoline was prepared by a sequence of reactions like that used for [II], *p*-chlorophenyllithium being used in place of *m*-chlorophenyllithium. This compound, as well as [II], showed *antimalarial* activity.

This suggested an examination of a chlorine-free type, because some quinoline antimalarials are known to retain their biologic effect without the presence of a chlorine. 6 - Methoxy - 2 - phenyl - 4 - [(α - methyl - δ - diethylaminobutyl) - amino]-quinoline was synthesized, and found to be active in experimental malaria.

Although the positions of the chlorine in the new compounds previously mentioned are without appreciable effect, the position of the methoxy group is important. A chlorine-free compound having the methoxy group in the phenyl and not in the quinolyl nucleus was prepared. This 2-(2′ - methoxyphenyl) - 4 - [(α - methyl - δ - diethylaminobutyl) - amino] - quinoline [IV] was found to be inactive.



Experimental

***m*-Chlorophenyllithium.**—To a vigorously stirred, clear filtered solution of 0.2 mole of *n*-butyllithium in 250 cc. of ether, cooled to −35°, was added 38.3 g. (0.2 mole) of *m*-chlorobromobenzene in 50 cc. of ether. Fifty-cc. aliquots were withdrawn at three-minute intervals and carbonated with finely powdered dry-ice. The yields of *m*-chlorobenzoic acid were: 50.3% (3 min.); 66% (6 min.); 69.7% (9 min.); 67.7% (12 min.); and 48.4% (16 min.). Therefore, the optimal yield of this RLi compound at −35° is obtained over a range of six to twelve minutes. From a related experiment at room temperature and for a twelve minute period, the yield of crude *m*-chlorobenzoic acid was 29.4%. Mr. Wright Langham obtained 50% of crude acid (m. p. 145–149°) or 42% of purer acid (m. p. 149–151°) by the rapid addition at room temperature of 0.03 mole of *n*-butyllithium to 0.02 mole of *m*-chlorobromobenzene, with carbonation being carried out at the end of two minutes.

Temperature Effect on Addition of *m*-Chlorophenyllithium to 6-Methoxyquinoline.—These addition reactions were carried out as an index to the more favorable temperature of addition of the RLi compound to some of the quinolines. The yields of anil addition product (2-*m*-chlorophenyl-6-methoxyquinoline) were: 11.1% (−35°); 29.6% (−7 to −5°); 49–54% (0°); and 16.7% (36°).

6-Methoxy-2-(3′-chlorophenyl)-quinoline.—To a solution of *m*-chlorophenyllithium (prepared from 0.2 mole of *m*-chlorobromobenzene) was added, with vigorous stirring and in a dry nitrogen atmosphere, 15.9 g. (0.1 mole) of 6-methoxyquinoline in 100 cc. of ether. The ice-bath was removed, and stirring was continued for ten minutes. After hydrolyzing by pouring the entire reaction mixture into ice water, the ether layer was separated, concentrated

to about one-half the volume, and to this solution was added a hot alcoholic solution of 27 g. of picric acid. The picrate was filtered off (after chilling the solution in an ice box overnight), dried, and decomposed by boiling with dilute alkali. The crude red-brown product was dissolved in hot benzene–petroleum ether (b. p. 60–70°) mixture and separated from an insoluble dark-colored gum by filtration. On cooling, there was obtained 11.9 g. of almost colorless crystals of 6-methoxy-2-(3′-chlorophenyl)-quinoline melting at 110–111°. An additional 1.4 g. from the filtrate gave a total yield of 49.3%. From a duplicate experiment, the yield was 53%. When the synthesis was carried out at −35°, the yield was only 11.1%; and a preparation at room temperature gave 16.7%.

Anal. Calcd. for $C_{16}H_{12}ONCl$: N, 5.20. Found: N, 5.28.

The **picrate,** prepared in a customary manner, as glistening yellow crystals, melted at 196–197°.

Anal. Calcd. for $C_{22}H_{15}O_8N_4Cl$: N, 11.24. Found: N, 11.35.

6-Methoxy-2-(3′-chlorophenyl)-quinoline-N-oxide.—A 700 cc. chloroform solution of 32.5 g. (0.12 mole) of 6-methoxy-2-(3′-chlorophenyl)-quinoline and 32 g. (0.23 mole) of perbenzoic acid was kept in an ice box for three days. The ruby red solution was concentrated to a volume of about 250 cc., diluted with 100 cc. of ethanol, brought to a boil and then added with stirring to a hot concentrated alcoholic solution of 32 g. of hydrated picric acid. On cooling, the yellow crystalline picrate (m. p. 155–158°) precipitated. The unrecrystallized picrate was dried and then decomposed by dilute alkali to yield 25 g. (73%) of the crude N-oxide (m. p. 147–149°). Recrystallization from a 1:1 alcohol–benzene mixture gave 23 g. (67%) of N-oxide melting at 153–154°.

Anal. Calcd. for $C_{16}H_{12}O_2NCl$: N, 4.91. Found: N, 4.99.

The **picrate,** prepared in hot alcohol solution from the N-oxide, separated on cooling as pale yellow rosets melting at 158.5–159°.

Anal. Calcd. for $C_{22}H_{15}O_9N_4Cl$: N, 10.89. Found: N, 10.96.

4-Chloro-6-methoxy-2-(3′-chlorophenyl)-quinoline.—Ten grams (0.035 mole) of 6-methoxy-2-(3′-chlorophenyl)-quinoline-N-oxide was treated with 43 g. (0.28 mole) of phosphorus oxychloride. Reaction was instantaneous, and the mixture was heated, first on a water-bath for ten minutes, and then gently over asbestos for twenty minutes. The mixture was then poured upon 300 g. of chopped ice, and the crude chlorination product filtered off. An additional quantity was obtained by making the filtrate alkaline. Crystallization from a 3:1 ethanol–pyridine mixture gave a product melting at 153–154°. The yield was 6.7 g. (63.2%). A mixed m. p. with the parent N-oxide (which melts at the same temperature) was 129–133°. From a second preparation, the yield was 63.8%.

Anal. Calcd. for $C_{16}H_{11}ONCl_2$: N, 4.61. Found: N, 4.77.

The same compound (mixed m. p.) was obtained by interaction of 1.1 g. (0.0057 mole) of 4-chloro-6-methoxyquinoline and *m*-chlorophenyllithium in ether in a yield of 34.7%.

6-Methoxy-2-(3′-chlorophenyl)-4-[(α-methyl-δ-diethylaminobutyl)-amino]-quinoline.—Four grams of 4-chloro-6-methoxy-2-(3′-chlorophenyl)-quinoline and 5.0 g. (2.4 equivalents) of 1-diethylamino-4-aminopentane were heated at 200–205° for 100 hours. The melt was worked up in the manner described later for the preparation of the 4′-chlorophenyl isomer. The 6-methoxy-2-(3′-chlorophenyl)-4-[(α-methyl-δ-diethylaminobutyl)-amino]-quinoline was obtained as a yellow, amorphous powder in a yield of 3.4 g. (60.7%).

Anal. Calcd. for $C_{26}H_{32}ON_3Cl$: N, 9.87. Found: N, 9.63.

The compound is soluble in cold ethanol, forming a brown solution with a marked greenish fluorescence. It is also soluble in cold acetone and in cold benzene with red-blue fluorescence, but difficultly soluble in ether.

6-Methoxy-2-(4′-chlorophenyl)-quinoline.—To an ether solution of *p*-chlorophenyllithium (prepared from 0.2 mole of *p*-chlorobromobenzene) was added a solution of 27 g. (0.18 mole) of 6-methoxyquinoline in 30 cc. of ether. The addition was over a two-minute period, and stirring was continued for an additional five minutes. The orange colored, crystalline intermediate N-lithium compound settled out immediately. After hydrolysis, the ether layer was dried; and removal of the ether left an oily residue which crystallized on cooling to long needles melting at 194–195°. Recrystallization from an ethanol–pyridine mixture did not raise the melting point. The yield was 23 g. (50.2%).

Anal. Calcd. for $C_{16}H_{12}ONCl$: N, 5.20; Cl, 13.15. Found: N, 5.35; Cl, 12.99.

The **picrate,** prepared from a hot glacial acetic acid solution of the quinoline compound and a hot ethanolic solution of picric acid, formed yellow glistening crystals which melted at 205°.

Anal. Calcd. for $C_{22}H_{15}O_8N_4Cl$: N, 11.24. Found: N, 11.30.

6-Methoxy-2-(4′-chlorophenyl)-quinoline-N-oxide.—A tetrachloroethane solution of 19 g. (0.07 mole) of 6-methoxy-2-(4′-chlorophenyl)-quinoline was added slowly with shaking to an ice-cold solution of 18.4 g. (0.13 mole) of perbenzoic acid in 500 cc. of chloroform. Oxidation proceeded slowly as indicated by the gradual conversion of the difficultly soluble parent compound to the more soluble N-oxide. At the end of one week, the red solution was concentrated to a volume of about 400 cc.; and extracted with dilute alkali. After drying and further concentration, the oil was dissolved in ethanol and treated with a slight excess of picric acid in hot alcohol to give 27 g. (73%) of the picrate (m. p. 171–172°). From the picrate and alkali was obtained the N-oxide which after crystallization from ethanol softened at 164° and melted at 166–168°. The yield of pure N-oxide was 11 g. (55%).

Anal. Calcd. for $C_{16}H_{12}O_2NCl$: N, 4.91; Cl, 12.42. Found: N, 4.74; Cl, 12.22.

4-Chloro-6-methoxy-2-(4′-chlorophenyl)-quinoline.—Seven grams (0.025 mole) of 6-methoxy-2-(4′-chlorophenyl)-quinoline-N-oxide was treated with 40 g. (0.26 mole) of phosphorus oxychloride in the manner described for the other chlorination. After hydrolysis, the gummy material solidified to an amorphous body, which after crystallization from hot methanol melted at 163.5–164°. The yield was 5.7 g. (76.5%).

Anal. Calcd. for $C_{16}H_{11}ONCl_2$: N, 4.61; Cl, 23.33. Found: N, 4.72; Cl, 23.06.

A mixed m. p. with a specimen prepared from 6-methoxy-4-chloroquinoline and *p*-chlorophenyllithium in 48% yield showed no depression. A mixed m. p. with the parent N-oxide was 138–145°.

6-Methoxy-2-(4′-chlorophenyl)-4-[(α-methyl-δ-diethylaminobutyl)-amino]-quinoline.—Two and one-half grams of 4-chloro-6-methoxy-2-(4′-chlorophenyl)-quinoline and 2.85 g. (2.2 mole equivalents) of 1-diethylamino-4-aminopentane were heated at 200° for 72 hours. The melt was dissolved in warm ethanol, and added to a slight excess of dilute alkali. The gummy product was dissolved in warm ethanol and precipitated as a yellow amorphous product by the slow addition of water. The yield of dry powdery product was 2.4 g. (69%). The compound is soluble in cold ethanol, forming a brown solution which has a blue-green fluorescence.

Anal. Calcd. for $C_{26}H_{32}ON_3Cl$: N, 9.87. Found: N, 9.72.

2-(2′-Methoxyphenyl)-quinoline.—To an ether solution of *o*-methoxyphenyllithium (prepared by a halogen-metal interconversion starting with 0.26 mole of *o*-bromoanisole, in a three-minute reaction with *n*-butyllithium) was added 28.5 g. (0.22 mole) of freshly distilled quinoline in 30 cc. of ether. The reaction was carried out at −14° over a period

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of about twelve minutes, and hydrolysis was effected by ice water. The picrate, formed from the hydrolyzate, was decomposed by boiling with 5% sodium hydroxide. After distilling off the benzene used to extract the oil, the largest fraction was a heavy yellow oil distilling at 201–204° (2 mm.) (chiefly at 203.5°). The yield was 24 g. (41.2%).

Anal. Calcd. for $C_{16}H_{13}ON$: N, 5.96. Found: N, 6.11.

In two subsequent preparations, approximately the same yields were obtained, an 18% recovery of quinoline was effected, and no *n*-butylquinoline was isolated. Accordingly, it appears that an improved yield might be had by a longer period of reaction of the RLi compound and quinoline at the temperature used.

2-(2′-Methoxyphenyl)-quinoline hydrochloride was prepared in quantitative yield by treating a dry ether solution of the quinoline compound with hydrogen chloride. The hydrochloride is precipitated from an ethanolic solution by dry ether, as cream colored, fine crystals which melt at 184.5–185° with decomposition. The salt is easily hydrolyzed to the free base.

Anal. Calcd. for $C_{16}H_{14}ONCl$: N, 5.16; Cl, 13.06. Found: N, 5.17; Cl, 12.74.

2-(2′-Methoxyphenyl)-quinoline picrate, prepared from either the free base or the hydrochloride, melts at 177–178°.

Anal. Calcd. for $C_{22}H_{16}O_8N_4$: N, 12.07. Found: N, 12.01.

2-(2′-Methoxyphenyl)-quinoline-N-oxide.—A one-liter chloroform solution of 46.4 g. (0.2 mole) of 2-(2′-methoxyphenyl)-quinoline and two equivalents of perbenzoic acid were kept in a refrigerator for two days. The solution was concentrated to a volume of about 300 cc., and to it was added a hot solution of 52 g. of picric acid in 300 cc. of ethanol. The crude picrate, decomposed by dilute alkali, gave a dark tan product. Crystallization from ethanol–water gave 34 g. (68.6%) of large, glassy, tan-colored crystals melting at 178–178.5°.

An alternate procedure for isolating the N-oxide is to concentrate the chloroform solution to one-third its volume; extract with dilute alkali to remove the benzoic acid; dry the chloroform solution over sodium sulfate, and then recrystallize the 16.2 g. of crude residue (after removing the chloroform) from ethanol. The yield was 11.7 g. (64%) of product melting at 178–178.5°.

Anal. Calcd. for $C_{16}H_{13}O_2N$: N, 5.58. Found: N, 5.76.

The **picrate** of 2-(2′-methoxyphenyl)-quinoline-N-oxide melts at 133.5–134°.

Anal. Calcd. for $C_{22}H_{16}O_9N_4$: N, 11.67. Found: N, 11.66.

4-Chloro-2-(2′-methoxyphenyl)-quinoline.—From a reaction between 5.8 g. (0.023 mole) of 2-(2′-methoxyphenyl)-quinoline-N-oxide and 21.5 g. (0.14 mole) of phosphorus oxychloride was obtained 3.5 g. (56.5%) of the 4-chloro compound as pale yellow needles melting at 96–98° after crystallization from petroleum ether (b. p. 60–68°). The compound is very soluble in ethyl ether, hot methanol, and hot ethanol. A mixed m. p. determination with a specimen prepared from *o*-methoxyphenyllithium and 4-chloroquinoline showed no depression.

Anal. Calcd. for $C_{16}H_{12}ONCl$: N, 5.20; Cl, 13.15. Found: N, 5.37; Cl, 12.91.

The **picrate** of 4-chloro-2-(2′-methoxyphenyl)-quinoline melts at 200–201°.

Anal. Calcd. for $C_{22}H_{15}O_8N_4Cl$: N, 11.24. Found: N, 11.19.

Quinoline-N-oxide hydrochloride was prepared with some modifications of the procedure of Meisenheimer.[5] The yield, in the following typical experiment, was practically quantitative. A 600-cc. chloroform solution of 25.2 g. (0.2 mole) of quinoline and 32.2 g. (0.23 mole) of perbenzoic acid was kept in an ice box for thirty-six hours. After concentrating to a volume of about 400 cc., the solution was extracted with 10% hydrochloric acid, and the extract washed with chloroform. The extract was evaporated to dryness under reduced pressure, and the residue was crystallized by dissolving in hot absolute ethanol followed by the addition of anhydrous ether. The product was filtered, after cooling, and dried ***in vacuo*** over calcium chloride. The hydrochloride melted at 130–132°, and the picrate at 142–143°. The 4-chloroquinoline was prepared from the N-oxide by Meisenheimer's[6] procedure, with the yield and m. p. reported by him.

2-(2′-Methoxyphenyl)-4-[(α-methyl-δ-diethylaminobutyl)-amino]-quinoline.—Four grams of 4-chloro-2-(2′-methoxyphenyl)-quinoline and 5.15 g. (2.2 mole equivalents) of 1-diethylamino-4-aminopentane were heated at 190–200° for seventy-five hours. The product was purified by distillation (b. p. 248–255° (0.025 mm.)). The yellow oil cooled at room temperature to a glass-like, transparent substance, and the yield was 4 g. (69%).

Anal. Calcd. for $C_{25}H_{33}ON_3$: N, 10.74. Found: N, 10.56.

6-Methoxy-2-phenylquinoline.—From 12.7 g. (0.08 mole) of 6-methoxyquinoline and 0.1 mole of phenyllithium was obtained 12.4 g. (66%) of pure product, melting at 132–133°. (The m. p. of the picrate was 205°.) These constants agree with those reported by Döbner,[6] who prepared 6-methoxy-2-phenylquinoline by decarboxylation of α-phenylquininic acid; the latter was prepared in an 18% yield from *p*-anisidine, pyruvic acid and benzaldehyde.

6-Methoxy-2-phenylquinoline-N-oxide.—From a reaction between 22.9 g. (0.17 mole) of perbenzoic acid in 400 cc. of chloroform and 26.5 g. (0.11 mole) of 6-methoxy-2-phenylquinoline was obtained, through the picrate, 6-methoxy-2-phenylquinoline-N-oxide as thick, lustrous crystals melting at 170–171° after crystallization from ethanol. The yields were in the range of 55–65%.

Anal. Calcd. for $C_{16}H_{13}O_2N$: N, 5.58. Found: N, 5.66.

4-Chloro-6-methoxy-2-phenylquinoline.—From 15.7 g. (0.063 mole) of 6-methoxy-2-phenylquinoline-N-oxide and 76.5 g. (0.5 mole) of phosphorus oxychloride was obtained 13.7 g. (81%) of 4-chloro-6-methoxy-2-phenylquinoline as long needles melting at 110–111° after crystallization from ethanol. In smaller-sized preparations using 1–5 g. of the N-oxide, the yields were in the range of 88–91%. Incidentally, the over-all yield by our three-stage procedure starting with 6-methoxyquinoline is larger than that obtained by the longer method of John and Lukas.[7]

The same compound (mixed m. p.) was obtained (in 61.5% yield) by the reaction of 4-chloro-6-methoxyquinoline with phenyllithium. The 4-chloro-6-methoxyquinoline, together, coincidentally, with 2-chloro-6-methoxyquinoline, was prepared by the method of Magidson and Rubtsov.[8] The yield of the 4-chloro isomer was 35.5%, and that of the 2-chloro isomer was 58.4%. The necessary precursor, 6-methoxyquinoline-N-oxide hydrochloride, was obtained in 87.5% yield; m. p., 192–194°, and the m. p. of the picrate was 173–174°.[8]

6-Methoxy-2-phenyl-4-[(α-methyl-δ-diethylaminobutyl)-amino]-quinoline.—Four grams of 4-chloro-6-methoxy-2-phenylquinoline and 5.15 g. (2.2 mole equivalents) of 1-diethylamino-4-aminopentane were heated at 135° for twenty-four hours, at 175–180° for twenty-four hours and then at 210° for twenty-four hours. From the glassy melt was obtained (after solution in ethanol and treatment with 2% sodium hydroxide) 4 g. (69%) of a pale tan, amorphous powder, insoluble in water, and soluble in ethanol acetone and benzene. In the latter two solvents the compound exhibits a weak bluish fluorescence.

Acknowledgments.—The authors are grateful to Parke Davis and Company for arranging for the biological tests, the results of which will be reported in detail elsewhere. In addition to the general results mentioned previously, the following data include some of the intermediates examined for antimalarial activity in avian infections: 4-chloro-6-methoxy-2-phenylquinoline, 2-(2′-methoxyphenyl)-quinoline hydrochloride, 6-methoxy-2-(4′-chlorophenyl)-quinoline, 6-methoxy-2-(4′-chlorophenyl)-quinoline-N-oxide, 4-chloro-6-methoxy-2-(4′-chlorophenyl)-quinoline, 6-methoxy-2-(3′-chlorophenyl)-quinoline, 6-methoxy-2-(3′-chlorophenyl)-quinoline-N-oxide, and 4-chloro-6-methoxy-2-(3′-chlorophenyl)-quinoline were inactive; and 4-chloro-2-(2′-methoxyphenyl)-quinoline was of doubtful activity.

Summary

Four α-aryl-γ-chloroquinolines have been conveniently prepared through a three-step sequence of reactions involving: (1) RLi addition to the anil linkage; (2) N-oxide formation of the anil addition product; and (3) halogenation of the latter with phosphorus oxychloride. Condensation of these variously substituted γ-chloroquinolines with 1-diethylamino-4-aminopentane resulted in a series of compounds having essentially the functional groups of the more highly fused atabrine.

Antimalarial activity in avian malaria was shown by 6-methoxy-2-(3′-chlorophenyl)-4-[(α-methyl - δ - diethylaminobutyl) - amino] - quinoline, and by the isomeric (4′-chlorophenyl) compound. The presence of chlorine is not a necessary condition for activity, for 6-methoxy-2-(phenyl) - 4 - [(α - methyl - δ - diethylaminobutyl) - amine]-quinoline is also active. However, the position of the methoxy group (in the chlorine-free type) is important, because 2-(2′-methoxyphenyl) - 4 - [(α - methyl - δ - diethylaminobutyl)-amino-quinoline, unlike the 6-methoxy isomer, is inactive.

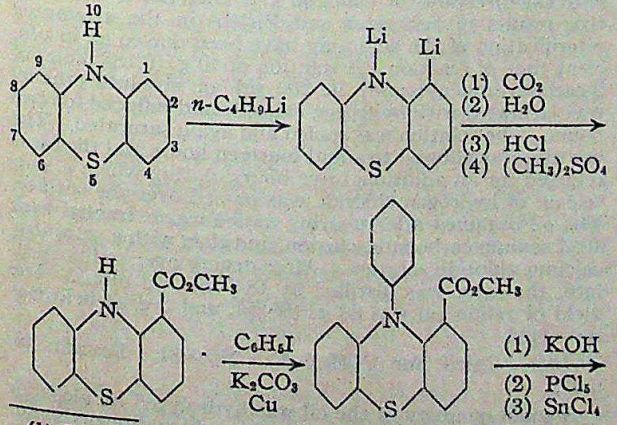
The Metalation of Phenothiazine[1]

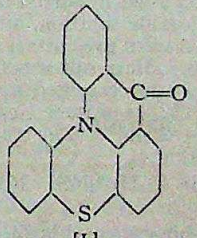
BY HENRY GILMAN, DAVID A. SHIRLEY AND PAUL R. VAN ESS

Phenothiazine is mono-metalated by *n*-butyllithium to give an RLi compound which, subsequent to carbonation, yields a mono-carboxylic acid. On the basis of earlier studies on metalations,[2] it appeared probable that metalation occurred in the 1- or the 4-position. After some unsuccessful attempts to prepare 1-carboxyphenothiazine by ring closure reactions, the acid obtained by metalation was shown to have the carboxyl group in the 1-position by the following indirect proof.



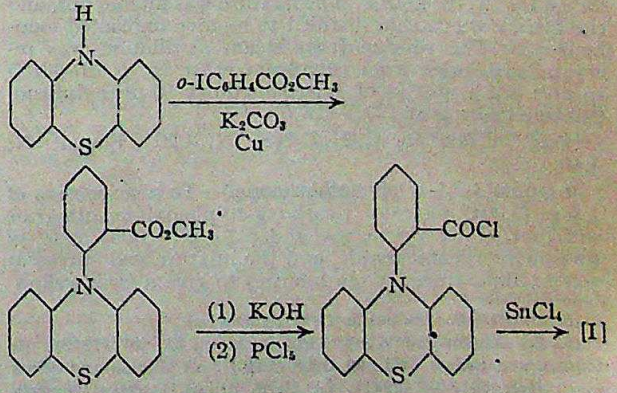
(1) Paper LIV in the series: "The Relative Reactivities of Organometallic Compounds"; the preceding paper is in THIS JOURNAL, 65, 1729 (1943).

(2) See p. 536 of Gilman, "Organic Chemistry," John Wiley and Sons, Inc., New York, N. Y., 1943.



[I]

The identity of 9-quino(3,2,1-kl)phenothiazinone [I] prepared by the above sequence of reactions was established by comparison with the product obtained by the following transformations



The metalation of phenothiazine by *n*-butyllithium in the 1-position is of interest for two reasons. First, all previously described nuclear

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

substitution reactions of phenothiazine take place in the 3-position, or para to the nitrogen. This is an additional[2] illustration of the applicability of metalation in making available positions otherwise inaccessible by the more common nuclear substitution reactions. Second, in view of a subsequent observation, one might have expected metalation to be ortho to sulfur rather than ortho to nitrogen. In a reaction[3] in which molar equivalents of N-ethylcarbazole and dibenzothiophene were allowed to compete for one molar equivalent of *n*-butyllithium, the dibenzothiophene was metalated exclusively.

It should be mentioned that exceptions to the rule of metalation by *n*-butyllithium of an ortho-position to a hetero element are methyl phenyl sulfide,[4a] triphenylamine,[4b] and the closely related triphenylarsine[4c] and triphenylphosphine.[4d]

Experimental

Metalation of Phenothiazine.—To 800 ml. of an ethereal solution of *n*-butyllithium, prepared from 104 g. (0.76 mole) of *n*-butyl bromide and 20 g. (2.9 g. atoms) of lithium was added slowly with stirring 40 g. (0.20 mole) of phenothiazine.[5] The mixture was stirred at room temperature under an atmosphere of dry nitrogen for twenty hours, and then allowed to stand an additional fifteen hours before pouring jetwise on a slurry of ether and excess crushed solid carbon dioxide. The mixture was allowed to stand until all solid carbon dioxide had disappeared, and was then hydrolyzed by the addition of excess water. The aqueous layer was separated, and the aqueous extracts were acidified with hydrochloric acid to precipitate 32 g. of crude acid. This solid was dissolved in a minimal amount of 10% sodium hydroxide solution, and then 40% sodium hydroxide was added until precipitation of the sodium salt was complete. This sodium salt was filtered off, dissolved in water, and the solution acidified with hydrochloric acid to precipitate 25 g. (52%) of pure 1-carboxyphenothiazine which melted at 264–264.5°. The compound can be crystallized from 70% ethanol.

Anal. Calcd. for $C_{13}H_9O_2NS$: N, 5.76. Found: N, 6.01.

The 1-carbomethoxyphenothiazine, melting at 113–113.5°, was obtained in a 32% yield by the action of dimethyl sulfate on an alkaline solution of the acid.

1-Carbomethoxy-10-phenylphenothiazine.—Four grams (0.016 mole) of 1-carbomethoxyphenothiazine, 100 g. of iodobenzene, 20 g. of finely ground anhydrous potassium carbonate, and 2.5 g. of copper bronze were stirred and refluxed for twelve hours. The mixture was filtered hot, and the filtrate was steam distilled to remove unreacted iodobenzene. The residue from steam distillation was recrystallized twice from petroleum ether (b. p. 80–110°) to give 3.2 g. (60%) of 1-carbomethoxy-10-phenylphenothiazine melting at 123.5–124.5°.

Anal. Calcd. for $C_{20}H_{15}O_2NS$: N, 4.20. Found: N, 4.40.

9-Quino(3,2,1-*kl*)phenothiazinone.[6]—To a suspension of 1.5 g. (0.0047 mole) of 1-carboxy-10-phenylphenothiazine in 60 ml. of dry xylene was added 1.4 g. (0.0067 mole) of phosphorus pentachloride, and the mixture was stirred at room temperature for ten minutes to give a clear yellow-brown solution. The solution was cooled in an ice-bath, and a solution of 6.25 g. (0.024 mole) of anhydrous stannic chloride in 20 ml. of xylene was added dropwise to the stirred solution over a period of ten minutes. The stirring was continued for forty-five minutes after the addition had been completed. The dark red mixture was hydrolyzed by the dropwise addition of 25 ml. of cold concentrated hydrochloric acid followed by 30 ml. of water. The yellow xylene layer was separated, washed with dilute sodium carbonate solution to remove acid, and evaporated to dryness to yield a yellow solid. This solid was recrystallized from a mixture of benzene–petroleum ether (b. p. 80–110°) to give 1.2 g. (85%) of bright yellow-green minute crystals. The ketone melted at 218–219°.

Anal. Calcd. for $C_{19}H_{11}ONS$: N, 4.64; mol. wt., 301. Found: N, 4.55; mol. wt. (benzene, cryoscopic), 300.

10-(2′-Carbomethoxy)-phenylphenothiazine.—A mixture of 13.2 g. (0.05 mole) of methyl *o*-iodobenzoate, 10 g. (0.05 mole) of phenothiazine, 6 ml. of nitrobenzene, 7.5 g. of potassium carbonate, 85 ml. of xylene, and 0.2 g. of copper bronze was stirred and refluxed for fourteen hours. The mixture was filtered hot and washed with boiling xylene. Upon cooling, green crystals were precipitated from the xylene solution. Recrystallization from xylene gave 7.0 g. (42%) of light green prisms melting at 143–144°.

Anal. Calcd. for $C_{20}H_{15}O_2NS$: N, 4.20. Found: N, 4.32.

10-(2′-Carboxy)-phenylphenothiazine.—A suspension of 6.5 g. (0.020 mole) of 10-(2′-carbomethoxy)-phenylphenothiazine in 125 ml. of 15% aqueous potassium hydroxide was refluxed for five hours. The resulting solution was diluted with water and acidified with hydrochloric acid to give a quantitative yield of acidic product melting at 209–210°. One recrystallization from glacial acetic acid gave red-yellow plates melting at 214–215°.

Anal. Calcd. for $C_{19}H_{13}O_2NS$: N, 4.38; neut. equiv., 319. Found: N, 4.60; neut. equiv., 320 and 313.

Ring Closure of 10-(2′-Carboxy)-phenylphenothiazine to 9-Quino(3,2,1-*kl*)phenothiazinone.—One and five-tenths grams (0.0047 mole) of 10-(2′-carboxy)-phenylphenothiazine was treated with phosphorus pentachloride and anhydrous stannic chloride in xylene by the procedure described previously. The product weighed 0.85 g. (60%) and melted at 219°. A mixed m. p. with the compound obtained from the metalation-acid showed no depression.

Attempted Ring Closures. [A] 2-Carboethoxydiphenylamine.—This reaction involved heating 2-carboethoxydiphenylamine with sulfur as a means of preparing 1-carboethoxyphenothiazine. First, 2-carboxydiphenylamine was prepared in 86% yield in essential accordance with the directions of Ullmann and Dieterle.[7] The negative results of Schroeter and Eisleb[8] in the attempted esterification of the acid may have been due to an insufficient time of reaction. A solution of 40 g. (0.188 mole) of 2-carboxydiphenylamine in 200 ml. of absolute ethanol was saturated with hydrogen chloride and refluxed for two hours. The solution was cooled and again saturated. The mixture was allowed to stand fourteen hours and then was refluxed for an additional five hours, during which a slow stream of hydrogen chloride was passed over the surface. The oil obtained after pouring on ice was extracted with 10% sodium carbonate solution, and then with a saturated calcium chloride solution. After drying over sodium sulfate, the ester was distilled at 184–187° (6 mm.). The yield of yellow oil was 33 g. (80%), and 5 g. of acid was recovered.

Anal. Calcd. for $C_{15}H_{15}O_2N$: N, 5.81. Found: N, 6.07.

A small quantity of the oil was hydrolyzed by alcoholic potassium hydroxide to give 2-carboxydiphenylamine (mixed m. p.).

A solution of 4.26 g. (0.02 mole) of 2-carboxydiphenyl-

amine, 1.28 g. (0.04 g. atom) of sulfur, and 0.04 g. of iodine in 20 ml. of *o*-dichlorobenzene was refluxed at 180° for fifteen minutes. The acid is unstable under these conditions for carbon dioxide as well as hydrogen sulfide was evolved. The reaction mixture yielded 2.2 g. of the acid.

In another experiment, 4.82 g. (0.02 mole) of 2-carboethoxydiphenylamine and 1.28 g. of sulfur was heated without solvent in a bath at 285–300°. Hydrogen sulfide was evolved slowly at first, and then the odor of ethyl mercaptan was quite pronounced. Heating was discontinued after two hours, when the evolution of gas had ceased. The products isolated were 1.5 g. of the ester initially used, 0.2 g. of phenothiazine, but no phenothiazine-ester. The phenothiazine is probably formed as a consequence of pyrolysis of the ester, or decarboxylation of the acid (formed by cleavage of the ester) to give diphenylamine which then reacts with sulfur in the usual manner.

[B] Coupling Reactions with 2,2′-Diaminodiphenyl Disulfide.—One of these coupling reactions was patterned after the method used by Kehrmann and Nossenko[9] for the preparation of 1-nitrophenothiazine. A solution of 2,2′-diaminodiphenyl disulfide,[10] 2-bromo-3-nitrobenzoic acid,[11] and of sodium acetate in ethanol was refluxed for twenty-four hours. The diamine and acid were recovered.

A second coupling reaction was a modification of a procedure by Ullmann and Hoz.[12] A mixture of 2,2′-diaminodiphenyl disulfide, potassium *o*-chlorobenzoate, sodium acetate, amyl alcohol, and a trace of copper bronze was refluxed for two hours. The diamine and *o*-chlorobenzoic acid were recovered.

Summary

Phenothiazine is metalated by *n*-butyllithium in the 1-position or ortho to the nitrogen. The structure of the 1-carboxyphenothiazine, obtained by carbonation of the metalation product, was established indirectly by cyclization reactions.

A Large-Scale Preparation of D-Altrose. D-Altrose Oxime and its Rate of Mutarotation[1]

BY ROBERT C. HOCKETT AND LEONARD B. CHANDLER[2]

In 1926, Kunz and Hudson,[3] by the action of aluminum chloride on a chloroform solution of octaäcetyl β-lactose, obtained the "acetochloro" derivative of a new disaccharide which they named neolactose, and which was proved to be a D-galactosyl-D-altrose. Richtmyer and Hudson[4] later improved this preparation by using phosphorus pentachloride along with aluminum chloride, isolated crystalline neolactose and a number of its derivatives, and showed how crystalline D-altrose may be obtained from the disaccharide despite the tendency of this hexose to form an anhydride when it is treated with hydrochloric acid.

When a sample of D-altrose was needed in this Laboratory, we undertook to repeat the preparation described by these authors, both on a much increased scale and with the introduction of short-cuts to eliminate a number of manipulations.

The chief modification was as follows: "α-aceto-chloroneolactose" formed from octaäcetyl lactose but not isolated, was subjected directly to hydrolysis by hydrochloric acid in a water–acetone solution under such conditions as to (1) hydrolyze the chlorine, (2) to remove the acetate groups, and (3) to break the disaccharide link all in a single operation yielding a mixture containing hydrochloric acid, acetic acid, glucose, galactose, altrose and altrosan. Hydrochloric acid was removed with lead carbonate followed by silver carbonate, metallic ions by hydrogen sulfide, acetic acid by distillation, and glucose and galactose by yeast fermentation. Finally, altrose and altrosan were recovered as D-altrose dibenzyl mercaptal as described by Richtmyer and Hudson.[4] From this derivative the crystalline sugar was obtained without seed, as described by Richtmyer and Hudson.[4]

The over-all yield from one kilogram of D-lactose monohydrate was 18 g. of crystalline D-altrose or 3.7% of the theoretical. A more efficient method of preparation of this sugar from α-methyl-D-glucoside was subsequently described by Richtmyer and Hudson.[5]

The oxime of D-altrose and measurements of the rate of mutarotation of this derivative in aqueous solution are described for the first time.

We wish to thank Doctors Hudson and Richtmyer, with whom we made arrangements in connection with this work.

Experimental

D-Altrose Oxime.—Two grams (0.0111 mole) of crystalline altrose was treated with 0.0282 mole of hydroxylamine in methanol at room temperature overnight. After a brief warming on the steam-bath, the solution was concentrated to a colorless sirup (diminished pressure) which was dissolved in a minimum volume of dry methanol. Absolute ethanol was added to turbidity and the solution soon deposited 1.7 g. of fine prisms. Recrystallized by dissolving in 10 cc. of water, filtering, concentrating to a sirup and repeating the process described above, the compound was obtained with a maximum melting point of 143–144° and a

rotation[6] at equilibrium (103 hr.) of −9.8° (*C*, 2.408; *t*, 24.9°; H_2O). The crystals are easily soluble in water, slightly in methanol, and insoluble in ethanol, ether, acetone and chloroform.

Anal. Calcd. for $C_6H_{13}O_6N$: C, 36.9; H, 6.66; N, 7.17. Found: C, 36.9, 37.1, 36.7; H, 6.15, 6.84, 6.86; N, 6.93, 7.04.

Mutarotation of D-Altrose Oxime.—A sample of 0.2422 g. of twice recrystallized material was dissolved into 10.06 cc. of aqueous solution. Twenty-two measurements of the rotations were made in a 2-dm. tube at 25.0 ± 0.5°. The reaction followed an unimolecular course, the calculated velocity constant ($k_1 + k_2$) being 0.0040 with an average variation of ±0.0001. In making this calculation the value obtained for the rotation at t = 748 min. was taken as the rotation at infinite time rather than that at t = 6540 min. since hydrolysis is appreciable after very long contact with water. The *p*H of the water was 5.8.

By plotting log ($\alpha_t - \alpha_\infty$) against time in minutes, a very nearly straight line was obtained. By extrapolation of this line to zero time, the value of log ($\alpha_0 - \alpha_\infty$) was determined graphically and the initial specific rotation[6] found to be −64.0°.

(6) All rotations referred to in this paper represent specific rotations of the D line of sodium unless specified otherwise. Concentrations are grams of solute in 100.0 cc. of solution.

Summary

A large-scale and abbreviated procedure for the preparation of crystalline D-altrose from D-lactose by the method of Richtmyer and Hudson is described.

The oxime of D-altrose is described and measurements of its rate of mutarotation recorded.

Condensation of Cyclohexene Oxide, 1,2-Dichlorocyclohexane, and 3,4-Dichlorohexane with Anisole[1]

BY CHARLES C. PRICE AND GEORGE P. MUELLER[2]

This investigation was undertaken to explore the possibility of synthesizing vicinal *bis*-(*p*-hydroxyphenyl)-hexanes and cyclohexanes by some modification of the Friedel–Crafts type reaction. Such substances are of particular interest in connection with their ability to simulate the physiological activity of the hormone, estrone.

Kursanoff[3,4] has reported the isolation of a diphenylcyclohexane, m. p. 169–171°, which he believed to be the 1,2-isomer, from the aluminum chloride-catalyzed condensation of 1,2-dichlorocyclohexane with benzene. This material has now been shown to be the 1,4-isomer.[5,6] Nenitzescu and Curcaneanu isolated a greater amount of liquid 1,3-diphenylcyclohexane than the crystalline 1,4-isomer. It is thus obvious that, as so frequently happens with the Friedel–Crafts reaction, rearrangement occurred in the replacement of the chlorine atoms. Other similar rearrangements in vicinal, negatively-substituted halides also have been observed.[7]

It was hoped that, due to the greater reactivity of the aromatic nucleus in anisole or phenol, or by modification of the conditions of the Friedel–Crafts condensation, this tendency toward rearrangement might be modified. This hope was only partially realized. Condensations of anisole with 1,2-dichlorocyclohexane using aluminum chloride as the catalyst or with cyclohexene oxide or 1,2-dihydroxycyclohexane using boron fluoride as the catalyst produced poor yields of mixtures of condensation products from which two diastereoisomeric 1,3-dianisylcyclohexanes (I and II), *m*-dianisylbenzene (III) and anisylcyclohexane (IV) were isolated and identified. The fact that no 1,4-dianisylcyclohexane or *p*-dianisylbenzene was isolated is an indication that the tendency to rearrangement was at least somewhat less with anisole than with benzene.

The terphenyl was assigned the meta-orientation on the basis of the non-identity of the free phenol, its dimethyl ether and diacetate with the corresponding ortho and para isomers[8] and zinc dust distillation to yield a small amount of material with the proper melting point for *m*-terphenyl itself.

The 1,3-dianisylcyclohexane, the free phenol and its diacetate each differs from the known 1,1-isomers.[9]

The production of 1,3-dianisylcyclohexane, as well as *m*-dianisylbenzene and anisylcyclohexane, may be accounted for by the intermediate formation of 3-anisylcyclohexene (V). The anisyl group in the cycloölefin should direct addition of a second molecule of anisole to form 1,3-dianisylcyclohexane.[10] Disproportionation of hydrogen between the 3-anisylcyclohexene (V) and the 1,3-dianisylcyclohexanes would account for the

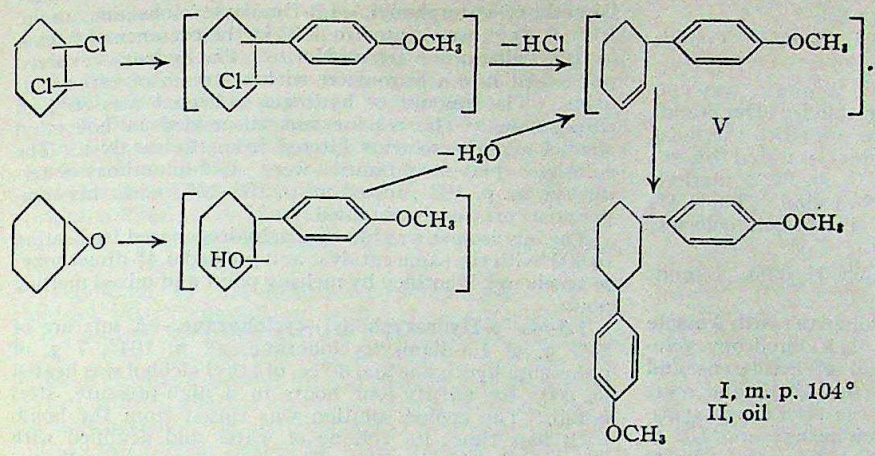
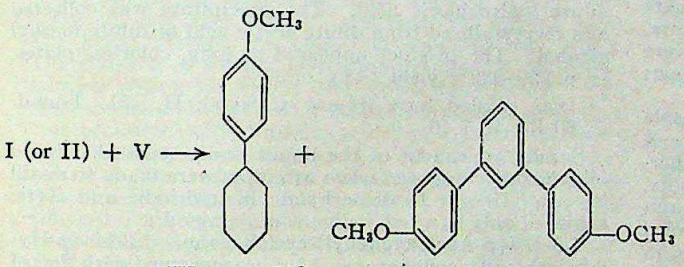
anisylcyclohexane (IV) and *m*-dianisylbenzene (III) actually isolated.



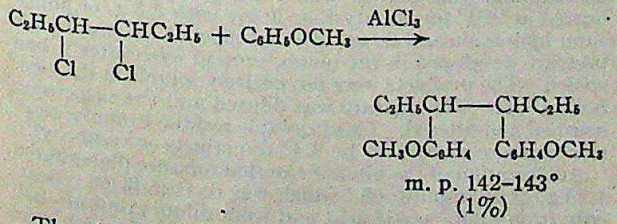
I, m. p. 104°
II, oil



IV, m. p. 58° III. m. p. 198°

For the case of the cyclohexene oxide, opening of the oxide ring has been shown in general to involve an inversion of configuration[11] and would thus produce the *trans*-alcohol as indicated. Dehydration of the corresponding alcohol without the methoxyl group has already been shown to produce 3-phenylcyclohexene.[10]

The open-chain analog of 1,2-dichlorocyclohexane, 3,4-dichlorohexane, was also condensed with anisole. This halide was extremely unreactive in the presence of aluminum chloride but it was possible to obtain a 14% yield of condensation product from which a 1% yield of hexestrol dimethyl ether was crystallized. In view of the work of Nenitzescu,[7,12] it seems likely that the remainder of the condensation product consisted of isomers of hexestrol.



m. p. 142–143°
(1%)

The dihalide used was obtained by ethylation of acetylene with ethyl bromide[13] (20% yield), hydrogenation to *cis*-3-hexene[14] (95% yield) and chlorination[15] (84% yield).

The crystalline and oily isomers of 1,3-*bis*-(*p*-hydroxyphenyl) - cyclohexane and 4,4″-dihydroxy-*m*-terphenyl were found to possess no estrogenic activity when administered to spayed mice in doses up to 0.4 mg. per mouse. 1,3-*bis*-(*p*-Hydroxyphenyl)-cyclohexane showed no androgenic activity at a maximum total dose of 18 mg. per animal in castrated rats.[16]

Experimental[17]

Condensation of Cyclohexene Oxide with Phenol in the Presence of Boron Fluoride.—Boron fluoride was passed through a stirred mixture consisting of 28.8 g. (0.306 mole) of phenol and 5.0 g. (0.051 mole) of cyclohexene oxide at 40–70°. After six hours the purple complex was decomposed in water, extracted with 75 cc. of benzene and the benzene solution washed thoroughly with water and dried. The benzene and excess phenol were removed by distillation, the latter at 16 mm. pressure, and 7.5 g. of a dark oil remained as residue.

A portion of this was dissolved in aqueous sodium hydroxide; in a few minutes a crystalline sodium salt had separated from the solution. All qualitative tests for phenolic compounds failed as did attempts to crystallize the free phenol, its benzoate, 3,5-dinitrobenzoate, *p*-toluenesulfonate, picrate or aryloxyacetic acid derivatives.

A second reaction was carried out using five times the above quantities of reactants by passing boron fluoride through the mixture for ten hours. Fractional distillation of the crude oil yielded 8.9 g. of an oil, b. p. 135–175° (9 mm.). This crystallized upon cooling. It was redistilled and recrystallized, m. p. 103.4°, and proved to be *trans*-1,2-dihydroxycyclohexane. From this fraction a small amount of *p*-cyclohexylphenol was also obtained, m. p. 125–128°.[18] It was identified by conversion to the 3,5-dinitrobenzoate, m. p. 164–166°, and by analysis.

Anal. Calcd. for $C_{12}H_{16}O$: C, 81.76; H, 9.15. Found: C, 81.86; H, 8.71.

Condensation of Cyclohexene Oxide with Anisole in the Presence of Boron Fluoride.—Boron fluoride was bubbled into a mixture of 25 g. (0.255 mole) of cyclohexene oxide and 165 g. (1.53 mole) of anisole at 50° for three hours, with constant stirring. The dark-red complex was decomposed with 400 cc. of water. The organic liquid was extracted with ether, washed thoroughly with water and distilled at reduced pressure from a Claisen flask modified with a Vigreux column.

The first fraction collected was a colorless liquid, b. p. 89–91° (1 mm.). This was redistilled, b. p. 273–276° (740 mm.), and recrystallized several times from dilute ethyl alcohol. The colorless plates, m. p. 56.8–57.5°, were, according to these physical constants,[4] *p*-cyclohexylanisole. It was obtained in 8% yield.

A second fraction, 20 g., was collected, b. p. 95–183°

(1 mm.). Redistillation gave a colorless oil, b. p. 160–165° (1 mm.); n^{25} 1.5694. This proved to be the liquid isomer of 1,3-dianisylcyclohexane. It contained an impurity which gave the liquid a violet fluorescence.

Anal. Calcd. for $C_{20}H_{24}O_2$: C, 81.04; H, 8.16. Found: C, 81.50; H, 8.39.

The third fraction, b. p. 190–245° (1 mm.), was collected as a brown oil, part of which crystallized after standing for a few days. A little ether was added to the mass and the crystals collected. They were purified by recrystallization from petroleum ether (b. p. 96°), methylcyclohexane, and ethyl, butyl or amyl alcohol. The 4,4″-dimethoxy-*m*-terphenyl crystallized in large, colorless plates, m. p. 197–198° (cor.).

Anal. Calcd. for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25. Found: C, 82.67; H, 6.55.

Condensation of 1,2-Dihydroxycyclohexane with Anisole in the Presence of Boron Fluoride.—1,2-Dihydroxycyclohexane was prepared by the method of Senderens and Aboulenc.[19] The equimolecular mixture of *dl* and *meso* forms was used, m. p. 73°.[20] As in the preceding experiment, 27 g. (0.233 mole) of the cyclohexane and 152 g. (1.4 mole) of anisole were stirred at 45° for three hours while boron fluoride was bubbled through the mixture. The same products as in the preceding condensation were isolated with an over-all yield of condensed material about one-fourth as great.

Condensation of 1,2-Dichlorocyclohexane with Anisole in the Presence of Anhydrous Aluminum Chloride.—A 500-cc. flask was equipped with a reflux condenser, thermometer, sealed stirrer and dry-solid addition appendix. 1,2-Dichlorocyclohexane,[21] 41.8 g. (0.273 mole), and anisole, 155 g. (1.43 mole), were placed in the flask and cooled to 5°; 15 g. of anhydrous aluminum chloride was added in small enough portions that the temperature did not rise appreciably. The mixture was stirred for six hours and permitted to stand for sixteen hours in the ice-bath. When worked up, as before, the complex yielded 20 g. of an oil which deposited 2 g. of 4,4″-dimethoxy-*m*-terphenyl upon standing. The crystals were separated and the oil distilled. The lower-boiling fractions yielded 1,2-dichlorocyclohexane and 3 g. of *p*-cyclohexylanisole.

A fraction, 8 g., b. p. 180–220° (3 mm.), was redistilled and a portion, b. p. 191–205° (1 mm.), partially crystallized. The whole was dissolved in a large volume of hot methyl alcohol. A small amount of the terphenyl crystallized and was separated from the solution. Upon standing overnight the solution deposited more crystals, 2 g. of long, white needles. These were recrystallized three times from methyl alcohol and once from ethyl alcohol, m. p. 102.8–104.0°. This proved to be the solid isomer of 1,3-dianisylcyclohexane.

Anal. Calcd. for $C_{20}H_{24}O_2$: C, 81.04; H, 8.16; mol. wt., 296.39. Found: C, 80.93; H, 7.81; mol. wt., 280 (Rast).

The oil remaining from evaporation of the recrystallization liquors was combined with the corresponding fraction from another run, and from 10 g. of oil 4 g. was collected, b. p. 207–210° (1 mm.); n^{25} 1.5769. This oil was the liquid form of 1,3-dianisylcyclohexane, isolated before from cyclohexene oxide and anisole. Its structure and relationship to the solid isomer above was shown by catalytic dehydrogenation to 4,4″-dimethoxy-*m*-terphenyl.

A similar reaction using 76.5 g. (0.5 mole) of the cyclohexane, 324 g. (3.0 mole) of anisole and 50 g. (0.37 mole) of aluminum chloride at 0° for fifty hours gave 16 g. of crude condensation products which were separated into 2 g. of *p*-cyclohexylanisole, 3.5 g. of the crystalline cyclohexane, 9 g. of the oily isomer and 0.5 g. of the terphenyl. The same reaction at 15° for sixty-five hours produced 30 g. of condensation products.

The course of the reaction did not appear to differ materially if carried out at 150–160° for two hours. An attempt to use carbon disulfide as a solvent resulted in a vigorous reaction which produced only ill-smelling, sulfur-containing oils and much tar.

Dehydrogenation of 1,3-Dianisylcyclohexane: 4,4″-Dimethoxy-*m*-terphenyl.—1,3-Dianisylcyclohexane, m. p. 104°, 0.10 g., was heated to 300° in the presence of 0.05 g. of 10% palladium black on Norite. The hydrogen evolved was swept into a nitrometer with a stream of carbon dioxide. The amount of hydrogen collected was 86% of three moles. The residue was suspended in hot ethyl alcohol and the solution filtered from the catalyst. The colorless plates obtained were 4,4″-dimethoxy-*m*-terphenyl, m. p. 193°, mixed m. p. 196–197° with this compound as previously obtained.

The oily isomer was likewise dehydrogenated by heating to 300° with the same catalyst and yielded 4,4″-dimethoxy-*m*-terphenyl, identified by melting point and mixed melting point.

1,3-*bis*-(*p*-Hydroxyphenyl)-cyclohexane.—A mixture of 2.47 g. of 1,3-dianisylcyclohexane, m. p. 104°, 7 g. of potassium hydroxide and 40 cc. of ethyl alcohol was heated at 200° for twenty-four hours in a high-pressure, steel bomb. The cooled solution was rinsed from the bomb with four times its volume of water and acidified with dilute hydrochloric acid. The precipitate was collected and recrystallized from dilute acetic acid or dilute methyl alcohol. The product appeared as long, colorless plates, m. p. 229–232°; yield 2.18 g. or 97%.

Anal. Calcd. for $C_{18}H_{20}O_2$: C, 80.56; H, 7.51. Found: C, 80.40; H, 7.76.

Similar treatment of the liquid isomer yielded only an oil which decomposed when attempts were made to distill it. An attempt to demethylate in hydriodic and acetic acids led only to a red, iodine-containing oil.

1,3-*bis*-(*p*-Acetoxyphenyl)-cyclohexane.—1,3-*bis*-(*p*-Hydroxyphenyl)-cyclohexane, 0.5 g. was warmed with 2 g. of freshly-fused sodium acetate and 10 cc. of acetic anhydride on a steam-bath for three hours. The mixture was hydrolyzed in water, yielding the theoretical amount of product. This was recrystallized four times from methyl alcohol, m. p. 74.5–75.5°.

Anal. Calcd. for $C_{22}H_{24}O_4$: C, 74.98; H, 6.86. Found: C, 74.87; H, 7.05.

4,4′′-Dihydroxy-*m*-terphenyl.—The dimethoxy compound, 0.35 g., was heated with 1.0 g. of potassium hydroxide and 20 cc. of ethyl alcohol at 200° for twenty-four hours. The solution was treated as before and 0.29 g. (93%) of the diphenol was obtained. The product crystallized from dilute acetic acid or dilute methyl alcohol as fine plates having a slight lavender tint, m. p. 182–183°.

Anal. Calcd. for $C_{18}H_{14}O_2$: C, 82.42; H, 5.38. Found: C, 82.41; H, 5.51.

Demethylation was also accomplished in 94% yield by refluxing 0.85 g. of the ether with 3 cc. of hydriodic acid (d. 1.7) and 6 cc. of glacial acetic acid for three hours. Dilution and cooling precipitated the product.

The potassium hydroxide cleavage could not be successfully repeated on occasions. An experiment that behaved anomalously was one in which 2.5 g. of the ether was heated at 200° for twenty-four hours with 7.5 g. of potassium hydroxide and 20 cc. of ethyl alcohol. Considerable pressure developed in the bomb, present even after it had cooled. The products were not entirely soluble in the alcoholic alkali. The mixture was diluted and the suspension warmed and filtered. This insoluble residue from the reaction mixture proved to be 4,4″-dimethoxy-*m*-terphenyl.

Acidification of the filtered reaction mixture precipitated 1.25 g. of an impure solid which was recrystallized repeatedly from dilute acetic acid and from dilute ethyl alcohol; white plates, m. p. 66.0–67.5°, were obtained which were insoluble in 10% sodium hydroxide. This was probably 4,4″-dimethoxyperhydro-*m*-terphenyl. The analysis indicated a substance containing about four more hydrogen atoms than 4,4″-dimethoxyperhydroterphenyl.

Anal. Calcd. for $C_{20}H_{36}O_2$: C, 77.86; H, 11.76. Calcd. for $C_{20}H_{36}O_2 \cdot {}^1/_2C_2H_6O$: C, 76.08; H, 11.86. Found: C, 76.73, 76.90; H, 12.59, 12.89.

In agreement with its formulation as the ether, this compound was resistant to the action of sodium dichromate and sulfuric acid in water at the reflux temperature. Demethylation with constant-boiling hydriodic acid in glacial acetic acid yielded a white product crystallizing from the acid mixture. Attempts to recrystallize this only gave gels, even from large amounts of benzene or alcohol. The gel was dried, m. p. 245–295°.

4,4″-Diacetoxy-*m*-terphenyl.—This derivative was obtained by treating the diphenol with fused sodium acetate and acetic anhydride, as described above. The compound was recrystallized from ethyl alcohol and obtained as white needles, m. p. 130.1–131.5°.

Anal. Calcd. for $C_{22}H_{18}O_4$: C, 76.28; H, 5.24. Found: C, 76.39; H, 5.79.

Oxidation of 4,4″-Dihydroxy-*m*-terphenyl.—The diphenol, 0.1 g., was refluxed with 8 cc. of water, 0.1 cc. of 10% sodium hydroxide and 1.0 g. of potassium permanganate. The solution was cooled, acidified and the manganese dioxide dissolved by additions of sodium bisulfite. The resulting solution contained only a slight haze of insoluble material. It was evaporated to dryness and some of the salt residue heated for three minutes at 160° with resorcinol and one drop of concentrated sulfuric acid. The fused mixture was cooled and diluted with water. The addition of sodium hydroxide produced a red-brown solution with a weak, but deep green fluorescence. This fluorescence and color had a very different character than that produced with phthalic acid. It matched perfectly with the colors obtained from iso- and terephthalic acid controls. The red solution obtained with resorcinol and sulfuric acid under the same conditions was of a distinctly different character.

Oxidations with 50% nitric acid yielded a yellow powder containing nitrogen. The crude product melted at 218–225°. This was not identified.

Zinc Dust Treatment.—A 0.05-g. sample of the cyclohexane was heated at 250° for one hour with 10% palladium-on-Norite catalyst. Zinc dust, 0.1 g., was then added to the melt. The heating was continued for two hours at 300°. The mixture was cooled, pulverized and extracted with benzene. When concentrated, decolorized, filtered and concentrated again to 0.3 cc., the benzene solution yielded a minute amount of crystals. The melting point of 85–90° indicated that this material was *m*-terphenyl (m. p. 89°).[22]

Condensation of Anisole with 3,4-Dichlorohexane in the Presence of Anhydrous Aluminum Chloride.—In the apparatus described previously for the Friedel–Crafts reactions were placed 7.75 g. (0.05 mole) of 3,4-dichlorohexane,[13,14,15] 14.4 g. (0.3 mole) of anisole and 50 cc. of petroleum ether (b. p. 95–96°). The reactants were cooled to 2° and 5 g. of anhydrous aluminum chloride was added in small portions to the stirred mixture. The reaction mixture was then heated to 80° for one and one-half hours, but no gas evolution was observed. Another 5-g. portion of catalyst was added, and subsequent heating to 95° brought about hydrogen chloride evolution for one hour. Heating was continued for ten hours.

The mixture was decomposed in water and treated in the usual manner. Distillation yielded 3 cc. of clear liquid, b. p. 90–123° (1 mm.), and 1 cc. of viscous straw-yellow liquid, b. p. 140–190° (1 mm.). The yield of the latter fraction was 7%.

To a mixture of 3.88 g. (0.025 mole) of 3,4-dichlorohexane, 5.4 g. (0.05 mole) of anisole and 25 cc. of petroleum ether was added 6.7 g. (0.05 mole) of anhydrous aluminum chloride during an hour. The reaction was heated on a steam-bath for four hours. The mixture was cooled and treated as before. This time 2.6 g. of liquid, b. p. 95–150° (1 mm.), and 0.9 g. of a viscous straw-colored oil, b. p. 150–190° (1 mm.), were collected. The latter fraction was combined with the similar product above and methylated, using alternately 2 cc. of dimethyl sulfate and 2.5 cc. of 20% sodium hydroxide. The excess dimethyl sulfate was destroyed with ammonia and the product extracted with ether.

Distillation of the dried ethereal extract yielded a cloudy, yellow oil, b. p. 180–190° (1 mm.). This was diluted with an equal volume of petroleum ether (b. p. 38–45°), seeded and placed in the refrigerator. After four days about 0.05 g. of crystals had been deposited. These were purified by recrystallization from methyl alcohol and appeared as needles, m. p. 142–143° (cor.). A mixed melting point with an authentic sample of hexestrol dimethyl ether[23] remained unchanged.

Anal. Calcd. for $C_{20}H_{26}O_2$: C, 80.59; H, 8.74. Found: C, 80.35; H, 8.89.

The yield of the unmethylated oil was about 14% and that of the crystals about 1%, calculations being based on the amount of 3,4-dichlorohexane used in both reactions.

Summary

1,2-Dichlorocyclohexane and cyclohexene oxide react with anisole in the presence of aluminum chloride or boron fluoride to form a solid and a liquid 1,3-dianisylcyclohexane, *p*-cyclohexylanisole and 4,4″-dimethoxyterphenyl.

3,4-Dichlorohexane condenses with anisole to give a small amount of oily products from which a 1% yield of hexestrol dimethyl ether was isolated.

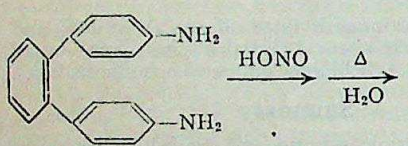
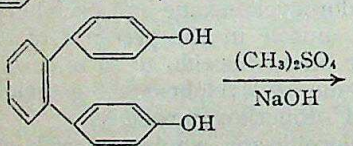
The Synthesis of Two Dihydroxyterphenyls

BY CHARLES C. PRICE AND GEORGE P. MUELLER[1]

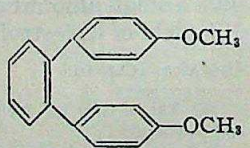
In an attempt to prepare 1,2-di-(*p*-methoxyphenyl)-cyclohexane by the condensation of *p*-methoxyphenylmagnesium bromide with 1,2-dibromocyclohexane, the only products which were isolated in a pure state were 4,4′-dimethoxybiphenyl (I) and a substance (II), m. p. 273–275°, having the proper elementary analysis for a dimethoxyterphenyl.

The possibility that this substance was the dimethoxy-*o*-terphenyl resulting from dehydrogenation of the desired 1,2-di-(4-methoxyphenyl)-cyclohexane was dispelled by synthesis of 4′,4″-dimethoxy-*o*-terphenyl (IV) through tetrazotization of the corresponding diamine, recently described by Allen and Pingert.[2] The hydrolysis with steam proceeded in practically quantitative yield. Methylation of the phenol, however, yielded an isomer of the product (II) from the Grignard condensation.



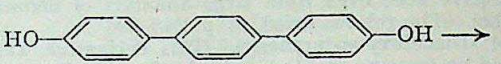


III, m. p. 231°

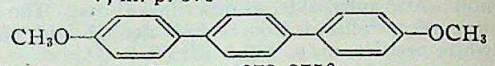


IV, m. p. 106°

Demethylation of the unknown dimethoxyterphenyl (II) followed by permanganate oxidation yielded terephthalic acid, which was identified as the dimethyl ester. The *p*-terphenyl derivative was, therefore, synthesized in the same manner[3–6] as the ortho isomer above and it proved to be identical with the Grignard condensation product.

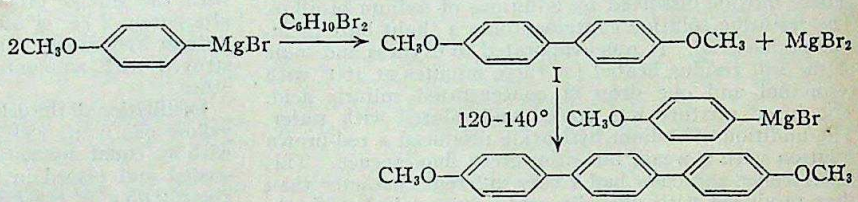


V, m. p. 375°



II, m. p. 273–275°

An experiment demonstrated that this dimethoxy-*p*-terphenyl could arise from a condensation of 4,4′-dimethoxybiphenyl and *p*-methoxyphenylmagnesium bromide.



This reaction recalls the formation of isoamylbenzene as a by-product in the demethylation of anisole with isoamylmagnesium bromide.[7,8] Coupling reactions of Grignard reagents with aryl ethers have also been reported by Fuson and Speck.[9]

Experimental[10]

4′,4″-Dihydroxy-*o*-terphenyl.—The tetrazotization of 4′,4″-diamino-*o*-terphenyl was carried out as prescribed by Allen and Pingert, using 2.6 g. (0.01 mole) of the diamine in 200 cc. of water, 17 cc. of 6 *N* hydrochloric acid solution and 1.38 g. (0.02 mole) of sodium nitrite in water. Apparatus had previously been arranged consisting of a 1-l. three-necked flask fitted with a 30-in. Allihn condenser, and a vertical glass tube measuring 2.5 by 100 cm. Into the top of the latter a 6-mm. glass tube projected 3 cm., and through this was passed steam from boiling, distilled water. Projecting exactly as far into the large tube was the tip of an addition funnel which had been drawn to a capillary at a slight angle so that the solution dripping therefrom would flow down the wall of the column instead of dropping through. This addition funnel was packed in an ice-bath. A little water was placed in the three-necked flask and this was kept boiling while, with the passage of steam down through the tube, the tetrazonium chloride solution was added very slowly. The flask had collected about 850 cc. of water by the time the addition was completed. White needles, sometimes containing an orange impurity, separated from the solution; the yield of the crude material, m. p. 223–228°, was 2.58 g. or 98%. Four recrystallizations from benzene gave colorless plates, m. p. 230.2–231.4° (cor.).

Anal. Calcd. for $C_{18}H_{14}O_2$: C, 82.42; H, 5.38. Found: C, 82.39; H, 5.62.

4′,4″-Diacetoxy-*o*-terphenyl.—By warming 0.5 g. of the diphenol with 2 g. of freshly-fused sodium acetate in 10 cc. of acetic anhydride for two and one-half hours, hydrolyzing the suspension in cold water and collecting the remaining solid, the theoretical quantity, 0.66 g., of crude, dry product was obtained, m. p. 175–183°. After four re-

crystallizations from 50% ethyl alcohol the tiny platelets melted at 186.0–186.4° (cor.).

Anal. Calcd. for $C_{22}H_{14}O_4$: C, 76.28; H, 5.24. Found: C, 76.43; H, 5.41.

4′,4″-Dimethoxy-*o*-terphenyl.—The diphenol, 0.20 g., was shaken at 80° with 2 cc. of dimethyl sulfate for a few minutes, 2 cc. of 20% sodium hydroxide solution was added and shaking was continued for a short time. This procedure was repeated three times and the mixture cooled and treated with an excess of aqueous ammonia. The product was collected and dried. The yield of crude material was 0.22 g., or the theoretical quantity. Five recrystallizations from ethyl alcohol produced long, flat needles, m. p. 104.8–106.4° (cor.).

Anal. Calcd. for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25. Found: C, 82.90; H, 6.43.

4,4″-Diamino-*p*-terphenyl.—4,4″-Dinitro-*p*-terphenyl, 3.02 g., was suspended in 100 cc. of benzene and hydrogenated at 2000 lb. per sq. in. and 100° for two hours in the presence of Raney nickel. The white diamine crystallized in the bomb as beautiful leaflets, m. p. 240–244°.[11] The product was separated from the catalyst by diluting the mush to 200 cc. with benzene, filtering and concentrating. The recovery from two crops was 1.45 g. or 59%. The diamine was very slightly soluble in 5% hydrochloric acid solution; its solutions in organic solvents exhibited violet fluorescence.

4,4″-Diamino-*p*-terphenyl dihydrochloride was prepared by suspending some of the powdered diamine in 5% hydrochloric acid solution and heating at 95° for a few minutes. Its identity was confirmed by precipitation of the same product by the passage of hydrogen chloride through the benzene liquors containing the diamine. The white powder was nearly insoluble in water. It darkened at 315°; m. p. 355–370°, with decomposition.

4,4″-Dihydroxy-*p*-terphenyl.—4,4″-Diamino-*p*-terphenyl dihydrochloride, 1.56 g., was suspended in 200 cc. of water containing 10 cc. of concentrated hydrochloric acid solution and the mixture treated at 0° with 0.69 g. of sodium nitrite. After an hour of stirring, the excess nitrous acid was destroyed by the addition of urea and the suspension was filtered through an ice-cold Büchner funnel. The tetrazonium chloride was decomposed with steam as before and the pink micro-plates appearing were collected from the hot water. The yield of crude material was about 0.1 g. This is not surprising in view of the considerable residue remaining after filtration of the tetrazonium chloride solution. Purification was effected by shaking the diphenol with 6 cc. of 10% sodium hydroxide solution and 50 cc. of water, filtering, acidifying and centrifuging. This product was washed three times with water and recrystallized three times from ethyl alcohol. The fine, white plates melted at 375°. With very slow heating they melted below this temperature with decomposition. The diphenol is but slightly soluble in dilute alkali solutions, but these solutions show violet fluorescence.

Anal. Calcd. for $C_{18}H_{14}O_2$: C, 82.42; H, 5.38. Found: C, 82.37; H, 5.45.

4,4″-Diacetoxy-*p*-terphenyl.—4,4″-Dihydroxy-*p*-terphenyl, 0.050 g., was warmed with acetic anhydride and fused sodium acetate in the usual way and the mixture hydrolyzed. The crude, dry product weighed 0.085 g., and, when recrystallized three times from ethyl alcohol, appeared as colorless plates, m. p. 244.3–245.3° (cor.).

Anal. Calcd. for $C_{22}H_{18}O_4$: C, 76.28; H, 5.24. Found: C, 76.30; H, 5.37.

4,4″-Dimethoxy-*p*-terphenyl.—The methylation was carried out as with the ortho isomer. The product was recrystallized three times from benzene. It formed white micro-plates, m. p. 273–275°.

Anal. Calcd. for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25. Found: C, 82.89; H, 6.55.

(11) The sample of dinitroterphenyl used contained other isomeric nitroterphenyls which were not completely removed.

Reaction of *p*-Methoxyphenylmagnesium Bromide with 1,2-Dibromocyclohexane.—*p*-Methoxyphenylmagnesium bromide was prepared from 14.6 g. (0.6 mole) of magnesium turnings, 100 cc. of dry ethyl ether and 112.4 g. (0.6 mole) of *p*-bromoanisole in 100 cc. of dry ether. The conventional Grignard-type apparatus with a 500-cc. addition funnel, a sealed stirrer and a condenser carrying a drying tube at the top, all attached to a 500-cc. three-necked flask, was used. After formation of the Grignard reagent was complete, 48.4 g. (0.2 mole) of 1,2-dibromocyclohexane was added at once, the condenser set downward for distillation and ether removed until the volume of the remaining solution was 200 cc. At this time 200 cc. of dry butyl ether was introduced, and the temperature of the mixture brought gradually to 120° where it was maintained for five and one-half hours with constant stirring. After standing at room temperature overnight the mixture was poured into one-half liter of crushed ice containing 35 cc. of concentrated sulfuric acid. A liter of ethyl ether was added, the water layer separated and extracted twice with ether. During these extractions a gray solid separated at the liquid–liquid interface. This was collected on a Büchner funnel and dried; it weighed 0.65 g. and sublimed at 250–300° (1 mm.) to yield clear, colorless plates which were recrystallized three times from benzene; m. p. 273–275°. This product proved to be 4,4″-dimethoxy-*p*-terphenyl. It did not depress the melting point of an authentic sample of this compound. The ether was heated in a steel bomb at 200° for twenty-four hours with 5 g. of potassium hydroxide and 20 cc. of ethyl alcohol. The product, 0.065 g. of the phenol from 0.10 g. of the ether, was soluble in alkali but insoluble in benzene, acetone and alcohol. It was warmed on a steam-bath in 5% sodium hydroxide while a 2% potassium permanganate solution was added until the green manganate color persisted; about 125 cc. was required. The resulting mixture was cooled, acidified and clarified with sodium bisulfite. The fine, white powder separating was collected on a 4-mm. filter. This was soluble in 5% sodium bicarbonate solution. It sublimed above 300°. The dimethyl ester was prepared,[12] m. p. 140–140.5°. Dimethyl terephthalate melts at 140–141° and a mixture of the two had the same melting point.

The ethereal filtrates from the original Grignard reaction were dried over anhydrous sodium sulfate and concentrated at reduced pressure in a dry air stream. The solid separating was collected, crystallized once from a mixture of benzene and petroleum ether (b. p. 95–96°), from which it separated as a mush. This was dried and sublimed at 150° (0.2 mm.) and recrystallized twice from methylcyclohexane. The compound, 4,4′-dimethoxybiphenyl, separated as plates from this solvent but as needles, m. p. 174.5–175.6°, from methyl alcohol.

Anal. Calcd. for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59; mol. wt., 214.25. Found: C, 78.24; H, 6.68; mol. wt., 194, 208 (Rast).

Distillation of the ethereal liquors gave several liquid and solid fractions, one of which, 1.12 g., was collected at 135–146° (0.2 mm.) and proved to be more of the biphenyl making the total recovery of this product from the reaction 2.18 g.

Reaction of *p*-Methoxyphenylmagnesium Bromide and 4,4′-Dimethoxybiphenyl.—*p*-Methoxyphenylmagnesium bromide was prepared, as before, from 3.65 g. (0.15 mole) of magnesium turnings under 20 cc. of dry ether and 28.1 g. (0.15 mole) of *p*-bromoanisole in 25 cc. of dry ether. The mixture was stirred and warmed for half an hour after the Grignard formation seemed complete. 4,4′-Dimethoxybiphenyl, 2.0 g., and 50 cc. of dry butyl ether were added at once, the condenser set downward for distillation and the temperature of the stirred mixture raised slowly to 140° where it was maintained for eight hours. The mixture was cooled and held below 15° while 50 cc. of

6 *N* sulfuric acid solution was slowly added. Ethyl ether was added, as before, and the solids separating were collected and dried. Sublimation of the 2.5 g. of crude products so obtained yielded 0.7 g. of 4,4′-dimethoxybiphenyl at a bath temperature up to 150° (0.005 mm.) and 0.1 g. of impure 4,4″-dimethoxyterphenyl up to 280°. The residue was infusible. The terphenyl fraction was recrystallized three times from toluene but still softened at 268° and was not entirely fused at 285° though most melting occurred at 275°. The presence of higher-melting impurities is thus indicated, probably the analogous dimethoxyquaterphenyls or even higher members.

Summary

4′,4″-Dihydroxy-*o*-terphenyl and 4,4″-dihydroxy-*p*-terphenyl, the dimethyl ethers and diacetates have been prepared and characterized.

The reaction between 4,4′-dimethoxybiphenyl and *p*-methoxyphenylmagnesium bromide has been found to form small amounts of 4,4″-dimethoxy-*p*-terphenyl.

The Pinacols and Pinacolone from *p*-Methoxyacetophenone

BY CHARLES C. PRICE AND GEORGE P. MUELLER[1]

The successful dehydration of the pinacols from acetophenone[2,3] and *p*-hydroxyacetophenone[4] to the corresponding butadiene prompted an attempt to carry out a similar conversion for the two stereoisomeric pinacols from *p*-methoxyacetophenone. In every instance, however, dehydration resulted in rearrangement to the pinacolone.

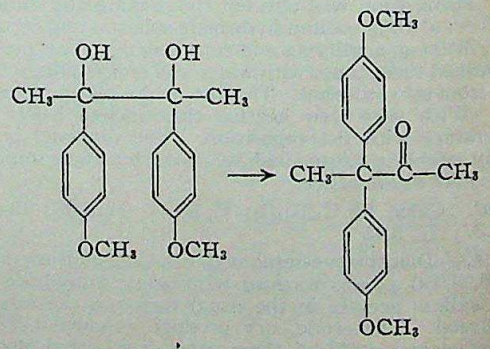
p-Methoxyacetophenone pinacol was prepared in 90% yields by electrolytic reduction of the ketone in potassium acetate, water and alcohol.[5] The crude product, upon repeated recrystallization from methyl alcohol or glacial acetic acid, gave the low- and high-melting isomers, respectively. The low-melting isomer showed some tendency toward solvate formation, the analyses of the compound indicating one-half molecule of methanol present before intensive drying. Also, recrystallization of this isomer, m. p. 122–123°, from ethylene glycol gave material melting at 111–113°; one recrystallization from methanol restored the melting point to its former value. The higher-melting isomer, m. p. 168–169°, was also obtained upon reduction of the ketone by aluminum amalgam in moist ether.

Oxidation of the low-melting isomer with lead tetraacetate yielded *p*-methoxyacetophenone, which was isolated quantitatively as the phenylhydrazone.

Several unsuccessful attempts were made to dehydrate this pinacol. Fraser[3] studied the yields obtained upon dehydration of acetophenone pinacol with acetyl chloride in terms of the time of reaction and found seven minutes at reflux with an equal weight of the acid chloride to be the optimum conditions. Such a reaction carried out with *p*-methoxyacetophenone pinacol (with a trace of hydroquinone present to inhibit polymerization) produced 74% of the pinacolone rather than the diene. A crystal of iodine dropped into the melted pinacol at 150° caused vigorous gas-evolution. The oil realized upon cooling did not show positive reactions either for an unsaturated or ketone derivative.

Both isomeric pinacols were treated repeatedly with fused sodium acetate in acetic anhydride, acetic anhydride and dry pyridine, and the high-melting isomer with benzoyl chloride and sodium hydroxide, but in no instance was esterification of the hydroxyl groups achieved. Any attempt to esterify these groups by an acidic reagent resulted in pinacolone rearrangement.

This rearrangement was conveniently carried out at room temperature in acetic anhydride, a trace of sulfuric acid serving as the catalyst. By analogy with 4,4-dianisyl-3-hexanone, which was obtained upon rearrangement of *p*-methoxypropiophenone-pinacol,[6] it was anticipated that this pinacolone should be 3,3-dianisyl-2-butanone.



This pinacolone did not undergo the iodoform reaction as modified by Fuson and Tullock.[7] This was not conclusive evidence for the absence of the acetyl grouping, however, for Poggi[8] has shown that pinacolone itself would not undergo the iodoform reaction when the procedure of Lieben[9] was

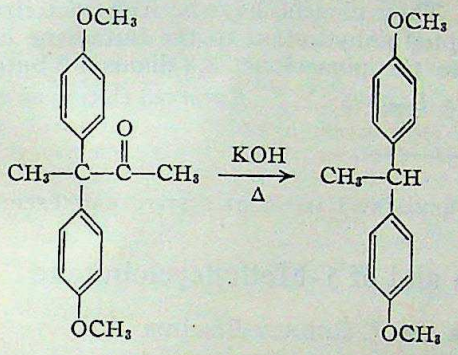
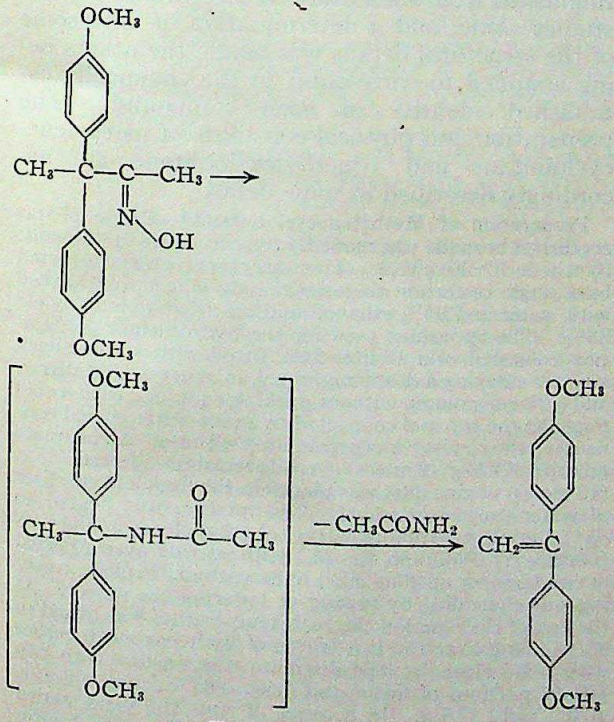
used. Fuson and Tullock observed that pinacolone would undergo the reaction in dioxane solution but that a longer period of heating was necessary.

The ketone was cleaved by molten potassium hydroxide to give a compound having the composition of 1,1-dianisylethane, m. p. 72°. The melting point of this compound has been reported as 59.4° by Lunjak.[10]



The oxime of 3,3-dianisyl-2-butanone was prepared. It proved to be insoluble in alkali. When shaken with phosphorus pentachloride in dry ether this oxime apparently underwent a Beckmann rearrangement. The product, m. p. 141–143°, contained no nitrogen, but showed definite unsaturation. It proved to be 1,1-dianisylethene.[11]



Experimental[12]

2,3-Dianisyl-2,3-dihydroxybutane.—Apparatus for the electrolytic reduction[13] consisted of a 400-cc. beaker, which formed the anode compartment, the anode itself being a sheet of metal bent into a cylinder to fit around an alundum cup which formed the cathode compartment. A rubber stopper fitting into this cup carried the cathodes and an Allihn condenser. In all reductions the area of the cathode was 100 sq. cm. and the total current 2 amp., making the density 0.02 amp. per sq. cm. The combinations of lead anode and cathode or of tin cathode and iron anode were found to be quite satisfactory.

p-Methoxyacetophenone, 20 g., was introduced into a catholyte consisting of 30 g. of potassium acetate, 55 cc. of ethyl alcohol and 25 cc. of water. This mixture was placed in the alundum cup. In some experiments two equivalents of ethyl acetate were added to neutralize the alkali liberated during the reduction. The anolyte consisted of a 40% aqueous solution of potassium carbonate. A current was passed at 110 v. until 120% of the theoretical amount had been used. The entire reduction took place at the refluxing temperature of the catholyte. The catholyte was poured into a liter of cold water and the oil precipitating gradually crystallized and was collected on a filter. The yield of this crude product was 18 g. or 90%. In another experiment where 33 g. of the ketone was reduced in the presence of ethyl acetate the crude product was steam distilled, giving 27 g. of product. The crude material from the first reduction melted at 114–135°.

Repeated recrystallization of the crude product from methyl alcohol gave the low-melting form, m. p. 122–123°. This isomer was quite soluble in glacial acetic acid.

Anal. Calcd. for $C_{18}H_{22}O_4$: C, 71.50; H, 7.34. Found: C, 71.10; H, 7.50.

Similar treatment of the crude pinacol with glacial acetic acid, or even one recrystallization therefrom followed by repeated recrystallization from ethyl alcohol, yielded the high-melting form, m. p. 168–169°.

Anal. Calcd. for $C_{18}H_{22}O_4$: C, 71.50; H, 7.34. Found: C, 71.16; H, 7.22.

Approximately 3 g. of amalgamated, granulated aluminum, 5 g. of *p*-methoxyacetophenone and 30 cc. of moist ether were shaken in a flask for three days, after which the ether was evaporated and the residue warmed with methyl alcohol and filtered. The solution deposited a few crystals of a compound, m. p. 162–165°, which did not depress the melting point of the high-melting isomer obtained above.

Oxidation with Lead Tetraacetate.—The low-melting pinacol, 1.51 g. (0.005 mole), was suspended in 10 cc. of glacial acetic acid and 2.25 g. (0.005 mole) of lead tetraacetate was added to the mixture. After both reactants had dissolved, addition of 1.5 g. of phenylhydrazine in 5 cc. of glacial acetic acid immediately precipitated 2.56 g. of orange *p*-methoxyacetophenone phenylhydrazone. After three recrystallizations from ethyl alcohol it melted at 136–138° (dec.) and did not depress the melting point of an authentic sample of the hydrazone. This derivative decomposed upon standing for three days at room temperature.

Pinacolone Rearrangement: 3,3-Dianisyl-2-butanone.—On addition of one drop of sulfuric acid, 0.5 g. of the low-melting pinacol suspended in 2.5 cc. of acetic anhydride dissolved immediately. Water precipitated the pinacolone which was recrystallized several times from ethyl alcohol, m. p. 69.7–71.5°. The high-melting isomer behaved likewise and yielded the same product. From 7.0 g. of the crude mixture of pinacols, 4.1 g. or 63% of the theoretical amount of the pinacolone was realized.

Anal. Calcd. for $C_{18}H_{20}O_3$: C, 76.03; H, 7.09. Found: C, 76.14; H, 7.27.

The **oxime** was insoluble in strong alkali and was recovered unchanged following two hours of heating in a sealed tube at 100° with concentrated hydrochloric acid. It crystallized from a large volume of ethyl alcohol in fine, colorless needles, m. p. 192–194°.

Anal. Calcd. for $C_{18}H_{21}O_3N$: C, 72.22; H, 7.07. Found: C, 71.75; H, 6.95

Cleavage of the Pinacolone: 1,1-Dianisylethane.—The pinacolone, 1.5 g., was heated for thirty minutes with 20 g. of potassium hydroxide at 170–180°. The cooled melt was dissolved in 100 cc. of water and the insoluble material collected on a filter. This was recrystallized three times from ethyl alcohol, appearing as fine, white platelets, m. p. 70–72°. A 50–50 mixture of this compound with the original ketone melted around 60°.

Anal. Calcd. for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49. Found: C, 79.47; H, 7.80.

Beckmann Rearrangement: 1,1-Dianisylethene.—A suspension of 0.77 g. of 3,3-dianisyl-2-butanone oxime and 0.2 g. of phosphorus pentachloride in 30 cc. of pure, dry ether was shaken for twenty minutes, or until the oxime had dissolved. When the solution was allowed to stand overnight in the cold it deposited large, clear hexagonal plates. Evaporation and recrystallization yielded 0.47 g. of 1,1-dianisylethene, m. p. 141–143°.[11]

Anal. Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71. Found: C, 80.06; H, 6.16.

Summary

Electrolytic reduction of *p*-methoxyacetophenone has been found to produce a mixture of the two possible diastereoisomeric pinacols in excellent yield. These pinacols have been characterized but attempted dehydration to the butadiene has led only to the pinacolone, 3,3-dianisyl-2-butanone.

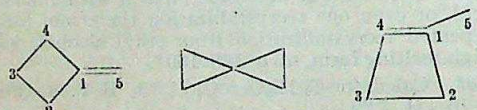
The Structures of Methylenecyclobutane and of 1-Methylcyclobutene

BY W. SHAND, JR., VERNER SCHOMAKER AND J. RODNEY FISCHER

The hydrocarbon prepared by Gustavson[1] by the action of zinc dust on pentaerythrite tetrabromide has been subjected to an intensive chemical investigation[2] on the basis of which structure (I) has been assigned to this substance. The structure may be regarded as definitely established in spite of the appearance of a recent article by Rogowski,[3] who advocated the spiropentane[3a] structure (II) on the basis of electron diffraction studies. A more recent electron diffraction investigation by Bauer and Beach[4] with results in essentially complete disagreement with those of Rogowski is compatible with structure (I) and eliminates structure (II). The hydrocarbon (III) was also first obtained by Gustavson.[5] It is not as readily accessible as (I) and consequently has received less attention from chemists; its structure, however, is not in doubt.[2]



(I) (II) (III)

The present investigation was undertaken with the aim of isolating methylenecyclobutane and 1-methylcyclobutene in a state as pure as possible and verifying their structures by the electron diffraction method. It was found, however, that the two compounds cannot readily be distinguished from each other by electron diffraction studies alone, and a determination of only some of the structural details was made, the others being assumed to correspond to the chemically established identity of each compound. The preparation and physical constants of methylenecyclobutane and 1-methylcyclobutene are accordingly described in some detail.

Preparation of Methylenecyclobutane.[6]—Crude pentaerythrityl bromide was made by the procedure in "Organic Syntheses."[7] Five moles of pentaerythrytol was converted in a single operation to tetrabromide which was washed with water and 95% ethanol[7] and air-dried, average yield 88%. The apparatus used for the hydrocarbon preparation consisted of a 12-liter flask fitted with a three-neck adapter carrying a dropping funnel, mercury-sealed stirrer, and a 38-cm. column without packing equipped with a cold finger at the top and connected to an ice-water cooled condenser; the receiver was surrounded with ice. An intimate mixture of 776 g. (2 moles) of crude tetrabromide and 785 g. (12 moles) of zinc dust was placed in the flask and one liter of water *cautiously* added. The mixture was heated to 85° on a water-bath and 500 cc. of ethanol was added portionwise (*cf.* Philipow, *loc. cit.*) with stirring over a period of two hours or until no more hydrocarbon distilled; frothing was controlled by raising or lowering the stirrer. At the end of the reaction the bath temperature was raised to 95°, forcing over the last traces of hydrocarbon together with some alcohol. The distillate was washed with two 100-cc. portions of water and dried over calcium chloride at 0°, yield 115 g. In a series of runs the yield varied between 70 and 90%. A quantity of the crude hydrocarbon (1340 g.) was twice fractionated through a 22-mm. inside diameter column, 6.5 ft. long, packed with glass helices and fitted with a total reflux, variable take-off

head. About 80% of the distillate[8] boiled at 41.0–41.7° at 750 mm.; this material was refractionated a third time through a 3-foot column packed with helices and a middle portion reserved for electron diffraction study, b. p. 41.39° at 750 mm., n^{10}D 1.4266, n^{15}D 1.4236, n^{20}D 1.4210, d^{20}_4 0.7401, d^{25}_4 0.7349. The product obtained by Whitmore and Williams and used by Bauer and Beach, and identified as methylenecyclobutane by ozonolysis had the constants b. p. 41.3° at 746 mm., n^{20}D 1.4203–6.

Preparation of 1-Methylcyclobutene.—Although Philipow[2] claimed to have fractionated this hydrocarbon from the mixture obtained on treating pentaerythrite tetrabromide with zinc dust, the presence of a constant boiling fraction in this range could not be detected.[9] Several unsuccessful attempts were made to prepare methylcyclobutene by isomerization of methylenecyclobutane over an alumina catalyst at 300°. The greater part of the hydrocarbon was converted to lower boiling material but apparently this consisted almost entirely of products of ring-splitting.[10] Attempts to dehydrate 1-methylcyclobutanol[5,6,11] were also unsuccessful; the use of 60% sulfuric acid and of anhydrous oxalic acid gave polymers while the tertiary alcohol was recovered unchanged after refluxing with iodine.

1-Chloro-1-methylcyclobutane was prepared in 80% yield by treating methylenecyclobutane with excess concentrated aqueous hydrochloric acid at 0°. After shaking for one hour, the lighter phase was washed with sodium carbonate solution, dried over calcium chloride and distilled, b. p. 90–91° at 745 mm., n^{20}D 1.4311, n^{25}D 1.4288, d^{20}_4 0.9495, d^{25}_4 0.9444. The corresponding bromide was prepared in 72% yield from methylenecyclobutane and 62% aqueous hydrogen bromide at 0°, mixing by hand at first and then shaking mechanically for one hour. The bromide layer was worked up in the above manner, b. p. 55–57° at 100 mm., n^{20}D 1.4698, n^{25}D 1.4673, d^{20}_4 1.3179, d^{25}_4 1.3110. 1-Iodo-1-methylcyclobutane was prepared by shaking 68 g. (1 mole) of methylenecyclobutane in a glass-stoppered bottle with a solution of 154 g. (1.2 moles) of hydrogen iodide in 200 g. of glacial acetic acid at 0°.[5] The reaction mixture was poured into one liter of water, the heavy phase separated and washed with bisulfite and carbonate solutions and finally with water, crude yield 94%. At 20 mm. the product boiled at 40–42°, n^{25}D 1.5215, d^{20}_4 1.604, yield 76%.

The chloride, bromide, and iodide were added dropwise under identical conditions to a 100% excess of a boiling solution of potassium hydroxide dissolved in cellosolve (ethylene glycol monoethyl ether). The mixed hydrocarbons produced were collected (yields from chloride 40%, bromide 60%, iodide 60%) and roughly analyzed by comparison[6] of densities and refractive indices with the values found for the pure hydrocarbons. The material obtained from the chloride and from the bromide contained methylenecyclobutane and 1-methylcyclobutene in a ratio of about 2:1, while in the case of the mixture obtained from the iodide, the reverse ratio obtained.

A modification of the original method of Gustavson[5] was therefore employed for the preparation of 1-methylcyclobutene in quantity. Fifty-six grams (1 mole) of potassium hydroxide was dissolved in 250 cc. of cellosolve (cellosolve gave higher yields than ethanol or ethanol–water) and this solution heated to boiling in a 500-cc. flask fitted with dropping funnel and reflux condenser through which water at 45° was circulated. The outlet at the top of the condenser led to another condenser set for downward distillation which was cooled by ice-water and then into a receiver cooled in a dry-ice bath. Ninety-eight grams (0.5 mole) of crude tertiary iodide was added dropwise over a period of two hours to the refluxing alkali solution and the hydrocarbon product washed with ice-water and dried over magnesium perchlorate, yield 20.4 g.

The crude hydrocarbon mixture (233 g.) from several of the above experiments was fractionated twice through the 6.5 ft. column described previously, using, because of the small amount of material available, a higher boiling hydrocarbon still-base. A third fractionation was carried out using a spinning band column similar to the one described by Baker, *et al.*[12] This column had the equivalent of 18 theoretical plates at the reflux rate and throughput used. The considerable portion of material which boiled at 37–38° at 748 mm. in this third fractionation was fractionated again with the spinning band column to obtain material of constant refractive index, b. p. 37.1° at 750 mm., n^{18}D 1.4088, d^{20}_4 0.7244, d^{25}_4 0.7188. This material was used for the electron diffraction investigation.

Electron Diffraction Investigation

Experimental.—The electron diffraction apparatus used in this investigation has been described by Brockway.[13] The camera distance was 10.89 cm., and the wave length of the electrons, determined from transmission photographs of gold foil, was 0.0615 Å. The photographs, made with the samples at about 25°, showed eight maxima and minima extending to s_0 values of about twenty-nine.

Interpretation.—Both the radial distribution method[14] and the correlation method[15] were used in interpreting the electron diffraction photographs. The radial distribution curves were calculated according to the formula where $I(s_k)$

$$rD(r) = \sum_k I(s_k) e^{-as_k^2} \sin s_k r$$

is a visually estimated intensity assuming no falling off of intensity with s_k, and a is chosen so that $e^{-as^2_{max.}} = 0.10$. A plot of the visually estimated intensities was divided into about 50 segments, and the $I(s_k)$'s taken at each endpoint.[16]

Theoretical intensity curves were calculated using the simplified theoretical scattering formula

$$I(s) = \sum_i \sum_j Z_i Z_j \frac{\sin r_{ij} s}{r_{ij}} e^{-a_{ij} s^2}$$

The constant a_{ij} in the exponential temperature factor term was given the value 0.002 for bonded C—H terms, 0.004 for non-bonded C—H terms, and 0.0 for all C—C terms. The contribution of C—H terms is important out to about $s = 20$.

Methylenecyclobutane.—The radial distribution curve shown at the top of Fig. 1 can be interpreted on the basis of a model with structure (I). Peaks occur at 1.09 Å., corresponding to the C—H bond, 1.55 Å., the C—C single-bond distance, 2.20 Å., the cross-ring distance, and 2.61 Å.,

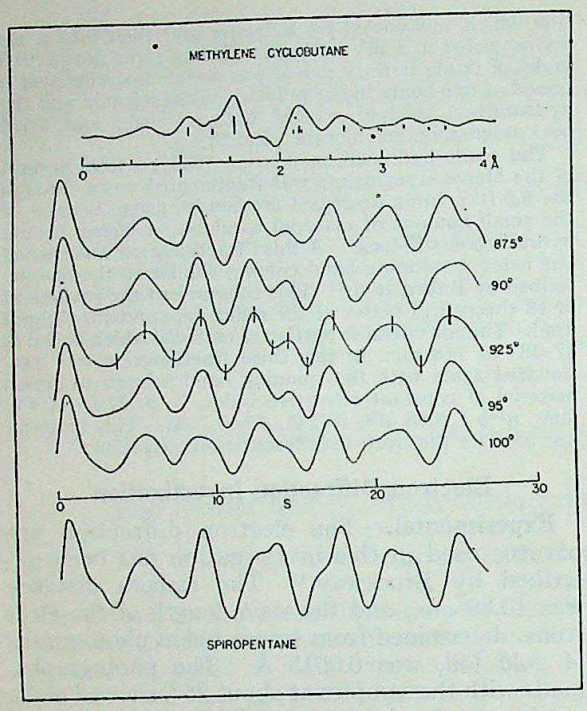

Fig. 1.

the distance between the side-chain carbon and the non-bonded adjacent ring carbon atom. The double-bond distance is not resolved, although a small inflection occurs at 1.33 Å. The spiropentane structure (II) as reported by Rogowski[3] can be ruled out, since it would give only two main peaks, at about 1.54 and 2.87 Å. Other structures differing widely from (I) with respect to their interatomic distances can likewise be ruled out by comparison with the radial distribution function. The chemical identification was accordingly accepted, and theoretical intensity curves calculated for structure (I).

Certain simplifying assumptions were made to reduce the number of structural parameters. The C—H bond distances were taken to be 1.09 Å., and the H—C—H angle on the ring to be 116°. The plane of these H—C—H's was perpendicular to the ring plane and bisecting the ring angles. Moreover, the carbon atoms were assumed to be coplanar and the C—C single-bond distances were taken as being all alike, reducing the problem to one of three parameters, namely, the C—C single-bond distance, the C—C double-bond distance, and an angle of the ring. The single-bond distance was taken from the radial distribution curve to be 1.55 Å., while the double-bond distance and the $\angle C_4C_1C_2$ were varied in calculating the theoretical intensity curves. Curves calculated for values of $\angle C_4C_1C_2$ varying from 87.5° to 100° with a double-bond distance of 1.34 Å. are shown in Fig. 1. The characteristic features of the observed pattern are the roundedness of the first maximum, the shelf-like appearance of the fourth maximum, the roundedness and almost complete

mentary asymmetry of the sixth and seventh maxima. The eighth maximum (not shown) was a sharp peak whose position varied little from curve to curve. Best agreement is given by the curve marked 92.5°. The non-bonded C···C distances in this model are 2.14, 2.24, 2.65 and 3.48 Å.; most of the important C···H distances fall at about 2.20 Å. These distances and their relative weights are shown with the radial distribution curve in Fig. 1. Curves calculated with double bond distances of 1.30 and 1.38 Å. do not give as good agreement with the observed pattern. In general the second minimum is raised, the sixth maximum becomes more symmetrical, and the seventh maximum asymmetrical on the inner side instead of the outer side. Best agreement for these curves is found for $\angle C_4C_1C_2 = 90°$ and C=C = 1.30Å. This is to be expected since for these values of the parameters the distances $C_5\cdots C_2$, $C_5\cdots C_4$, and $C_5\cdots C_3$ are the same as for the 92.5° model with C=C = 1.34 Å. The main difference arises in the cross-ring distances, which are different in the 92.5° model, and alike in the square model.

The effect of removing the restrictions that the ring be coplanar, and that the C—C single-bond distances be all alike was investigated, these variations being made separately. Curves were calculated in which the C_5, C_1, C_2 and C_4 atoms were coplanar (as in ethylene), and the C_3 atom moved perpendicular to this plane. Curves were also calculated for coplanar models with C—C single-bond distances adjacent to the double bond different from those opposite the double bond. Although these theoretical curves showed small but definite points of disagreement with the observed pattern, especially at the second minimum and the sixth and seventh maxima, it became evident that with the available data the complete correlation procedure with the admission of these additional variations could not be made to give more precise information than was already available from the radial distribution function. The final parameter determination was accordingly carried out with the assumptions mentioned in the preceding paragraph.

Quantitative comparison (Table I) of the observed and calculated s values $\left(s = \frac{4\pi}{\lambda}\sin\theta/2\right)$ also shows that the best agreement is for the 92.5° model with C—C single-bond distance 1.55 Å. and C—C double-bond distance 1.34 Å. The 90° model with C—C single-bond distance 1.55 Å. and C—C double-bond distance 1.30 Å. shows a larger average deviation. As discussed above this curve is also considered less satisfactory on the basis of qualitative agreement with the appearance of the observed pattern. The final results are C—C = 1.55 ± 0.02 Å., C=C = 1.34 ± 0.03 Å., and $\angle C_4C_1C_2 = 92.5° \pm 2°$, in fair agreement with Bauer and Beach, who reported C—C = 1.56 ± 0.03 Å., C=C = 1.34 ± 0.02 A., and $\angle C_4C_1C_2 =$ 90°.

In spite of the exclusion of the spiropentane model by the radial distribution curve, a theoretical intensity curve shown in Fig. 1 was calculated for the spiropentane model of Rogowski[3] for the full s_0 range of our pictures. This curve is in essentially complete disagreement with the observed diffraction pattern, although the positions of the main features are similar.[4]

1-Methylcyclobutene.—The appearance of the diffraction pattern is generally similar to that observed for methylenecyclobutane, but shows numerous distinct points of difference. For 1-methylcyclobutene the first maximum is broader, and higher on the inner side; the shelf-like fourth maximum is less distinctly separated from the third; the fifth minimum is broader and the fifth maximum rises more gradually on the inner side. The sixth maximum is stronger and sharper, and the seventh maximum shows structure on the outer side, which is not too clearly distinguishable. The stronger peaks of the radial distribution curve marked RD in Fig. 2 are at 1.09, 1.54, 2.16 and 2.72 Å. The double-bond distance is not resolved. It was varied from 1.30 to 1.38 Å. in calculating the theoretical intensity curves.

Since the double bond is in the ring in 1-methylcyclobutene there is no doubt that the carbon atoms are coplanar. The same assumptions regarding the hydrogen atoms were made as above. The C—C single-bond distance was taken from the radial distribution curve to be 1.54 Å. The angle $C_5C_1C_2$ was varied from 110 to 140°. About 25 theoretical curves were calculated, of which representative examples are shown in Fig. 2. Curves A to G have double-bond distance 1.34 Å. and the $\angle C_5C_1C_2$ indicated; curves H and I have double-bond distances 1.30 and 1.38 Å., respectively, with $\angle C_5C_1C_2 = 125°$. In all except curves F and G the ring structure was made symmetrical ($\angle C_2C_3C_4 = \angle C_1C_2C_3$; $\angle C_3C_4C_1 = \angle C_4C_1C_2$). For curve F the ring was distorted by increasing the $\angle C_4C_1C_2$ by 5°, and in curve G by decreasing the same angle 5°, changes in other angles being made symmetrically but retaining the same external $\angle C_5C_1C_2$ (= 125° in these curves). On the basis of the features of the observed pattern described above, best agreement was found for the symmetrical ring with double-bond distance 1.34 Å. and 120° < angle $C_5C_1C_2$ < 130°.[17] Curve C (125°) was chosen as best, with calculated non-bonded C···C distances 2.11, 2.71, 2.74 and 3.63 Å. The most important C···H terms are in the neighborhood of 2.20 Å.

(17) The $C_5\cdots C_2$ and $C_5\cdots C_3$ distances and their associated C···H terms, which together are the most important in determining the structure-sensitive features of the theoretical curves, are equal at about $\angle C_5C_1C_2 = 125°$. Consequently a considerable variation of this angle in either direction produces only relatively small differences in the resulting curves, and prevents a close determination of the angle. Similarly curves calculated for distortions of 2 and 5° of the ring in either direction in the manner described above show that distortion of about 5° in either direction is required to produce definite disagreement for the best curve, and does not improve agreement for the other curves.

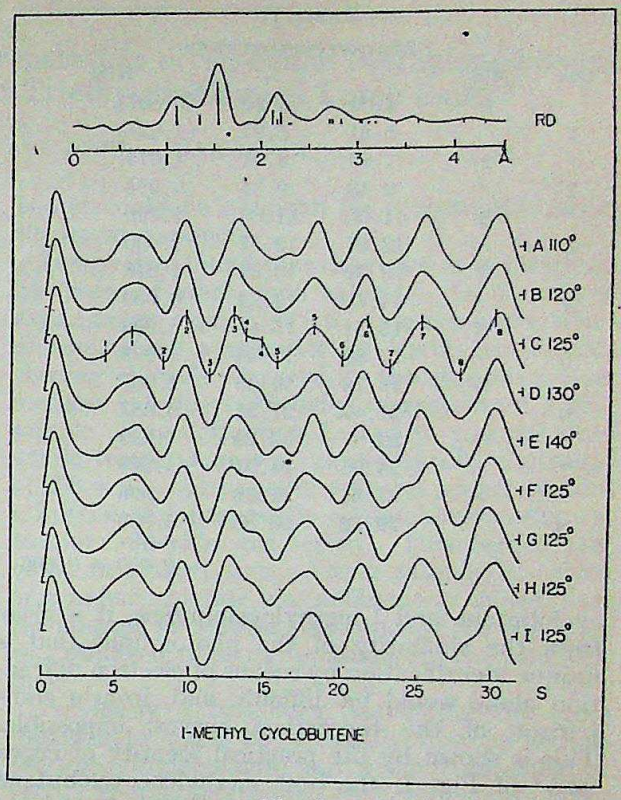

Fig. 2.

These distances with their relative weights are shown on the curve RD of Fig. 2. Quantitative comparison of observed and calculated s values for Curve C (125°) is made in Table II. Our final results are C—C = 1.54 ± 0.03 Å., C=C = 1.34 ± 0.03 Å., $\angle C_5C_1C_2 = 125° \pm 4°$, $\angle C_4C_1C_2 = 93°40' \pm 3°$, etc. (*i. e.*, symmetrical ring structure ±3° distortion).

cyclobutane and 1-methylcyclobutene, it is clear from the similarity of the photographs that a unique identification by means of electron diffraction alone would be difficult, and, from a comparison of the theoretical curves, impossible. This is shown by the practical identity of curve 92.5° of Fig. 1, the best methylenecyclobutane curve, with the 1-methylcyclobutene curves B (120°) and C (125°) of Fig. 2.[18] This is to be expected for molecules whose scattering distances (r_{ij}'s) differ only in what amounts to second order effects: about 70% of the scattering (based on the weight of the coefficients Z_iZ_j/r_{ij}) is due to r_{ij}'s identical for the two models and the remainder is due to r_{ij}'s which are not markedly different. It should be emphasized again that the attempt to differentiate between different chemical structures by the electron diffraction method may not always lead to a unique result, especially when a reasonably great variation of the models representing the various chemical structures is allowed. Where the proposed structures are, however, fundamentally different in geometrical design, the corresponding sets of interatomic distances are usually quite different and a definite choice is made possible.[19] Thus the comparison of the theoretical curves and the diffraction photographs provides definite detailed evidence that neither of our substances is spiropentane.

(18) The similarity of the theoretical curves was overlooked by Bauer and Beach[4] because an error in the cross-ring distance was made in the calculation of their curves E for 1-methylcyclobutene and F for 3-methylcyclobutene. Their model E (private communication from Professor Bauer) was nearly the same as our D (130°).

(19) See for example R. A. Spurr and V. Schomaker, *loc. cit.*; J. Waser and V. Schomaker, THIS JOURNAL, 65, 1451 (1943).

Moreover, a preliminary comparison of the radial distribution curves with the distances to be expected for the models in question at once makes improbable all of the other isomers which contain no four-membered ring, mainly because none of these would give a strong peak at about 2.2 Å. but only a C···H peak, while suggesting the possibility that for 3-methylcyclobutene a reasonable model leading to intensity curves in agreement with the photographs (especially of 1-methylcyclobutene) could be found. It was not thought profitable, however, further to consider these various structures inasmuch as there seemed to be no doubt about the chemical identification and it seemed likely that even after careful consideration by the correlation procedure not all of them could be ruled out with certainty.

The question of the distribution of "strain" in these molecules is of interest. In methylenecyclobutane the strain in the four-membered ring can be taken up by expanding the H—C—H angle to compensate for the compression of the C—C—C angle at the C_2, C_3 and C_4 positions; at C_1 such compensation cannot occur except by increase of the angle $C_4C_1C_2$, as observed. In 1-methylcyclobutene a symmetrical ring structure would be expected if the C_5C_1 single bond were sterically equivalent to the C—H single bond. The angle $C_5C_1C_2$ which distributes equally the distortions from the normal values of the bond angles about the C_1 carbon atom is 125°, in agreement with the angle 125 ± 4° found above. The angle distortion for the system C—C—C is then nearly equal to that for C=C—C, indicating that in this case at least the effective bending constants for the two systems are apparently not markedly different.

The results of Rogowski[3] are not clarified. A radial distribution analysis of his s_0 values leads to the distances 1.55 and 2.88 Å., in agreement with the spiropentane model. In the absence of more details on the preparation and physical constants of the substance used in his investigation no further explanation can be given than was offered by Bauer and Beach.

The authors wish to express their thanks to Dr. E. R. Buchman for suggesting this research, and for his assistance and interest in the work.

Summary

The preparation and physical constants of methylenecyclobutane and 1-methylcyclobutene are described. The electron diffraction investigation of these compounds shows that they are cyclic structures with the expected configurations and distances.

Studies in the Chromammines. III. Preparation of Di-acido Diethylenediamine Salts by Thermal Decomposition of Triethylenediamine Luteo Salts[1,2]

BY CARL L. ROLLINSON[3,4] AND JOHN C. BAILAR, JR.

It has been observed that $[Cr\ en_3]Cl_3 \cdot 3^1/_2H_2O$[5] and $[Cr\ en_3](SCN)_3 \cdot H_2O$ lose one-third of their ethylenediamine (and all their water of crystallization) when heated for several days, the former at 160°,[6] and the latter at 130°.[7,8,9,10] The products of thermal decomposition of the luteo chloride and luteo thiocyanate are, respectively, *cis*-$[Cr\ en_2Cl_2]Cl$[6] and *trans*-$[Cr\ en_2(SCN)_2]SCN$.[8]

These reactions are of practical importance as means for preparing salts of the *cis*- and *trans*-diacido series and as essential steps in *cis–trans* isomerization cycles.[11] The influence of the anion on the configuration of the product is theoretically significant. It is noteworthy that *trans*-$[Cr\ en_2Cl_2]Cl$ is not converted to the *cis* isomer when heated at 160°[12] nor is *cis*-$[Cr\ en_2(SCN)_2]SCN$ converted to the *trans* isomer at 130°.[8]

The order of temperatures at which the two luteo salts decompose, namely, $Cl^- > SCN^-$, is in accord with results reported for other metal ammines. The vapor pressure curves for a series such as $[Ni(NH_3)_6]X_2$ parallel the curves for the corresponding ammonium salts, NH_4X; *i. e.*, the order of temperatures at which a given pressure is reached is $I^- > Br^- > Cl^- > SCN^-$ for both the hexammine salts and the ammonium salts.[13]

The apparent simplicity of these reactions is misleading, however. Preliminary attempts to prepare the *cis*-dichloro salt by thermal decomposition of the luteo chloride were completely unsuccessful. Weighed samples of the latter were heated by various means under a variety of conditions, including temperatures ranging from 160 to 220°, times up to one month, application of vacuum and use of surface extenders such as ground Pyrex or green glass, ground porous plate and glass beads. Although the samples lost weight slowly, the yellow color of the luteo salt never changed to the characteristic red-violet of the *cis*-dichloro salt. None of the desired compound could be obtained by recrystallization of the brown products.

It was then found that the reaction is catalyzed by traces of ammonium chloride. In a series of experiments carried out to determine the effect of impurities, a quantity of triethylenediamine chromic chloride prepared by the chromic sulfate method (1) was repeatedly recrystallized and a sample of each fraction heated in a small oven whose temperature was automatically controlled at 208 ± 3°. The results were disappointing until a fraction unintentionally contaminated with ammonium chloride was tested. This turned red-violet in a short time. Other samples to which ammonium chloride was deliberately added were then heated for several hours and *cis*-$[Cr\ en_2Cl_2]Cl$ was obtained from the products by recrystallization.

Previously it had been found that the luteo thiocyanate could be thermally decomposed to the *trans*-dithiocyanato salt without difficulty at 130°. It was determined that ammonium thiocyanate rather than ammonium chloride is the catalyst in this case.

The preparative methods used account for our success with the thiocyanate and failure with the chloride in the preliminary experiments. Our samples of luteo thiocyanate had been prepared by reaction of the chloride with ammonium thiocyanate as described by Pfeiffer[10] and we found that such samples contain catalytic quantities of ammonium thiocyanate. On the other hand, our original luteo chloride was never in contact with ammonium salts since it was prepared directly from chromous chloride.[14] The luteo chloride which Pfeiffer decomposed was prepared by a method involving reaction of the luteo sulfate with ammonium chloride,[6] a fact whose significance was at first overlooked. Such samples still contain catalytic amounts of ammonium chloride after recrystallization.

To demonstrate conclusively the catalytic nature of these reactions, pure samples of luteo chloride and thiocyanate, to which ammonium chloride and ammonium thiocyanate, respectively, were added in various ways, were heated at controlled temperatures until decomposition was nearly complete as shown by weight loss. To insure freedom from ammonium salts except those intentionally added, the luteo chloride was prepared by the reaction of the sulfate with hydrochloric acid[1] and the luteo thiocyanate from the chloride by means of sodium thiocyanate[1]; the products were recrystallized. Pure samples of the

two salts as controls were heated along with those contaminated with ammonium salts. The effect of recrystallization of luteo chloride and thiocyanate contaminated with ammonium salts was also determined.

In all cases the contaminated samples decomposed faster than the controls. The pure luteo chloride turned brown while that to which ammonium chloride had been added turned red-violet. While Pfeiffer reported a temperature of 160° and a time of several days,[6] we found that thermal decomposition of the chloride is nearly complete in a few hours at 210°; this reaction is too slow to be practical even at 180°. Decomposition of the thiocyanate is also complete in a few hours, at 130°, instead of several days as was indicated by Pfeiffer[9]; the discrepancy may be due to difference in ammonium thiocyanate content of Pfeiffer's luteo thiocyanate and that used in the present investigation.

Recrystallization of the luteo thiocyanate containing ammonium thiocyanate greatly decreases the rate of thermal decomposition. Recrystallization of the luteo chloride containing ammonium chloride, on the other hand, causes no change in the rate of thermal decomposition. This may be due to the fact that the luteo thiocyanate is much less soluble than the chloride while ammonium thiocyanate is much more soluble than ammonium chloride. Consequently, recrystallization is more efficient in the case of the thiocyanate.

The specificity of catalyst action seems to indicate that negative ions from the catalyst molecules actually enter the complex nucleus. While ammonium thiocyanate catalyzes the thermal decomposition of the luteo thiocyanate, ammonium chloride does not, even though the luteo thiocyanate crystals obviously contain thiocyanate ions in tremendous excess over the amount required (in the form of ammonium thiocyanate) for catalysis. No attempt was made to test the effect of ammonium thiocyanate on the decomposition of the luteo chloride, since this reaction proceeds at practical rates only at temperatures above that at which ammonium thiocyanate is converted to thiourea.

The water of crystallization of both the luteo chloride and thiocyanate (accounting for 51.2 and 23.1%, respectively, of the total theoretical weight loss) is readily driven off whether or not a catalyst is present. Pure samples decompose rapidly to an extent corresponding approximately to the loss of water of crystallization and thereafter lose weight at a greatly decreased rate. On the other hand, samples contaminated with ammonium salts continue to decompose rapidly even after the weight loss corresponds to the water of crystallization, marked decrease in rate occurring only after considerable ethylenediamine has been driven off.

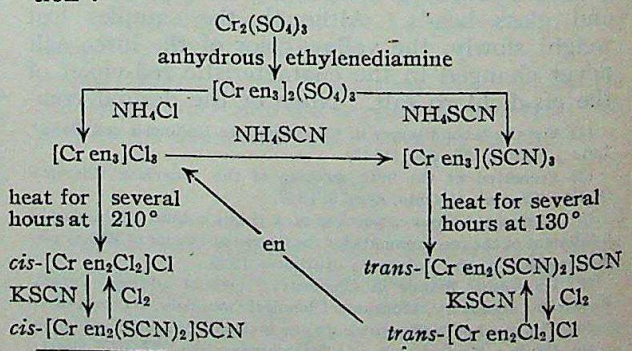
Determination of the conditions on which these reactions depend makes them available as synthetic procedures superior to the usual methods for preparing *cis*-$[Cr\ en_2Cl_2]Cl \cdot H_2O$ and *trans*-$[Cr\ en_2(SCN)_2]SCN \cdot H_2O$. The *cis*-dichloro salt is prepared from pure luteo chloride recrystallized from 1% ammonium chloride solution. The salt, spread in a thin layer, is heated for several hours at 208–212°. The course of the reaction is followed by weighing at intervals. The product may be recrystallized[15] but for most purposes it suffices to wash it with cold concentrated hydrochloric acid. A yield of 50% is easily obtained.

trans-$[Cr\ en_2(SCN)_2]SCN \cdot H_2O$ is prepared in a similar way from the luteo thiocyanate recrystallized from 25% ammonium thiocyanate solution. The salt is heated at about 130°, but not above 134°. The product is recrystallized from warm water. The yield is 60% or better.

These methods are definitely superior in convenience and efficiency to the usual procedures. The *cis*-dichloro salt is ordinarily prepared from potassium chromioxalate by a series of reactions involving synthesis of $[Cr\ en_2C_2O_4][Cr\ en(C_2O_4)_2]$ and $[Cr\ en_2(C_2O_4)]Cl$ as intermediates. Werner[16] reported a yield of only five grams of the *cis*-dichloro salt from one hundred grams of chromioxalate. The *cis*-dichloro salt may also be prepared by repeated evaporation of a solution of the luteo chloride with hydrochloric acid, but the yield is poor.[17]

Pfeiffer prepared *trans*-$[Cr\ en_2(SCN)_2]SCN \cdot H_2O$ by the action of ethylenediamine on $K_3[Cr(SCN)_6]$[8,9] as well as by thermal decomposition of the luteo salt. The yield by the former method is only 22% since separation of the *cis* and *trans* isomers is necessary. Pfeiffer's objection that the method of thermal decomposition is too slow is invalidated by the results of the present investigation.

The importance of these thermal decompositions is indicated by the following cycle based on reactions reported by Pfeiffer and co-workers[11] and those reported here and in a previous communication[1]:



(15) Ferguson (Thesis, University of Illinois, 1934) outlines a suitable procedure. Five grams of the salt is dissolved as quickly as possible in 20 cc. of water at 50–60°. The solution is rapidly filtered and 5 cc. of concentrated hydrochloric acid is added. On cooling in an ice–salt-bath, the solution deposits small red-violet needles of the pure salt.

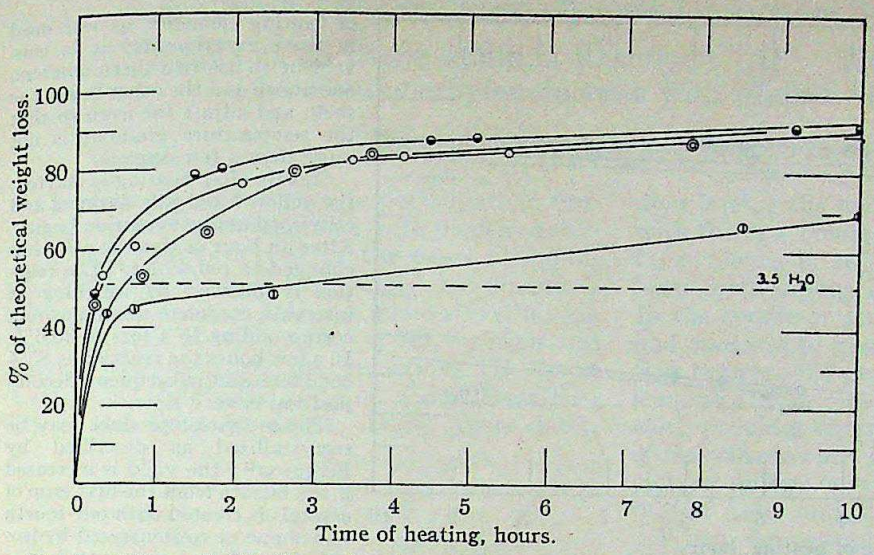

Fig. 1.—Effect of NH_4Cl on the thermal decomposition of $[Cr\ en_3]Cl_3 \cdot 3.5H_2O$ at 210°: ①, pure $[Cr\ en_3]Cl_3 \cdot 3.5H_2O$; ©, pure $[Cr\ en_3]Cl_3 \cdot 3.5H_2O$ ground with 2% solid NH_4Cl; ○, pure $[Cr\ en_3]Cl_3 \cdot 3.5H_2O$ recrystallized from 1% NH_4Cl solution; ◒, pure $[Cr\ en_3]Cl_3 \cdot 3.5H_2O$ recrystallized from 1% NH_4Cl solution, then from H_2O.

Repeated evaporation of the *cis*-dichloro salt with hydrochloric acid and mercuric chloride results in the formation of a mercury *trans*-dichloro double salt, but the yield is poor.[18] This *cis–trans* isomerization may be readily accomplished by use of the above reactions.

Preliminary rate studies indicate that these thermal decompositions are first order reactions, but lack of consistency of results of successive runs precludes a final conclusion. The method used, which evidently requires certain refinements, comprised heating the luteo chloride and thiocyanate (contaminated with ammonium salts) in an apparatus arranged to permit absorption and titration of the ethylenediamine evolved.

Experimental

Apparatus.—In determining the catalytic effect of ammonium salts, a small electric oven whose temperature could be closely controlled was used. This was made from a thin-walled refractory tube, closed at one end, 20 cm. long by 9 cm. inside diameter, wound with chromel wire and covered with alundum cement. The cylinder was enclosed in a transite box and fitted with a door made of transite. A thermometer and mercury thermoregulator were inserted through holes in the closed end of the cylinder. Temperature was controlled by auxiliary resistances which were short-circuited out of the system by a relay except when it was actuated by the thermoregulator.

(18) Ref. 6, p. 4279.

Thermal decomposition of larger quantities of the luteo chloride and thiocyanate, in preparation of the di-acido salts, was carried out in a large electric oven heated by a set of coils at the bottom. A baffle was placed over the coils to minimize the temperature gradient from the bottom to the top of the oven.

Catalytic Effect of NH_4Cl on the Thermal Decomposition of $[Cr\ en_3Cl_3] \cdot 3^1/_2H_2O$.—Pure luteo chloride, prepared by the method previously described,[1] was treated with ammonium chloride in various ways. One-gram samples of the products were heated in the small oven at 208–210° and weighed at intervals. Samples of the following were included for comparison: pure luteo chloride as a control; luteo chloride prepared from the sulfate by reaction with ammonium chloride; a sample prepared by recrystallization of luteo chloride contaminated with ammonium chloride.

The results are shown in Graph 1. It is evident that traces of ammonium chloride profoundly affect the course of the reaction and that the catalytic effect is not nullified by recrystallization of the luteo chloride containing ammonium chloride. It is also apparent that the luteo chloride prepared by action of ammonium chloride on the luteo sulfate contains catalytic amounts of ammonium chloride.

The effect of temperature on the course of the reaction was also determined. A 3-g. sample of pure luteo chloride recrystallized from 1% ammonium chloride solution was heated at 180° and weighed at intervals. The experiment was repeated at 170°. The data are plotted on Graph 2 with a plot of data for 210° for comparison. It is evident that the reaction would be inconveniently slow at 160° as specified by Pfeiffer.

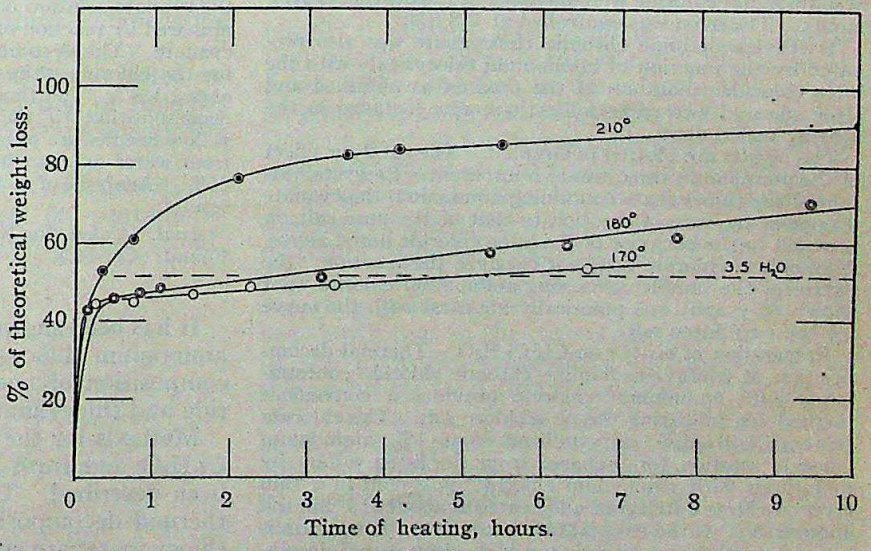

Fig. 2.—Effect of temperature on the thermal decomposition of $[Cr\ en_3]Cl_3 \cdot 3.5H_2O$ recrystallized from 1% NH_4Cl solution.

Catalytic Effect of NH_4SCN on the Thermal Decomposition of $[Cr\ en_3](SCN)_3 \cdot H_2O$.—Similar experiments were carried out with 3-g. samples of luteo thiocyanate containing small amounts of ammonium thiocyanate. To insure

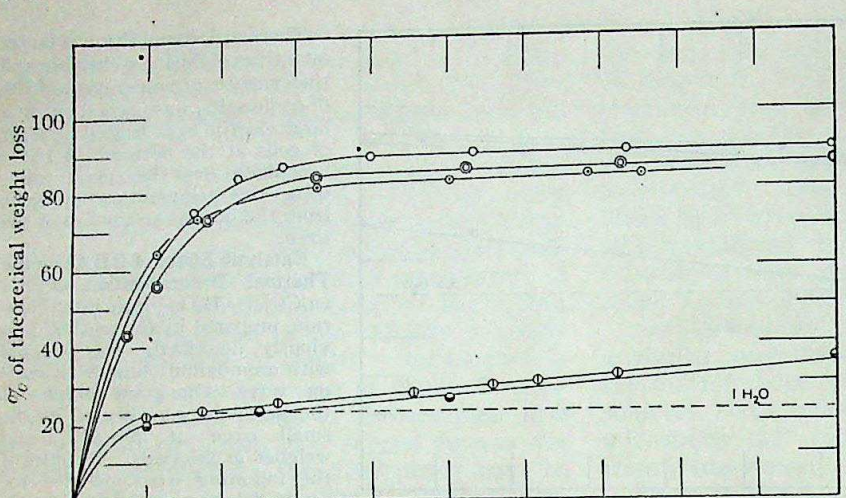

Fig. 3.—Effect of NH_4SCN on the thermal decomposition of [Cr en$_3$]$(SCN)_3$·H_2O at 130°: ⊕, pure [Cr en$_3$]$(SCN)_3$·H_2O; ©, pure [Cr en$_3$]$(SCN)_3$·H_2O ground with 2% solid NH_4SCN; O, pure [Cr en$_3$]$(SCN)_3$·H_2O recrystallized from 25% NH_4SCN solution; ◉, pure [Cr en$_3$]$(SCN)_3$·H_2O washed with saturated NH_4SCN solution; ◒, NH_4SCN-contaminated [Cr en$_3$]$(SCN)_3$·H_2O recrystallized from water.

freedom from ammonium salt except that intentionally added, the luteo thiocyanate was prepared from the pure chloride by means of sodium thiocyanate. Samples for thermal decomposition were prepared by adding ammonium thiocyanate to the triethylenediamine compound in various ways. A sample of the pure luteo thiocyanate, as a control, and a sample of the pure salt ground with 2% of ammonium chloride were included in the heating experiments. The oven was controlled at 128–130°.

Triethylenediamine chromic thiocyanate was also prepared by the reaction of ammonium thiocyanate with the luteo chloride. Samples of the product as obtained and after one and two recrystallizations were included in the heating experiments.

The results are plotted in Graph 3. The catalytic effect of the ammonium thiocyanate is apparent. Recrystallization of the thiocyanate containing ammonium thiocyanate decreases the rate of reaction to that of the pure salt, in contrast to the behavior of the luteo chloride noted above. Ammonium chloride does not catalyze the reaction; the curve for the sample containing ammonium chloride (not shown on graph) was practically identical with the curve for the pure luteo salt.

Preparation of *cis*-[Cr en$_2$Cl$_2$]Cl·H_2O.—Thermal decomposition of triethylenediamine chromic chloride contaminated with ammonium chloride provides a convenient method for preparing the *cis*-dichloro salt. The chloride [Cr en$_3$]Cl_3·$3^1/_2H_2O$ recrystallized from 1% ammonium chloride solution (or prepared from the luteo sulfate by metathesis with ammonium chloride) is spread in a thin layer on a large watch glass and heated at about 210° but not above 215°. If the temperature is too low, the reaction is inconveniently slow; if it is too high, deep-seated decomposition occurs with formation of brown reaction products. Some care must be taken to obtain the right temperature, especially with ovens in which there is a shelf above a set of heating elements, as was used in these experiments; it is convenient to use two thermometers, one above and the other below the shelf, and adjust the oven so that the temperature gradient is not more than a few degrees.

Shortly after heating is started, the yellow luteo salt darkens and ethylenediamine evolution begins. After an hour or two the color has changed to red-violet. The reaction is followed by weighing at intervals, complete decomposition corresponding to a loss of 30.6%. In a few hours the reaction is 85% complete and subsequent decomposition is very slow.

The red-violet product may be recrystallized as described by Ferguson[15]; the yield is increased if the filtrate from the first crop of crystals is treated with one-fourth its volume of concentrated hydrochloric acid and evaporated in a stream of air. However, the salt may be obtained pure enough for resolution and most other purposes by washing the product of thermal decomposition with ice-cold concentrated hydrochloric acid. The yield in either case is 50% or more. Analysis of a typical product by ignition of a sample to Cr_2O_3 gave the following results:

Anal. Calcd. for [Cr en$_2$Cl$_2$]Cl·H_2O: Cr, 17.51. Found: Cr, 17.6.

Preparation of *trans*-[Cr en$_2$(SCN)$_2$]SCN·H_2O.—Excellent yields of the *trans*-dithiocyanato salt may be obtained by a similar procedure. The starting material is pure luteo thiocyanate washed with saturated ammonium thiocyanate solution or unrecrystallized luteo thiocyanate prepared by reaction of the chloride with ammonium thiocyanate. The decomposition is carried out as described for the chloride; the temperature is not allowed to rise above 134°. The theoretical loss in weight for complete decomposition to the di-acido salt is 18.4%. Orange yellow needles are obtained by recrystallizing the product from water as described by Pfeiffer.[10] The yield is 60–65%. Analysis of a typical product gave the following results:

Anal. Calcd. for [Cr en$_2$(SCN)$_2$]SCN·H_2O: Cr, 14.29. Found: Cr, 14.4.

Summary

It has been shown that ammonium chloride and ammonium thiocyanate catalyze the thermal decomposition of triethylenediamine chromic chloride and thiocyanate, respectively.

Methods for the preparation of *cis*-[Cr en$_2$Cl$_2$]Cl·H_2O and *trans*-[Cr en$_2$(SCN)$_2$]SCN·H_2O have been described. These procedures, based on the thermal decomposition of the luteo chloride and thiocyanate, are superior to the usual methods in convenience and efficiency.

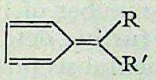
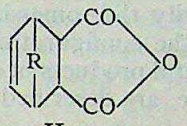
Studies on Diene-addition Reactions. II.[1] The Reaction of 6,6-Pentamethylenefulvene with Maleic Anhydride

BY R. B. WOODWARD AND HAROLD BAER

The capacity of fulvenes to participate in normal diene-addition reactions with maleic anhydride was first observed in the cases of 6,6-diphenylfulvene (I, R = R′ = C_6H_5), 6,6-dimethylfulvene (I, R = R′ = CH_3—), and 6-styrylfulvene (I, R = $C_6H_5CH{=}CH$—, R′ = H), by Diels and Alder,[2] who assigned the structures (II, R = $(C_6H_5)_2C<$ *or* $(CH_3)_2C<$ *or* $C_6H_5CH{=}CH{-}CH<$) to their products. Some years later,

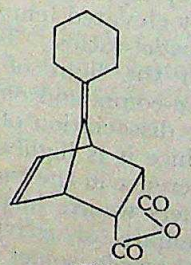


I

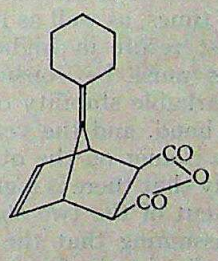


II

Kohler and Kable[3] obtained addition products from 6,6-tetramethylenefulvene (I, R,R′ = —$(CH_2)_4$—) and 6,6-pentamethylenefulvene (I, R,R′ = —$(CH_2)_5$—) with maleic anhydride. These adducts were hydrogenated to dihydroderivatives, from which cyclopentanone and cyclohexanone, respectively, were obtained on ozonization; these facts are in accordance with the formulations (II, R = $(CH_2)_4C{=}C<$ *or* $(CH_2)_5C{=}C<$). These investigators made the further striking observation that their adducts, as well as those obtained earlier by Diels and Alder, had the remarkable property of dissociating readily into their components, even on solution in the cold in a variety of solvents. Subsequently, Alder and Stein[4] called attention to the fact that the reaction of fulvenes with maleic anhydride is not stereochemically homogeneous, but leads in many cases to a mixture of products having different configurations. Thus, according to these workers, 6,6-pentamethylenefulvene gives approximately 40% of an adduct having the *endo-* (III) and 60% of a product with the *exo-* configuration (IV). No experimental evidence in support of these statements has been forthcoming in the intervening six years.[4] In the course of a related investigation, we have had occasion to make a careful study of the reaction between 6,6-pentamethylenefulvene and maleic anhydride. As will appear in the sequel, our work provides *experimental proof of the formation of the stereoisomers III and IV:* beyond this, our picture differs very considerably in detail from that of Alder and Stein.



III



IV

When 6,6-pentamethylenefulvene and maleic anhydride are allowed to react in benzene solution, at room temperature, an *α-adduct*, $C_{15}H_{16}O_3$, m. p. 132°, is obtained.[3] If, however, the mother liquor from the recovery of this product is allowed to stand for several weeks, very large beautiful crystals of a new, *β-adduct*, $C_{15}H_{16}O_3$, m. p. 93°, gradually separate. *Further, as the initial condensation is carried out at higher temperatures, the formation of the β-adduct takes place more rapidly, and less of the α-adduct is obtained.* These isomeric substances exhibit strikingly different behavior on solution in organic solvents. Solutions of the α-adduct, *e. g.*, in ethyl acetate or benzene, develop a deep yellow color, slowly in the cold, and very rapidly if warmed, as a result of partial dissociation into the (colored) fulvene and maleic anhydride. The β-adduct, on the other hand, is stable for relatively long periods, even in boiling solution. Only on heating for long periods above its melting point does the material gradually turn yellow.

Each of the adducts is reduced on shaking in ethyl acetate solution with hydrogen over reduced platinum oxide to a dihydro compound; the α-dihydro adduct melts at 146°, while the corresponding β-derivative has m. p. 104°. Kohler[3] has shown that in the case of the α-adduct, addition of hydrogen takes place exclusively on the ethene bridge, and further addition of hydrogen with saturation of the cyclohexylidene double bond is not possible. Similar phenomena are observed in the case of the new β-adduct. It is worthy of note that these results are concordant with the theory of catalyst hindrance developed *inter alia* by Linstead and his associates,[5] *viz.*, approach of a hydrogen-laden catalyst surface to the ethene bridge (arrows) of the model skeleton (V) would be relatively unhindered, while on the other hand approach to the other double bond would be difficult, if not impossible.

Both dihydro derivatives were stable, and therefore were used to determine the relationships be-

(4) This first suggestion of stereochemical complications in the reaction of fulvenes with maleic anhydride was made briefly by the German authors in a review article on their elegant work on the steric course of diene-addition reactions in general [*Angew. Chem.*, **50**, 514 (1937)]. However, in spite of intimations there and elsewhere [*cf.* Alder and Backendorf, *Ann.*, **535**, 102 (1938), Note 1] that experimental support for the ideas advanced would appear shortly, none has appeared in the considerable interval since 1937.

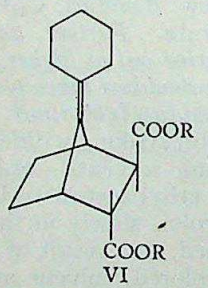
V

tween the isomeric initial adducts, since the dissociation of the latter themselves, at least in the case of the α-adduct, would have precluded their survival in the reactions necessary for configurational determination.

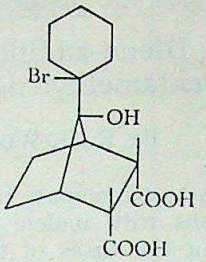
On catalytic esterification with methanol, the α-dihydro adduct was converted to an *oily* α-dihydrodimethyl ester, while the β-dihydro adduct gave a *crystalline* β-dihydrodimethyl ester, m. p. 65°. *Either dimethyl ester on boiling with sodium methoxide in methanol solution was inverted with the formation of the same trans-dihydrodimethyl ester, m. p. 75°.*[6] These facts demonstrate clearly that the latter compound has the structure (VI, R = CH_3), and that the difference



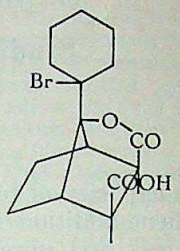
VI

between the initial α- and β-adducts is one of *endo-exo* isomerism. As a further check on the identity of the dimethyl esters, m. p. 75°, from the two sources, hydrolysis by acetic and hydrochloric acids of material prepared in either way gave the same *trans*-dihydrodicarboxylic acid (VI, R = H), m. p. 230–232° (dec.).

We are now in a position to determine which is the *endo*- and which the *exo*-series. On bromination of the α-dihydroanhydride (m. p. 146°) after long boiling in dilute acetic acid solution (to ensure opening of the anhydride ring), *a bromohydroxydicarboxylic acid* (VII), $C_{15}H_{21}O_5Br$, m. p. 153°, neutral equivalent, 179, was obtained. Similar treatment of the β-dihydroanhydride (m. p. 104°) gave a *bromolactone monocarboxylic acid* (VIII), $C_{15}H_{19}O_4Br$, m. p. 147°, neutral equivalent, 332. Since only *exo*-carboxyls are suitably placed for lactonization involving the cyclohexylidene double bond, it is evident that the bromination products have the structures (VII) and (VIII),[7] re-

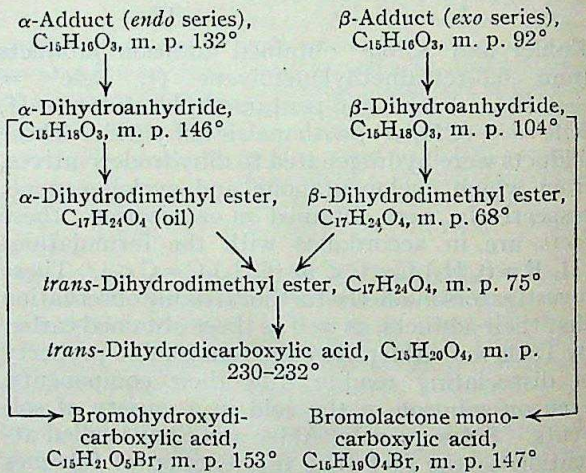


VII



VIII

spectively, and, consequently, *that the α-series has the endo-configuration, while the β-series are exo-derivatives, i. e., the α-adduct (m. p. 132°) has the structure (III), while the β-adduct (m. p. 93°) is to be formulated as (IV).* The accompanying chart will clarify the somewhat involved series of reactions of the configurational proof. A number of incidental products in each series, not further detailed here, are described in the experimental section.



We turn now to a more detailed discussion of the phenomena observed in connection with the formation and stability of the two addition products. We have demonstrated clearly that while the *endo* isomer is formed more rapidly, longer reaction times, as well as relatively elevated temperatures, result in higher *exo*/*endo* ratios. These facts must be considered in the light of the remarkable stability of the *exo*-compound on the one hand, and the very facile dissociation of the *endo* isomer on the other. Since it is highly unlikely that there is a great difference in the energy content of the two stereoisomers we are justified in assuming that the intermediate, or activated complex for the formation of the *endo* isomer is of lower energy than that involved in the *exo* addition. On this basis, the *endo* addition, having the lower energy barrier, will proceed more rapidly, but will compete less favorably as the reaction is carried out at higher temperatures, and the true equilibrium ratio, c_{exo}/c_{endo} will be more rapidly approached. Further, considering the reverse process, the *endo* isomer will pass relatively easily over the same (low) barrier, while the *exo* compound is stabilized by the higher barrier over

(6) For similar inversions, *cf.*, Hückel and Goth, *Ber.*, **58**, 447 (1925); Cook and Linstead, *J. Chem. Soc.*, 946 (1934); Linstead and Doering, THIS JOURNAL, **64**, 1991 (1942).

(7) There is some uncertainty in these formulations, in that the relative positions of the bromine and of the hydroxyl (or lactonic) substituents may be reversed. The point, of course, has no bearing on the configurational argument.

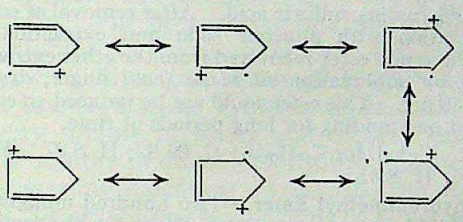
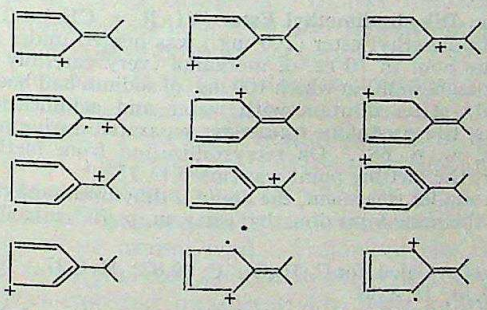
Digitized by Arya Samaj Foundation Chennai and eGangotri

which it must pass during the dissociation process. The situation is symbolized in Fig. 1, and is not an unfamiliar one in organic chemistry.[8] (In the diagram E_{ABexo} is assumed to be somewhat lower than E_{ABendo} since the *exo* isomer apparently preponderates under those conditions under which it is likely that true *exo-endo* equilibrium is most nearly approached.)

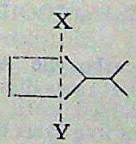
In mechanistic terms we are now faced with the problem of explaining the lower energy of the intermediate for *endo* addition. This may be interpreted in terms of the flat dipolar aggregate, $[A][B] \longleftrightarrow [A.]^+[B.]^- \longleftrightarrow [A]^+:[B]^-$, suggested by one of us as an intermediate in diene-addition reactions of this type.[1] The situation with regard to the distribution of charge over the diene moiety [A] of the intermediates is as follows; in the case of cyclopentadiene the charge will be distributed over the four carbon atoms of the unsaturated system:



In the case of the fulvenes, similar hybridization will likewise result in distribution of charge throughout the (now greater) conjugated system, *viz.*

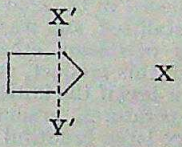


It is clear that in the fulvene case, loss of charge will be distributed over the molecule (IX) on both sides of the line XY



IX

Now when a maleic anhydride molecule adds to a fulvene, the addition takes place at the carbon atoms intersected by the line XY. Further, depending on whether the adding molecule lies to the left or right of the line XY, the *endo* or *exo* isomer will be obtained. It is now evident that in the fulvene case, attractive forces, arising both from exchange and charge overlapping, will be operative between the reacting fragments, whether the maleic anhydride molecule takes one position or the other and, further, that these attractive forces should be greater in the case of the intermediate for *endo* addition, in view of the somewhat greater concentration of charge within the pentacyclic ring. In the cyclopentadiene case it is clear that attractive forces will be operative only in the event that the molecule approaches from the left side of X′Y′ (*cf.* X). These relations will



be apparent from inspection of the space models of Fig. 2. (In these models, the opposite charges on each template, A [or A′] and B, are small, and equal to one another. The signs are intended to represent approximate *distribution*, rather than magnitude of charge.)

It is very likely that similar energetic conditions obtain in the diene-addition reactions of the simple dienes, in which only *endo* products are normally obtained. In this case, E^*_{ABexo} (*cf.* Fig. 1) is so high that none of the *exo* product is obtained under attainable conditions. In this connection it is worthy of note that in one case, that of the dimerization of cyclopentadiene,[9] the observed phemomena are similar to those noted in the case of the fulvenes: *i. e.*, at moderate temperatures, only the *endo* isomer is formed, while heating for long periods at elevated temperatures gives a mixture of *exo* and *endo* products. It is not unlikely that further cases will be found where variation of the experimental conditions will permit isolation of both steroisomers.

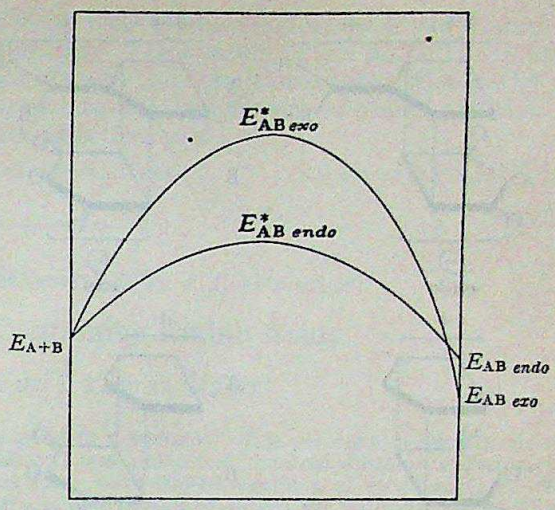


Fig. 1.

(8) Strictly speaking of course these considerations apply rigidly only to the *free* energies of the various processes. Since, however, the two isomers are both relatively rigid structures of equivalent symmetry, their entropies will be comparable, and we are justified in dealing with the absolute heat content of the various species.

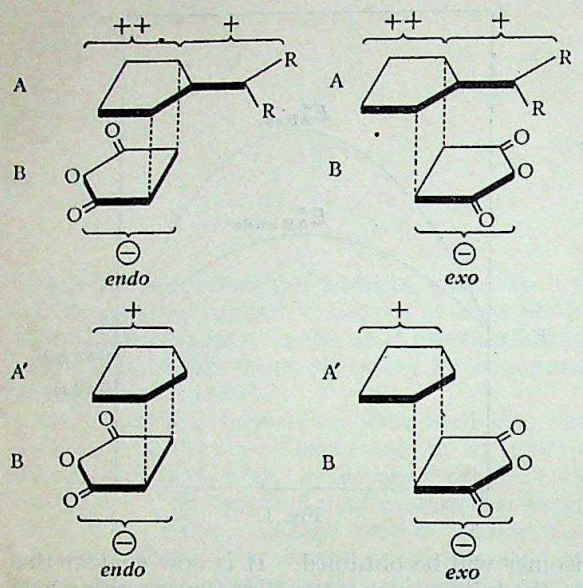

Fig. 2.—Models of intermediate complexes in the addition of maleic anhydride [B] to a fulvene [A] and to a simple diene [A']. Dotted lines indicate points of union in the final products.

Experimental

6,6-Pentamethylenefulvene was prepared according to Kohler's method.[3]

Condensation of 6,6-Pentamethylenefulvene and Maleic Anhydride.—All condensations were carried out with equimolar quantities of the reactants in concentrated benzene solution (fulvene/benzene = 1, by volume.) After standing (with or without heating) for specified times, the reaction mixture was placed in the cold room (5°), where the **α-adduct** (III) crystallized, and was collected and recrystallized from ether–petroleum ether, m. p. 132°. The mother liquors from this product, on standing for periods up to two weeks (or less if the initial reaction was carried out at higher temperatures) gradually deposited the **β-adduct** (IV) in very large beautiful plates, m. p. 87–90°, which on recrystallization from ligroin (b. p. 80–120°) had m. p. 92–93°. A sample recrystallized four times for analysis had m. p. 93.0–93.5°.

Anal. Calcd. for $C_{15}H_{16}O_3$: C, 73.9; H, 6.58. Found: C, 74.07; H, 6.75.

The following figures illustrate the effect of conditions on the yield of the α-adduct: ten minutes at 50°—20.8, 20.5%; 30 minutes at 60°—13.6, 14.5%; 60 minutes at 50°—3.1%.

The α-adduct, on solution in benzene or ethyl acetate, developed a yellow color, slowly in the cold, and rapidly on warming, while the β-adduct was apparently perfectly stable under these conditions.

β-Dihydroadduct.—On shaking with hydrogen over reduced platinum oxide, the β-adduct (3.2 g.) in 30 cc. purified[10] ethyl acetate consumed 315 cc. hydrogen (1 mole = 315 cc.) in *ca.* one-half hour at 26.5°, 776 mm., and the hydrogenation stopped. The residue after removal of solvent was thrice crystallized from ligroin (b. p. 90–120°), and dried *in vacuo* for three hours; needles, m. p. 103–104°.

Anal. Calcd. for $C_{15}H_{18}O_3$: C, 73.1; H, 7.37. Found: C, 73.3; H, 7.73.

Hydrogenation of the α-adduct under similar conditions gave the **α-dihydroadduct,**[3] m. p. 146°. Both dihydro adducts were readily converted into half-methyl esters by dissolving in methanol containing a drop of phenolphthalein solution, and adding 10% aqueous sodium hydroxide until the color persisted after boiling for a few minutes. After adding water to the cooled solution and acidifying with 10% hydrochloric acid, the substances were collected and recrystallized from ligroin. The **α-dihydromonomethyl ester** had m. p. 114°.

Anal. Calcd. for $C_{16}H_{22}O_4$: C, 69.05; H, 7.97. Found: C, 69.17; H, 8.39.

The **β-dihydromonomethyl ester had m. p. 118°.**

Anal. Calcd. for $C_{16}H_{22}O_4$: C, 69.05; H, 7.97. Found: C, 68.60; H, 7.92.

That these half-esters are different is evidenced by the mixed m. p., 89–92°.

In similar manner, using ethanol, certain half ethyl esters were prepared, *e. g.*, directly from the β-adduct, the **β-monoethyl ester,** m. p. 137–137.5°, was obtained.

Anal. Calcd. for $C_{17}H_{22}O_4$: C, 70.5; H, 7.6. Found: C, 70.57; H, 7.72.

From the α-dihydroadduct, an **α-dihydromonoethyl ester,** m. p. 104.5–105°, was prepared.

α-Dihydrodimethyl Ester.—One-half gram of the α-dihydroanhydride (m. p. 146°) was heated fifteen hours under reflux in 10 cc. of absolute methanol containing 0.2 cc. of 30% fuming sulfuric acid. After removal of solvent, neutralization with aqueous soda and extraction with ether, the crude ester recovered from the ether extract was purified by sublimation *in vacuo* (cold finger, dry ice), yield, 330 mg. This ester could not be induced to crystallize even on standing for long periods of time.

Anal. Calcd. for $C_{17}H_{24}O_4$: C, 69.82; H, 8.27. Found: C, 69.96; H, 8.31.

β-Dihydrodimethyl Ester.—Two hundred milligrams of the β-dihydroadduct (m. p. 104°) treated in the same way, gave 180 mg. of *crystalline* ester, recrystallized from methanol–water, m. p. 65°.

Anal. Calcd. for $C_{17}H_{24}O_4$: C, 69.82; H, 8.27. Found: C, 69.50; H, 8.59.

***trans*-Dihydrodimethyl Ester** (VI, R = CH_3).—The β-dihydrodimethyl ester (100 mg.) was heated under reflux for one hour in 10 cc. of methanol (very carefully dried over magnesium) in which 100 mg. of sodium had been dissolved. After dilution with water and acidification to litmus, the crystalline *trans*-ester separated during several hours, m. p. 68°. On recrystallization from methanol-water, the melting point was raised to 75°.

On similar treatment, the liquid α-dihydrodimethyl ester gave the same *trans* dimethyl ester, m. p. 75°, mixed m. p. 75°.

Anal. Calcd. for $C_{17}H_{24}O_4$: C, 69.82; H, 8.27. Found: C, 69.43; H, 8.36.

On saponification by heating with acetic and hydrochloric acids, the *trans* ester from either source gave the *trans*-dihydrodicarboxylic acid (VI, R = H), m. p. 230–232° (*dec.*).

Anal. Calcd. for $C_{13}H_{18}(COOH)_2$: neut. eq., 132. Found: neut. eq., 130.

Bromolactone Monocarboxylic Acid (VIII).—The β-dihydro adduct (m. p. 104°) was dissolved in glacial acetic acid, and water was added until the solution became cloudy. After boiling for five to six hours, the solution was rediluted with water until a slight cloudiness appeared. Bromine was then added dropwise until a slight yellow color persisted. After evaporation to very small volume (steam-bath), incipient precipitation was completed by immersion in ice. The collected solid was recrystallized from aqueous acetic acid, m. p. 146.5–147.5° (dec.).

Anal. Calcd. for $C_{15}H_{19}O_4Br$: C, 52.48; H, 5.58. Found: C, 52.41; H, 5.62. Calcd. for $C_{14}H_{18}O_2Br(COOH)$: neut. eq., 343. Found: neut. eq., 332.

Bromohydroxydicarboxylic Acid (VII).—Similar treatment of the α-dihydro adduct (m. p. 146°) gave the dibasic acid, recrystallized from aqueous acetic acid, m. p. 152–153° (dec.).

Summary

It is shown that in the addition of maleic anhydride to 6,6-pentamethylenefulvene, a dissociable *endo* product and a stable *exo* isomer are obtained. The relation of the properties of these isomers and the conditions under which they are formed to the mechanism of diene-addition reactions is discussed.

Hydantoins of Some Sulfur Containing Amino Acids

BY JOSEPH V. KARABINOS[1] AND J. LESTER SZABO

Introduction

The preparation of a number of hydantoins from amino acids has been described by Boyd.[1a] The hydantoins of the sulfur containing amino acids, cystine[2] and methionine,[1a] have been cited previously. The preparation of a thiol hydantoin in crystalline form, however, has not been described in the literature although Boyd[1a] did mention a non-crystalline cysteine hydantoin which was very soluble in water and alcohol but only slightly soluble in ether, chloroform and benzene.

In this communication we describe the preparation of the crystalline hydantoins of *l*-cysteine, *dl*-homocysteine, homocysteine and S-benzylhomocysteine. *l*-Cysteine hydantoin was obtained in good yield by treating *l*-cystine hydantoin with sodium in liquid ammonia. In like manner we have prepared *dl*-homocysteine hydantoin from the hydantoins of both homocystine and S-benzylhomocysteine. It is interesting to note that under the conditions used in this work, the hydantoin ring is stable to the reduction of sodium in liquid ammonia. The hydantoins of homocystine and S-benzylhomocysteine were obtained by the action of potassium cyanate and hydrochloric acid on the corresponding amino acid. Following the isolation of *l*-cysteine and *dl*-homocysteine hydantoins each was oxidized quantitatively with iodine to yield *l*-cystine- and *dl*-homocystine hydantoins, respectively.

In addition to the many sulfur compounds which have gained attention in therapeutic research certain hydantoins have likewise commanded interest, *e. g.*, in alleviating the symptoms of epilepsy. The fact that the hydantoins of *l*-cysteine and *dl*-homocysteine proved to be water soluble suggested possible practical applications.

Experimental Part

l-Cysteine Hydantoin.—Cystine hydantoin (29 g.) which was prepared according to the directions of Hess[2] was dissolved in 200 cc. of liquid ammonia to which sufficient sodium was added to maintain a blue color for ten minutes. The greater part of the ammonia was allowed to evaporate at room temperature and the last traces were removed in a vacuum. Ten per cent. hydrochloric acid (200 cc.) was added and the acid solution was extracted four times with 200-cc. portions of ethyl acetate. The extracts were combined, dried over sodium sulfate and the solvent was removed *in vacuo*. The white crystalline residue (15 g.) was easily recrystallized from water to give platelets melting at 144–145°.[3]

Anal. Calcd. for $C_4H_6O_2N_2S$: C, 32.87; H, 4.14. Found: C, 33.21; H, 4.14.

S-Benzylhomocysteine Hydantoin.—A mixture of 50 g. of S-benzylhomocysteine[4] and 22 g. of potassium cyanate was heated in 250 cc. of water for thirty minutes until a clear solution was obtained. When 10% hydrochloric acid (620 cc.) was added slowly, a solid precipitated which liquefied on heating. The mixture was heated on the steam-bath for several hours. After cooling the mixture, the crystals were collected on a filter. Following recrystallization from ethanol the material melted at 103–104° and weighed 45 g. (81%).

Anal. Calcd. for $C_{12}H_{14}O_2N_2S$: N, 11.19. Found: N, 11.43.

Homocystine Hydantoin.—Homocystine (10 g.) was suspended in 57 cc. of boiling water with 7.4 g. of potassium cyanate until complete solution was obtained. Ten per cent. hydrochloric acid (110 cc.) was added and the mixture evaporated on the steam-bath to about one-half the original volume. The homocystine hydantoin which crystallized from the cooled solution was collected by filtration, washed with water until chloride free and dried. The yield was 10 g. (82%); the compound melted at 204–205°.

Anal. Calcd. for $C_{10}H_{14}O_4N_4S_2$: N, 17.60. Found: N, 17.70.

***dl*-Homocysteine Hydantoin: (a) From Homocystine Hydantoin.**—To 5.2 g. of homocystine hydantoin in 50 cc. of liquid ammonia was added 1.8 g. of sodium. The ammonia was allowed to evaporate spontaneously. The residue was taken up in water and neutralized to a *p*H of 4 and extracted four times with 50-cc. portions of ethyl acetate. The extracts were combined, dried with sodium sulfate and the solvent removed *in vacuo*. The yield was 3.5 g. (67%) of a product melting at 120°.

(b) From S-Benzylhomocysteine Hydantoin.—To 6 g. of S-benzylhomocysteine hydantoin in 100 cc. of liquid ammonia was added 1 g. of sodium. The residue remaining after the evaporation of the ammonia was evacuated thoroughly, treated with 50 cc. of ice water, acidified with 12 cc. of concentrated hydrochloric acid and filtered. The solution was extracted twice with 10-cc. portions of benzene to remove toluene and dibenzyl and then with four 15-cc. portions of ethyl acetate. The ethyl acetate extracts were combined, dried and evaporated *in vacuo*. The residue weighed 3.5 g. (92%) and melted at 121–122°. Recrystallization from ethyl acetate did not raise the melting point.

Anal. Calcd. for $C_5H_8O_2N_2S$: C, 37.50; H, 5.03. Found: C, 37.83; H, 5.05.

Oxidation of Homocysteine Hydantoin.—Fifty mg. of homocysteine hydantoin was titrated with 2.9 cc. of 0.1 *N* iodine solution which is 93% of the theoretical. The crystals which precipitated were collected by filtration, dried and gave a m. p. of 201–203°. A mixed m. p. with homocystine hydantoin gave no depression.

Oxidation of Cysteine Hydantoin.—Sixty-four and a half mg. of cysteine hydantoin consumed 4.4 cc. of 0.1 *N* iodine solution which is the theoretical quantity. The crystals were collected on a filter and dried. The compound decomposed above 300° and gave a positive disulfide test.

Summary

1. The preparation of the hydantoins of *l*-cysteine, *dl*-homocysteine, S-benzylhomocysteine, and *dl*-homocystine has been described.

2. The hydantoin ring is stable to the reduction of sodium in liquid ammonia.

The Dehydration of Hydantoin-5-propionic Acid

BY J. LESTER SZABO AND JOSEPH V. KARABINOS

Introduction

If it is assumed that hydantoins may enolize, three possible structures (II, IV and VI) may be postulated for the compound obtained by the dehydration of hydantoin-5-propionic acid. Dakin[1] has stated that such an enolization (III ⇄ I) is possible since racemization of optically active hydantoins probably occurs through this mechanism.

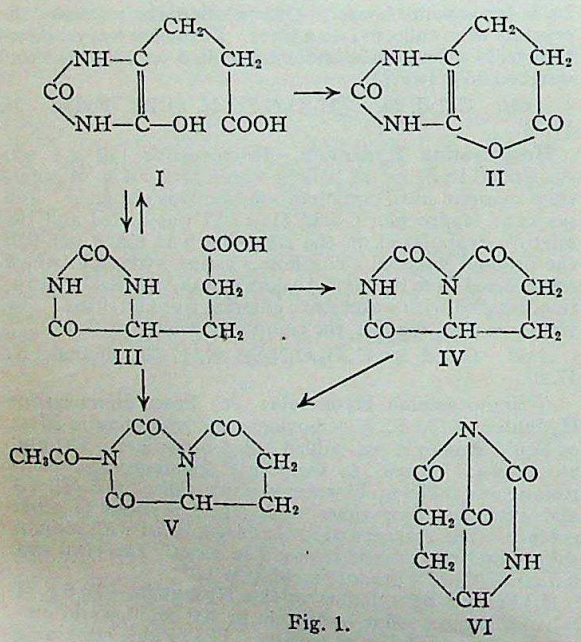

Fig. 1.

By the action of phosphoric anhydride on hydantoin-5-propionic acid (III) a molecule of water was split out and the resulting product obtained in good yield. Theoretically this could be either II, IV or VI. Acetylation of the acid as well as the lactam yielded the same mono-acetyl derivative (V). Neither the dehydration product nor the acetyl derivative reacted with aqueous potassium permanganate or bromine in carbon tetrachloride. The mono-acetyl derivative could not be acetylated further under conditions which yielded diacetyl hydantoin. These facts tend to indicate one of the lactam formulas (IV or VI).

However, the structure of the dehydration product was shown by the following experiment. 2-Thiohydantoin-5-propiolactam-1 (VIII) had been synthesized previously from pyrrolidone carboxylic acid and ammonium or potassium thiocyanate by Johnson and Guest[2] and also by Nicolet and Johnson.[3] By desulfurization of the thiohydantoin with chloroacetic acid they obtained hydantoin-5-propionic acid instead of hydantoin-5-propiolactam-1. Hydrolysis with dilute hydrochloric acid gave 2-thiohydantoin-5-propionic acid (IX). It was obvious, therefore, that if the acid (IX) could be converted back to the lactam (VIII) by dehydration with phosphoric anhydride, we could assume that hydantoin-5-propionic acid undergoes a similar reaction and that our dehydration product is the oxygen analog of VIII, *i. e.*, hydantoin-5-propiolactam-1 (IV). 2-Thiohydantoin-5-propionic acid (IX) was obtained by the hydrolysis of VIII and converted back to VIII by dehydration with phosphoric anhydride. We may assume, therefore, that the dehydration of hydantoin-5-propionic acid yields hydantoin-5-propiolactam-1 (IV) and not hydantoin-5-propiolactam-3 (VI) or the lactone (II).

Experimental

dl-**Hydantoin-5-propionic Acid (III).**—Hydantoin-5-propionic acid was prepared in a 62% yield from sodium glutamate and potassium cyanate according to the directions of Dakin.[1] After recrystallization from water, the product melted at 170°.[4]

Hydantoin-5-propiolactam-1 (IV).—Hydantoin-5-propionic acid (1.7 g.) was refluxed for two hours in 15 cc. of xylene containing 0.5 g. of phosphorus pentoxide. The mixture was allowed to stand overnight and crystals separated. The solvent was decanted and the crystals washed with 10 cc. of cold methanol and then recrystallized from 70% methanol. The yield was 1.2 g. (78%) of product melting at 196–198°. After three recrystallizations the substance melted sharply at 201°.

Anal. Calcd. for $C_6H_6O_3N_2$: C, 46.75; H, 3.92; N, 18.18. Found: C, 46.87; H, 4.12; N, 18.25.

1-Acetyl-hydantoin-5-propiolactam-1 (V).—A mixture of hydantoin-5-propionic acid (5 g.) and acetic anhydride (25 cc.) was refluxed for one hour. The excess solvent was removed by distillation *in vacuo* and the residue was crystallized by the addition of alcohol. Recrystallization from alcohol yielded 5 g. (88%) of product melting at 147–148°. One gram of this product was refluxed for four hours with acetic anhydride and recovered unchanged.

Anal. Calcd. for $C_8H_8O_4N_2$: C, 48.98; H, 4.11. Found: C, 48.96; H, 4.31.

Acetylation of Hydantoin-5-propiolactam-1.—Twenty-five mg. of hydantoin-5-propiolactam-1 was acetylated under the same conditions as the hydantoin-5-propionic acid and yielded a product melting at 147–148°. A mixed melting point with the product obtained by the acetylation of hydantoin-5-propionic acid showed no depression.

2-Thiohydantoin-5-propiolactam-1 (VIII).—Pyrrolidone carboxylic acid (VII) (40 g.) (from glutamic acid) and 28 g. of ammonium thiocyanate were warmed on a steam-bath with 180 cc. of acetic anhydride and 20 cc. of glacial acetic acid. A red solution was obtained which yielded 22 g. (43%) of crystals (m. p. 206–207°) after the addition of benzene. The recorded m. p. is 206–207°.

2-Thiohydantoin-5-propionic Acid (IX).—Two grams of (VIII) was refluxed with 25 cc. of 1 *N* hydrochloric acid for one-half hour and cooled. Two grams (90%) of acid (IX) melting at 121.5–122° crystallized out. The recorded m. p. is 122°.

Dehydration of 2-Thiohydantoin-5-propionic Acid (IX).—Two hundred mg. of IX was refluxed for two hours with 15 cc. of toluene containing 100 mg. of phosphorus pentoxide. The solvent was decanted while hot from a small amount of brown residue. On cooling crystals separated from the toluene solution. The yield was 120 mg. (66%) melting at 206–207°. A mixed m. p. with the lactam (VIII) gave no depression.

Acknowledgment.—We wish to thank Mr. John M. Kolbas for his assistance in the preparation of the manuscript.

Summary

The products obtained by the dehydration and the acetylative dehydration of hydantoin-5-propionic acid have been shown to possess the lactam structure IV and V.

NOTES

Synthesis of Bromoacetals

BY PAUL Z. BEDOUKIAN

Of the many syntheses of bromoacetal reported, that of Filachione[1] is the most convenient. It consists of slow addition of bromine to a mixture of vinyl acetate and alcohol at very low temperature (−40°). A recent modification of this method[2] involves very slow addition (ten hours) of bromine in the vapor form to a well-cooled mixture of vinyl acetate and alcohol.

The yields in both procedures are not high, being 46% for dimethyl acetal and 58–68% for diethyl acetal, and the method is rather cumbersome and time-consuming. Its chief disadvantage appeared to be the presence of methyl or ethyl alcohol during the bromination reaction, necessitating slow addition of bromine at low temperatures in order to prevent the bromination of the alcohol.

When bromine is added to a mixture of vinyl acetate and carbon tetrachloride at 0–10°, addition is very rapid and in the theoretical quantities. On adding the mixture to methyl or ethyl alcohol (99.5–100%) with cooling, a rapid reaction takes place with the formation of bromoacetal. This method is applicable to small or large scale preparations and the yields are of the order of 80–85% for dimethyl acetal and 75–80% for diethyl acetal.

Contrary to previous reports, bromoacetal freed from traces of bromoacetaldehyde by means of bisulfite or fractionation is not a lachrymator but does possess a rather pungent odor. On standing for several weeks a slight decomposition takes place with the formation of bromoacetaldehyde.

Experimental

Preparation of Bromoacetaldehyde Dimethyl Acetal.—One mole of vinyl acetate (86 g.) b. p. 71–73° was added to 150 ml. of carbon tetrachloride and cooled in an ice–water mixture. A mixture of 90 ml. of carbon tetrachloride and 160 g. of bromine was added to the vinyl acetate mixture with shaking, care being taken not to allow the temperature to rise above 10°. The addition took about twenty minutes and the end-point was reached when bromine no longer decolorized. The brominated mixture was then added to 350 ml. of methyl alcohol (99.5–100%), and cooled during the first hour to prevent rise in temperature as bromoacetal is formed. It was shaken occasionally and allowed to stand for two days. The mixture which consisted of two layers was diluted with one liter of water and the bromoacetal–carbon tetrachloride layer drawn off. The methyl alcohol–water mixture was further ex-

tracted twice with 150 ml. of carbon tetrachloride to recover the major portion of the dissolved bromoacetal. The carbon tetrachloride solutions were combined and distilled through a Whitmore–Fenske type column. Bromoacetaldehyde dimethyl acetal (124 g. or 83%) distils at 48–49° (14 mm.), n^{20}D 1.4450; d^{20}_4 1.430.

Preparation of Bromoacetaldehyde Diethyl Acetal.—The above procedure was repeated using 500 ml. of ethyl alcohol (99.5–100%) instead of 350 ml. of methyl alcohol. Distillation yielded bromoacetaldehyde diethyl acetal (151 g. or 77%), b. p. 64–65° (16 mm.), n^{20}D 1.4418; d^{20}_4 1.280. On using commercial 95% ethyl alcohol the yield was somewhat lower (142 g. or 72%).

An Improved Method for the Synthesis of Quinone

BY JOHN H. BILLMAN, BERNARD WOLNAK AND DAVID K. BARNES

In the course of another investigation it was necessary to prepare quinone in relatively large amounts. The procedure described in "Organic Syntheses"[1] requires vanadium pentoxide as a catalyst. Since there was no vanadium pentoxide available, we substituted an equivalent amount of ammonium metavanadate which worked equally well and gave comparable yields. In addition the reaction time was reduced to less than one third the time normally required. Other runs were made using increased amounts of ammonium metavanadate and warming the reaction mixture to 40° before adding the catalyst. It was found that the greater the amount of catalyst used the faster the reaction proceeded. Thus with 1.4 g. of ammonium metavanadate the reaction was complete in less than half an hour or about one-eighth the time normally required. The final procedure which was used is described in the experimental part.

Experimental

Quinone.—In a 2-liter round-bottom three-neck flask equipped with a mechanical stirrer and a thermometer were placed 1 liter of a 2% sulfuric acid solution, 110 g. of hydroquinone, and 60 g. of sodium chlorate. The mixture was vigorously stirred and warmed to 40°. At this temperature 1.4 g. of ammonium metavanadate was added. The flask was cooled from time to time, with tap water, so that the temperature did not rise above 42°. The reaction was over in less than thirty minutes. The mixture was cooled to 10°, then filtered with suction, and the quinone washed once with 100 ml. of cold water. After drying in a desiccator over calcium chloride the product weighed 97–99 g. and melted at 112–113°. Extraction of the filtrate and washings with three 100-ml. portions of warm benzene yielded 3–4 g. more of quinone, bringing the total amount to 101–103 g. (93–95% of the theoretical amount).

The quinone may be dried in about an hour in an oven at 100°. This should be done under a hood. There is about a 15% loss due to sublimation. Over calcium chloride, it takes from one to two days for the quinone to dry.

Preparation of *o*-Aminobenzyl and β-Aminoethyl Thiazolium Salts

BY HANS T. CLARKE

In view of the interesting observations recorded by Sealock and Goodland,[1] a description becomes necessary of the preparation of the thiazolium amino compounds which inhibit the enzymatic decomposition of the amine. After the recognition of the thiazole ring in thiamine,[2] these substances were synthesized early in 1936 for study as models, but they found useful application only after they had reached Dr. Sealock's Laboratory.

Experimental

3-*o*-Nitrobenzyl-4-methylthiazolium Chloride.—A mixture of 3.5 g. of *o*-nitrobenzyl chloride, 1 cc. of benzene and 2.0 g. of 4-methylthiazole was heated at 95–100° in a sealed tube for eighty to ninety hours. The crystalline product, well washed with ether and recrystallized from absolute alcohol, decomposed at 186.5–187°. The yield was 4.1 g. or 75%.

Anal. Calcd. for $C_{11}H_{11}O_2N_2SCl$: N, 10.4; Cl, 13.1. Found: N, 10.04; Cl, 13.1.

3-*o*-Aminobenzyl-4-methylthiazolium Chloride Hydrochloride.—A hot solution of 1.4 g. of the above nitro compound in 50 cc. of 2 *N* hydrochloric acid was boiled gently for an hour in the presence of 2.4 g. of granulated tin. As very little action had occurred, 3.4 g. of crystallized stannous chloride was added. The precipitate which formed slowly dissolved in the boiling mixture. The clear solution was warmed at 50° overnight, when most of the tin dissolved. The mixture was diluted, freed of tin salts with hydrogen sulfide and evaporated to dryness under reduced pressure. The residue was warmed with 4 cc. of absolute alcohol, when it rapidly became crystalline; it was filtered and washed with absolute alcohol. The product (about 0.9 g.) after recrystallization from aqueous alcohol decomposed over the range 204–212°.

Anal. Calcd. for $C_{11}H_{14}N_2SCl_2 \cdot H_2O$: C, 44.8; H, 5.1; N, 9.5; Cl, 24.1. Found: C, 45.3; H, 4.9; N, 9.2; Cl, 24.4.

3-β-Phthalimidoethyl-4-methylthiazolium Bromide.—Equimolecular quantities of β-bromoethylphthalimide and 4-methylthiazole were heated in a sealed tube at 95–100° for ten days, when the mixture had completely solidified. The product was washed with ether, and recrystallized from water as platelets, m. p. 238° with slight darkening.

Anal. Calcd. for $C_{14}H_{13}O_2N_2SBr$: N, 7.9; Br, 22.7. Found: N, 7.9; Br, 22.4.

3-β-Aminoethyl-4-methylthiazolium Bromide Hydrobromide.—A solution of 2.5 g. of the phthalimide thiazolium bromide in 10 cc. of 48% hydrobromic acid was boiled under reflux for forty hours, and allowed to cool to room temperature. The phthalic acid (1.0 g., 85%) was filtered off and washed with water; the filtrate and washings were combined and evaporated nearly to dryness, the residue treated with absolute alcohol, and the crystalline product well washed with absolute alcohol. It shrank at 218.5–219.5° and melted with decomposition at 222.5–223.5°; yield 2.1 g.

Anal. Calcd. for $C_6H_{12}N_2SBr_2$: N, 9.2; S, 10.5; Br, 52.7. Found: N, 9.1; S, 10.7; Br, 52.8.

Syntheses of Compounds Related to Vitamin K. II. *p*-(3-Alkyl-4-hydroxynaphthylazo)-benzenesulfonamides

BY EDITH JU-HWA CHU, ZOE-ING SHEN, TSUI-LIN CHIEN AND T. S. TUAN

In continuation of our work on compounds related to vitamin K[1] a number of 2-alkyl-1-naphthols have been synthesized and coupled with the diazotized sulfanilamide to yield the corresponding *p*-(3-alkyl-4-hydroxynaphthylazo)-benzenesulfonamides in which the alkyl groups are ethyl, *n*-propyl, *n*-butyl, isobutyl, *n*-amyl and *β*-phenylethyl, respectively. The parent substance, *p*-(4-hydroxynaphthylazo)-benzenesulfonamide was mentioned in the literature.[2]

All the *p*-(3-alkyl-4-hydroxynaphthylazo)-benzenesulfonamides were obtained in colored crystals except *p*-(3-isobutyl-4-hydroxynaphthylazo)-benzenesulfonamide which was a viscous mass and was difficultly purified. They possess no inhibitory effect on the growth of *Bacillus coli*, *Staphylococcus aureus* or *Streptococcus pyrogenes*.[3] The antihemorrhagic activity of these compounds and *p*-(3-methyl-4-hydroxynaphthylazo)-benzenesulfonamide will be reported later on. They behave as indicators, red in alkaline solution and yellow in acid solution.

TABLE I

Experimental

2-Alkyl-1-naphthols.—They were synthesized by Clemmensen reduction of 2-acyl-1-naphthols. Although the Stoughton method[4] of preparing 2-acyl-1-naphthols gave better result than other methods[5-9] described in the literature, the Fries rearrangement of *α*-naphthyl ester by means of aluminum chloride always gave the *p*-isomer and other by-products besides the desired 2-acyl-1-naphthol. Then the procedure was thus modified: A mixture of equal amounts of the *α*-naphthyl ester and freshly fused and powdered zinc chloride was heated on an oil-bath at 140–50° for an hour. The cold mass was treated with water to remove zinc chloride and the precipitate was recrystallized from a mixture of alcohol and acetone. The yields of 2-acyl-1-naphthols were much more satisfactory as shown in Table I. The use of anhydrous stannic chloride gave the same good results.

The 4-isobutyryl- and 4-*n*-valeryl-1-naphthols were quantitatively rearranged to the 2-isomers, respectively, by refluxing with 35% sodium hydroxide solution for two hours. However, the 4-acetyl-1-naphthol was not isomerized by the same treatment.

Among the 2-alkyl-1-naphthols prepared, the 2-*β*-phenylethyl-1-naphthol was not previously reported. It was obtained in colorless crystals from alcohol; yield, 23% and m. p. 77–78° (dec.). The reddish-orange needles of its picrate melt at 179–180 (dec.).

Anal. Calcd. for $C_{18}H_{16}O \cdot C_6H_3N_3O_7$: N, 8.81.[10] Found: N, 9.20.

***p*-(3-Alkyl-4-hydroxynaphthylazo)-benzenesulfonamides.**—An acetic acid solution of 0.01 g. mole of 2-alkyl-1-naphthol was gradually added to a diazotized solution prepared from 0.01 g. mole of sulfanilamide. The colored precipitate was filtered and then purified either by recrystallization from a suitable solvent or by dissolving in dilute sodium hydroxide and reprecipitating with dilute hydrochloric acid. The yields and properties are listed in Table II.

The Second Ionization Constant of Deuterocarbonic Acid

BY JAMES CURRY AND Z. ZIMMERMAN HUGUS, JR.

Introduction.—We have measured the e. m. f. of the following cells at 25°

H_2, $KHCO_3$, K_2CO_3, KCl, AgCl, Ag (I)

D_2, $KDCO_3$, K_2CO_3, KCl, AgCl, Ag (II)

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The potential of cell I is given by

$$E = E_0 - \frac{RT}{F} \ln m_H m_{Cl} - \frac{RT}{F} \ln f_H f_{Cl} \quad (1)$$

where E_0 is the standard electrode potential of the silver–silver chloride electrode in water referred to hydrogen, m is the concentration in molal terms and f is the activity coefficient of the quantities indicated by the subscripts.

The second thermodynamic ionization constant for proto-carbonic acid is

$$K_H = \frac{m_H m_{CO_3}}{m_{HCO_3}} \frac{f_H f_{CO_3}}{f_{HCO_3}} \quad (2)$$

Replacing m_H in (1) by its value from (2) and solving for the negative logarithm of the ionization constant we obtain

$$pK_H = \frac{E - E_0}{0.0591} + \log \frac{m_{HCO_3} m_{Cl}}{m_{CO_3}} + \log \frac{f_{HCO_3} f_{Cl}}{f_{CO_3}} \quad (3)$$

If we define pK_H as the sum of the first two terms on the right-hand side of (3) we then get

$$pK_H = pK_H^* + \log \frac{f_{HCO_3} f_{Cl}}{f_{CO_3}} \quad (4)$$

The analogous equations for cell II are

$$pK_D = \frac{E - E_0'}{0.0591} + \log \frac{m'_{DCO_3} m'_{Cl}}{m'_{CO_3}} + \log \frac{f'_{DCO_3} f'_{Cl}}{f'_{CO_3}} \quad (5)$$

$$pK_D = pK_D^* + \log \frac{f'_{DCO_3} f'_{Cl}}{f'_{CO_3}} \quad (6)$$

where K_D is the second ionization constant of deutero-carbonic acid and the primes refer to the values for D_2O. E_0' includes the standard electrode potential of the deuterium electrode and the silver–silver chloride electrode in D_2O.

Experimental.—The purification of the salts and deuterium oxide, the preparation of the silver–silver chloride electrode, the cell and the potentiometer have been described previously.[1] A detailed description of the hydrogen (deuterium) electrode will be given in another article. In order to avoid loss of carbon dioxide and consequent change in the carbonate-bicarbonate concentrations a device was developed which circulated the hydrogen in a closed system. This also allowed the use of macro quantities of deuterium but at the same time avoided the necessity of using a large quantity of this gas.

This device consisted of a short endless system of tubing which was fastened to the end of the cell containing the hydrogen electrode. One portion of the system was enlarged and contained a Bunsen valve. The pressure in part of the system could be increased by raising a column of mercury. This caused the hydrogen to bubble through the solution around the platinum electrode. The mercury was then lowered and the cycle repeated. A motor and eccentric raised and lowered the mercury column at a rate of fifteen times per minute. The electrode, itself was spiral in shape and was platinized in a conventional manner.

The hydrogen was obtained from a commercial tank and was purified by passing it through alkaline pyrogallol, sulfuric acid and distilled water. The deuterium was prepared by electrolyzing 98.9% D_2O. For one determination about 100 cc. of deuterium was used. The circulation system, including the cell, had a volume of 35 cc. and the excess gas was used for flushing purposes.

Constant readings were obtained with no great difficulty, the e. m. f. of the cell usually varied no more than 0.1 mv. over a period of an hour or two. Before measurements were made on cells (I) and (II) the reliability of the circulating device was tested on the cell H_2, HCl, AgCl, Ag. These measurements were found to be quite satisfactory.

Results.—The results obtained are summarized in the following table.

$E_0 = 0.2224$				$E_0' = 0.2190$	
Molality					
KCl	bicarbonate	K_2CO_3	$X \times 10^4$	E	pK^*
		H_2O			
0.01356	0.01572	0.01234	1.7	0.9263	10.158
.02841	.02976	.03055	2.4	.9129	10.133
		98.9% D_2O			
.01111	.01286	.01169	1.2	.9663	10.740
.02444	.02883	.02887	1.5	.9468	10.707
		$K_H/K_D = 3.95$			

Discussion.—The fourth column gives the amount of potassium carbonate hydrolyzed. This was calculated according to the method of MacInnes and Belcher[2] and was taken into account in calculating pK^*. The value of K_w for D_2O was taken as 0.16×10^{-14}. As is customary, the values of E have been corrected to a hydrogen (deuterium) pressure of one atmosphere.

The values obtained for pK_H^* agree well with those of MacInnes and Belcher at similar ionic strengths. The first agrees within 0.04%; the second within 0.3%.

E_0' is made up of the standard electrode potential of the silver–silver chloride electrode in D_2O and the deuterium ion–deuterium electrode. As in previous work[1] the standard electrode potential for the silver–silver chloride electrode was taken to be the same in D_2O as in H_2O. For the deuterium electrode the value obtained by Abel, Bratu and Redlich,[3] namely, 0.0034 volt, was used. These authors used a micro method to measure this value and it had been our original intention to redetermine it using our macro method but events precluded this.

In a comparative method, such as the present one, the quantity desired is K_H/K_D. This can be obtained through a knowledge of the ratio pK_H/pK_D and the value of K_H. Because the solutions used were quite dilute a close approximation to this latter ratio can be obtained by finding pK_H^*/pK_D^*, the numerator and denominator being taken at the same ionic strengths. The reason for this is that the logarithmic term of the ratio of activities in both (4) and (6) is small compared to pK^*.

Using the values of pK_D^* in the table and finding pK_H^* for the same ionic strengths from the work of MacInnes and Belcher, we calculate from the first measurement in D_2O that pK_H^*/pK_D^* is equal to 0.94590 and from the second a value of 0.94415. Thus, for the reasons given above, we can take the average of these to be equal to pK_H/pK_D. Using this average and MacInnes and Belchers' value of K_H, namely, 5.61×10^{-11},

the second ionization constant for deutero-carbonic acid may be calculated to be 1.42×10^{-11}. Thus K_H/K_D is equal to 3.95.

It should be pointed out that this value of K_H/K_D for the second ionization constant of carbonic acid agrees within 4% of that predicted by the curve of Rule and LaMer[4] and confirmed by Martin and Butler.[5]

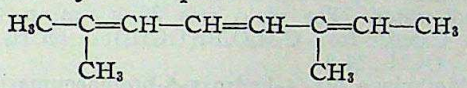
The Production of α- and β-Pyronene from *allo*-Ocimene

BY L. A. GOLDBLATT AND S. PALKIN[1]

Among the products obtained in the pyrolysis of α-pinene in the vapor phase,[2,3,4] at about 375°, the acyclic terpene



(2,6-dimethyl-2,4,6-octatriene) is of the greatest interest, both from a practical and theoretical point of view. The simultaneous formation of the monocyclic hydrocarbons α- and β-pyronene was first observed by Dupont and Dulou, who postulated[3] that they were obtained from α-pinene by a simultaneous and independent reaction, namely, rupture of the four-membered ring in α-pinene, and not by further isomerization of either *allo*-ocimene or dipentene, other products of the pyrolysis. They later reported[5] that this hypothesis had been confirmed.

In the course of the work of the Naval Stores Research Division on the vapor phase thermal isomerization of terpene hydrocarbons, it was found that the pyronenes are in fact obtained by the recyclization of *allo*-ocimene.[6]

The apparatus used for the pyrolysis is shown in Fig. 1. This consists essentially of a pyrolysis tube, together with a suitable condensing and receiving system. Heat for the pyrolysis tube is supplied by means of a bath of "HTS" (a commercial mixture of sodium and potassium nitrate and nitrite). This in turn is heated by passage of an electric current through 25 feet (resistance, 16 ohms) of no. 20 Nichrome wire wound on asbestos-paper covering a suitable length of ordinary 1.5-inch iron pipe. Temperature was controlled by a variable voltage transformer and measured by a movable thermocouple in a glass well placed vertically in the center of the reaction tube. In normal operation the temperature generally did not vary more than 5° for about half the length of the pyrolysis tube, although the temperature was materially lower at both ends. *allo*-Ocimene was supplied to the pyrolysis tube by a Tropsch and Mattox pump[7] capable of supplying *allo*-ocimene at a definite rate varying from about 50 to 750 cc. per hour with a precision of 1%. Flow of *allo*-ocimene supplied by the pump was made more uniform by inserting a coil of glass tape just inside the spherical joint.

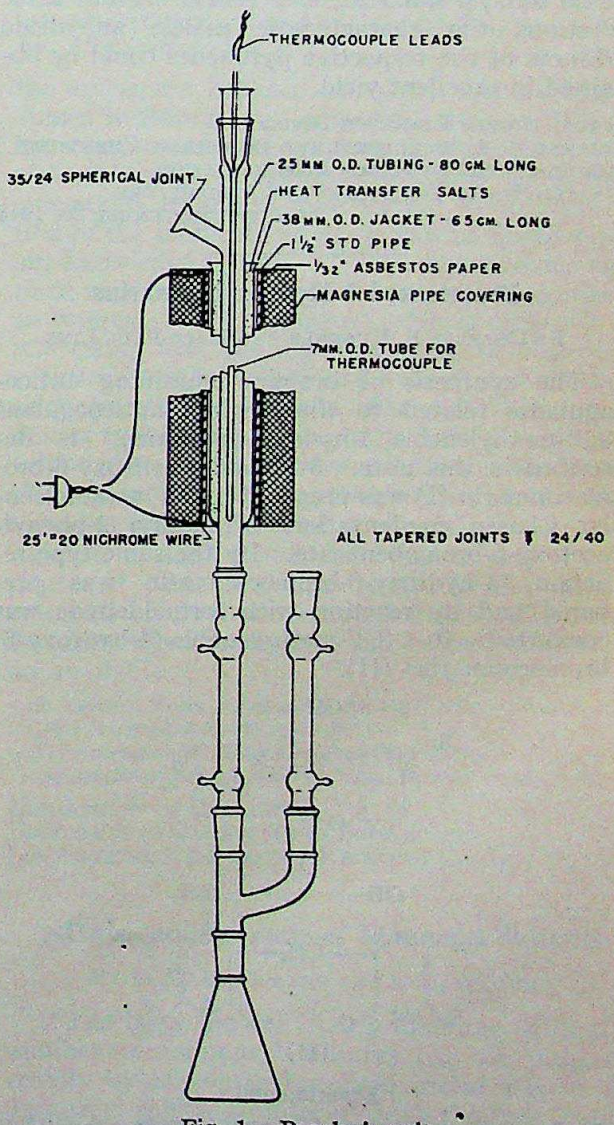


Fig. 1.—Pyrolysis unit.

Change in refractive index provides a convenient guide to the extent of isomerization. A sample of *allo*-ocimene having the characteristics

(6) Work of the Naval Stores Research Division on the vapor phase cyclization of *allo*-ocimene has been temporarily discontinued owing to preoccupation with problems more closely related to the war effort. Reporting of these preliminary results at this time is prompted by a communication from Dr. J. E. Hawkins and R. E. Fuguitt of the University of Florida, who have confirmed this observation from information obtained in the study of the thermal isomerization of α-pinene in the liquid phase, and who have generously undertaken to remove any question as to priority of this discovery in a forthcoming publication.

$n^{20}D$ 1.5449 and d^{20}_4 0.8083, when pyrolyzed under optimum conditions (a temperature of 400° and a through-put of 250 g. per hour) gave a product of $n^{20}D$ 1.4790. Considerable variations in through-put rate or pyrolysis temperature may be made without materially altering the extent of isomerization (as judged by change in refractive index).

A portion of the pyrolyzate obtained in this way ($n^{20}D$ 1.4795; d^{20}_4 0.8358) when fractionally distilled *in vacuo* was found to contain about 30% of α-pyronene and about 45% of β-pyronene, together with some unchanged *allo*-ocimene, dimer, and other unidentified hydrocarbons. The fractions containing the highest concentrations of α- and β-pyronene had the following characteristics: α-pyronene, b. p. 54–56° at 20 mm., d^{20}_4 0.8272, $n^{20}D$ 1.4672; β-pyronene, b. p. 62–64° at 20 mm., d^{20}_4 0.8481, $n^{20}D$ 1.4800. From these fractions the characteristic maleic anhydride adducts of the respective pyronenes could be obtained in excellent yield.

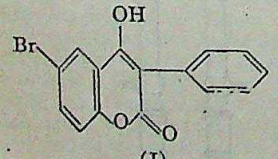
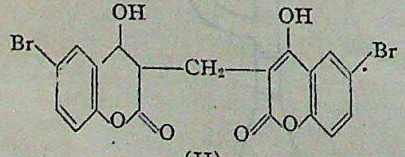
Brominated 4-Hydroxycoumarins

BY CHARLES F. HUEBNER AND KARL PAUL LINK

The synthesis of bromine-containing anticoagulants related to the original anticoagulant 3,3′-methylenebis-(4-hydroxycoumarin),[1] is described in this note. 3-Phenyl-4-hydroxy-6-bromocoumarin (I) was prepared by an intramolecular Claisen condensation[2] of methyl 2-phenylacetoxy-5-bromobenzoate. By the same type reaction, 4-hydroxy-6-bromocoumarin was prepared and by reaction with formaldehyde was converted to 3,3′-methylenebis-(4-hydroxy-6-bromocoumarin) (II).



(I)



(II)

Experimental

Methyl 2-Phenylacetoxy-5-bromobenzoate.—A mixture of 60 g. of phenylacetyl chloride and 90 g. of methyl 5-bromosalicylate[3] was heated under reflux on a steam-bath for four hours. Pyridine (30 ml.) was added and the heating was continued for four hours longer. The resulting oil was dissolved in ether and extracted successively with water, hydrochloric acid solution, and sodium carbonate solution. The ether solution was dried and the ester was crystallized by the addition of petroleum ether. After two recrystallizations from ethanol the product weighed 56 g., m. p. 68–70°. *Anal.* Calcd. for $C_{15}H_{10}O_3Br(OCH_3)$: OCH_3, 8.9. Found: OCH_3, 8.8.

3-Phenyl-4-hydroxy-6-bromocoumarin (I).—To a well-stirred melt of 20 g. of methyl 2-phenylacetoxy-5-bromobenzoate contained in a round bottom flask, 1.3 g. of sodium was added and the temperature was raised to 200°, at which point a spontaneous reaction occurred. External heating was discontinued and after thirty minutes the glassy mass was cooled and dissolved in water. The aqueous solution was acidified to *p*H 6, extracted with ether, and further acidified to *p*H 5. The product crystallizing between these two *p*H's was filtered and recrystallized twice from acetic acid. The yield was 8 g., m. p. 252–254°. *Anal.* Calcd. for $C_{15}H_9O_3Br$: C, 56.8; H, 2.8. Found: C, 57.0; H, 2.9.

Methyl 2-Acetoxy-5-bromobenzoate.—To 30 g. of methyl 5-bromosalicylate was added 80 ml. of acetic anhydride and 1 ml. of sulfuric acid. After thirty minutes the mixture was poured into ice water, the oil was washed with sodium carbonate solution, and crystallized from methanol–water. The yield was 20 g., m. p. 33–35°. *Anal.* Calcd. for $C_9H_6O_3Br(OCH_3)$: OCH_3, 11.4. Found: OCH_3, 11.3.

3,3′-Methylene bis-(4-hydroxy-6-bromocoumarin) (II).—4-Hydroxy-6-bromocoumarin was prepared in a manner similar to that described for 3-phenyl-4-hydroxy-6-bromocoumarin except that the reaction was run in kerosene and the final product was collected between *p*H 5.6 and 2.5. From 176 g. of ester, and 14.8 g. of sodium in 300 ml. of kerosene, 92 g. of crude 4-hydroxy-6-bromocoumarin was obtained. This crude product was refluxed in ethanol with an excess of formaldehyde. The methylenebis product which was extremely insoluble in alcohol crystallized after one hour. This product was filtered and recrystallized from cyclohexanone, yield 40 g., m. p. 326–327°. *Anal.* Calcd. for $C_{19}H_{10}O_6Br_2$: C, 46.2; H, 2.0. Found: C, 46.3; H, 2.3.

3,3′-Methylene bis-(4-hydroxy-6-bromocoumarin) dimethyl ether was prepared by the diazomethane technique. The ether was recrystallized from β-dichloroethyl ether, m. p. 218–220°. *Anal.* Calcd. for $C_{19}H_8O_6Br_2(OCH_3)_2$: OCH_3, 11.8. Found: OCH_3, 12.0.

The Dielectric Constants and Dipole Moments of Acetylenic Ethers

BY THOMAS L. JACOBS, JOHN D. ROBERTS AND W. G. MACMILLAN

The dielectric constants of pure samples of ethoxy-, butoxy- and phenoxy-acetylene[1] were measured at 25° by the heterodyne beat method as described by Wood and Dickinson.[2]

The frequency of the standard circuit was adjusted to that of the carrier wave of radio station KFAC which broadcasts on a frequency of 1300 kilocycles,[3] and the increment of capacity was

measured with a variable condenser which was carefully calibrated against a General Radio Precision Condenser (calibrated by the manufacturer at 1000 cycles per second). The cell was of the type described by Doborzynski[4] and the cell constant was obtained by measurements on purified samples of chlorobenzene, ethylene dichloride and benzene whose dielectric constants are known accurately (5.612, 10.36, 2.272 at 25°). Table I summarizes the results.

TABLE I

DIELECTRIC CONSTANTS AND DIPOLE MOMENTS OF ACETYLENIC ETHERS AND PHENYLACETYLENE

Compound, -acetylene	ϵ	M	d^{25}_4	$n^{25}D$	MR_D obs.	$(n^2_\infty)^{25°}$	μ
Ethoxy-	8.05	70.1	0.7874	1.3785	20.53	1.853	1.98
Butoxy-	6.62	98.2	0.8078	1.4033	29.66	1.925	2.03
Phenoxy-	4.76	118.1	1.0088	1.5143	35.27	2.216	1.41
Phenyl-	2.98	102.1	0.9243	1.5461	34.99	2.231	0.78

Dipole moments were calculated by the Onsager equation[5,6] and phenylacetylene was included for comparison. The value is in reasonable agreement with 0.77–0.87 found by measurements in benzene solution.[7] The values of n^2_∞ were obtained by extrapolating the molecular refraction to infinite wave length as was done by Böttcher.[8] The observed molecular refractions for the acetyleneic ethers are in close agreement with the calculated values so that no error was introduced by using the latter. Phenylacetylene shows a rather large exaltation, but even here the values for the dipole moment obtained using calculated or observed molecular refractions were not greatly different (0.78 instead of 0.75).

Böttcher[8] has calculated the dipole moments of a number of compounds from the dielectric constants of the pure liquids using Onsager's equation. His results for unassociated substances are in excellent agreement with dipole moments obtained from measurements in solution or in the vapor state except for anisole and diethyl ether, and for these he believed that the equation failed. His calculations appear to be in error for anisole, and the corrected figure lies between values obtained in solution and in the vapor. We have calculated the moments for phenetole and diphenyl ether and found fairly close agreement, so that Onsager's equation appears to give reasonable results with simple aromatic ethers. The values for diethyl ether from the Onsager equation are high as Böttcher reported, but better agreement is found for di-*n*-propyl ether. Table II compares the calculated values for these ethers with values from measurements in solution or in the vapor.

Despite the simplifying assumptions of symmetrical dipole configurations and non-association made in the derivation of the Onsager equation,

TABLE II[a]

DIPOLE MOMENTS OF ETHERS

Compound	n^2	ϵ	Ref.	μ Calcd.	μ_v	μ_s
Diethyl ether	1.798	4.376	9	1.47	1.18	1.2–1.3
Di-*n*-propyl ether	1.873	3.394[b]	10	1.31	1.18	1.16
Anisole	2.214	4.41	11	1.28	1.35	1.2
Phenetole	2.187	4.22	11	1.34	1.4	1.0
Diphenyl ether	2.388	3.686	11	1.17	1.14	1.13–1.17

[a] The values are at 20° unless otherwise stated. The calculated *MR*'s were used, but the exaltations are low with these compounds and μ is lowered but slightly by using *MR* obs. for the calculation. $\mu_{calcd.}$, μ_v and μ_s designate the dipole moments in Debye units from the calculations and from measurements in the vapor and in solution respectively. All μ_s values are in benzene except di-*n*-propyl ether which is in hexane. The values for the dipole moments in solution were taken from Landolt–Börnstein, "Physikalisch-chemische Tabellen," the second and third supplementary volumes, Julius Springer, 1931–1936. The values from measurements in the vapor phase are from Groves and Sugden, *J. Chem. Soc.*, 1779, 1782 (1937), except for diphenyl ether where their value of 1.35 appears less reliable than that found by Coop and Sutton, *J. Chem. Soc.*, 1869 (1938). [b] At 25.7°.

the agreement between calculated and measured values is satisfactory in general and, as Wilson[6] has commented, the equation appears to be empirically useful. Certainly the values for acetylenic ethers are not in gross error. No interpretation of the moments of ethers can be made without knowledge of the —C—O— bond angles and these may be quite different in unsaturated ethers as compared with saturated. Nevertheless it is interesting that the dipole moment of phenoxyacetylene is only slightly larger than those of other aromatic ethers while the alkoxyacetylenes give figures which are significantly higher. One interpretation of this difference is that in the latter there is a considerable contribution from resonance forms of the type $R—\overset{+}{O}=C=\bar{C}H$, an idea which is in accord with their greater rate of hydration.[12] An extended study of the dipole moments of vinyl and ethynyl ethers will be undertaken when more time and better equipment are available.

p-Bromoaniline Salts of Monoaryl Sulfates

BY D. H. LAUGHLAND AND LESLIE YOUNG

It has been shown[1] that *p*-toluidine salts of a number of monoaryl sulfates can be prepared readily by allowing the alkali metal salt of the monoaryl sulfate to interact with the base hydrochloride in an aqueous medium. With bases which yield relatively insoluble salts of monoaryl sulfates, this reaction is of value in the isolation of monoaryl sulfates from the urine of animals dosed

with phenols.[2] Experiments with *p*-bromoaniline suggested that this base might serve as a useful precipitant for monoaryl sulfates. For example, at 8° the solubility of potassium phenyl sulfate is 12.85 g. per 100 ml. of solution, whereas the solubility of *p*-bromoaniline phenyl sulfate is 1.04 g. per 100 ml. of solution. Several potassium monoaryl sulfates were prepared by the method of Burkhardt and Wood,[3] and were converted to their *p*-bromoaniline salts (see table) by the above method.[1] Although these derivatives are fairly insoluble, they are somewhat unstable, and their melting points are ill-defined.

The Action of Ammonia on Allophanic Azide

BY WERNER L. LIPSCHITZ

In contrast to Thiele and Uhlfelder[1] we were not able to prepare tetruret by the action of ammonia on allophanic azide, but, under the varied reaction conditions herein described, always obtained the normal amide, biuret, and in no experiment was a significantly different product formed which could be claimed to be tetruret.

(1) **Concentrated Ammonia.**—A suspension of allophanic azide (prepared from 41 g. of aminobiuret hydrochloride and 18.3 g. of sodium nitrite. *Anal.* Calcd. for $C_2H_3N_5O_2$: C, 18.6; H, 2.32. Found: C, 18.55; H, 2.34) in 30 cc. of water was treated with 250 cc. of 28% aqueous ammonia and, after the initial spontaneous reaction subsided, the mixture was maintained at 55–60° until a clear solution was obtained. The product (21 g.) separated from the concentrated and cooled solution was recrystallized from 100 cc. of boiling water and yielded 18 g. of pure biuret, which melted at 192° and did not depress the melting point of an authentic specimen. *Anal.* Calcd. for $C_2H_5N_3O_2$: C, 23.3; H, 4.86; N, 40.78. Found: C, 23.43; H, 4.45; N, 39.9.

(2) **Dilute Ammonia.**—The azide (3 g.) was added, during an hour and a quarter, to 31 cc. of 2% ammonia at 0° and stirring was continued for a half hour at room temperature. More 2% ammonia (15 cc.) was added, the mixture was shaken overnight at room temperature and, when heated to 70°, gave a clear solution which, when cooled, deposited 1.48 g. of crystalline product and, after concentration, yielded 0.87 g. more of the same material. The combined solids were recrystallized three times from ethanol and yielded pure biuret. *Anal.* Calcd. for $C_2H_5N_3O_2$: C, 23.3; H, 4.86. Found: C, 23.16; H, 4.76.

(3) **Liquid Ammonia.**—The azide (3 g. *Anal.* Calcd. for $C_2H_3N_5O_2$: C, 18.6; H, 2.32; N, 54.26. Found: C, 18.1; H, 2.84; N, 53.87) was dissolved in 125 cc. of liquid ammonia and, after one hour, the solvent was evaporated. On the Cryoscopic Constant of Camphor

BY JOHN E. RICCI

If the heat of fusion of camphor is 10.74 ± 0.40 cal. per g., then the limiting molecular freezing point depression for solutions in equilibrium with pure solid camphor must be $K_f = RT^2/1000\ l_f = 37.7 \pm 1.4$ deg. per mole as calculated by Frandsen,[1] who also measured the heat of fusion. Meldrum, Saxer and Jones[2] have reported, in some careful and well-planned experiments, that a cryoscopic constant of 39.7 (in sufficiently close agreement with the calculated value) is actually obtained in solutions of four different solutes in camphor; but that the molecular depression apparently increases, in every case, as the concentration of the solute decreases (below ~ 0.2 *m*) and approaches zero.

This would constitute a serious anomaly, if the facts are real. Deviations from the calculated depression are caused either by (A) deviation of the liquid solution from ideality in the positive or in the negative sense, or by (B) precipitation of a solid solution of camphor rather than of pure camphor.

(A) The deviations from ideality, in either direction, must vanish to zero with increasing dilution. Hence the observations cannot be the result either of repulsion, since the molecular depression should in that case start as the theoretical and then fall short of it, or of attraction, which should again give the theoretical depression in limiting dilution, with subsequent increase above the calculated value.

Solid solution would lead always to values lower than the theoretical (even to negative values) but never to values higher than the theoretical cryoscopic constant. For, in the ideal and limiting case, the apparent molecular depression then becomes

$$K_f' = K_f(1 - k)$$

where *k* is the distribution constant of the solute

between solid and liquid phases.[3] Since k cannot be negative, the limiting value of K_f' must be smaller than K_f. The unexpected behavior of camphor therefore cannot be caused by solid solution.

Since the theory cannot be satisfied, it seems that the experimental data must be at fault somewhere. The experimental values involved in the calculation of the ideal constant, K_f, are the melting point and the heat of fusion. The melting point, though somewhat uncertain, can hardly be so incorrect, especially as an absolute temperature, as to account for an almost 50% change in K_f. The fusion heat seems to have been measured with great care, and it similarly does not seem possible for it to be wrong by such a factor; Frandsen reports it as 10.74 ± 0.40 cal., and his data seem to justify this estimate.

There are, however, two points in Frandsen's report which indicate that the camphor under observation near its melting point was not absolutely pure; it appears that it may have been slightly impure at the outset or that it underwent some slight decomposition at temperatures at or near its melting point. Thus: (1) the cooling curve for the determination of the melting point shows a degree of rounding-off hardly consistent with purity; and (2) the agreement in the duplicate determinations of heat content for liquid camphor was not very close. Incidentally, the above suggestions about the impurity or the instability of the camphor used are made by Frandsen himself.

Now, while a slight degree of impurity or instability would hardly affect the measured melting point and heat of fusion to the extent here in question, it is possible to account, on such a basis, for the apparently anomalous molecular freezing point depressions reported by Meldrum. Even with initially pure camphor, it may be that the melting, mixing and grinding required in the preparation of the binary mixtures for melting point determinations, caused in each case a small and approximately constant extent of decomposition of the camphor. If this decomposition amounts to m' moles of foreign species per 1000 g. of camphor, then the true molecular depression would be $K_f = \Delta T_f/(m + m')$. If m' is very small, its neglect would have a negligible effect on K_f measured in high concentration, but would cause the apparent K_f' to rise higher and higher as the concentration decreases.

It is sufficient to assume m' equal to only 0.005, in Meldrum's experiments, to derive a molecular depression approximately constant throughout, within the probable experimental error (as shown in Fig. 1), and with an average value of 39.2° per mole, which is sufficiently close to the calculated limiting or ideal value. The constancy is even better than it seems, when it is remembered that

(3) Thus in Glasstone, "Text-Book of Physical Chemistry," D. Van Nostrand Co., New York, 1940, p. 641.

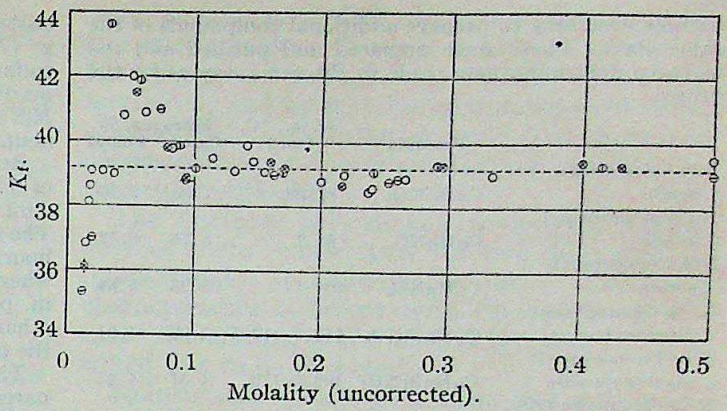

Fig. 1.—Solute key: ○, naphthalene; ⊕, *p*-bromodiphenyl; ⊖, phenylacetic acid; ⊗, ethylacetanilide.

the points at lowest concentration are likely to be experimentally the most uncertain (as pointed out by Meldrum himself). Since the temperatures in Meldrum's experiments seem to have been measured to a precision of only 0.05°, ΔT is probably dependable only within 0.05 to 0.10°. It follows then that at small values of m, even relatively large variations in the value of the ratio $\Delta T/m$ must be considered insignificant; for example, ±2 or 3 at m = 0.05, and as high as ± 8 at m (uncorrected) = 0.012. It is significant that the values of K_f now calculated from all the measurements with $\Delta T > 3°$, lie, with one exception, within one unit of the mean, 39.2, the average deviation being only 0.3 unit.

It should be pointed out that, depending on the molecular weight of the impurity, this value of m' would represent about 0.02 to 0.06% (for molecular weights of 50 to 150) by weight of the camphor used. Such contamination or decomposition would hardly be detectable in the melting point or in the heat of fusion of the substance, but would have the actual effect on the determination of K_f at very low concentrations which was observed by Meldrum.

We have here, in other words, another and very sensitive method for the determination of the purity (or the stability) of a substance. In the absence of solid solution, the molecular depression of the freezing point should approach the value calculated from its melting point and heat of fusion, in limiting dilution.

N^1-Acetyl-N^4-benzoyl-sulfanilamide

N^1-Acetyl-N^4-benzoyl-sulfanilamide, the simplest N^1-acyl-N^4-aracylsulfanilamide, has been prepared both by acetylation of N^4-benzoyl-sulfanilamide and by benzoylation of N^1-acetyl-sulfanilamide.

Acetylation of N^4-Benzoyl-sulfanilamide.—A solution of N^4-benzoyl-sulfanilamide (m. p. 285–286°[1]) (1.4 g.) in acetic anhydride (11 ml.) and anhydrous pyridine (6 ml.) was refluxed in a boiling water-bath for one hour, and then cooled. The solid was collected and dried; it weighed 1.14 g. (70%), m. p. 261–263°. The N^1-acetyl-N^4-benzoyl-sulfanilamide was recrystallized from ethanol; it formed needles melting at 262–263°. *Anal.* Calcd. for $C_{15}H_{14}O_4N_2S$: N, 8.80; neut. equiv., 318. Found: N, 9.01; neut. equiv., 317.

Benzoylation of N^1-Acetyl-sulfanilamide.—To a solution of 0.21 g. of N^1-acetyl-sulfanilamide[2] (m. p. 181–182°) in 2 ml. of pyridine, five drops of benzoyl chloride was added. The solution was refluxed in a boiling water-bath for one hour. It was then diluted with water and acidified, whereupon 0.29 g. of N^1-acetyl-N^4-benzoyl-sulfanilamide, m. p. 255–257°, precipitated. After crystallization from ethanol, it melted at 261–262° alone or when mixed with the product obtained by the first method.

The N^1,N^4-dibenzoyl-sulfanilamide has also been prepared by refluxing either sulfanilamide or N^4-benzoyl-sulfanilamide with excess of benzoyl chloride in the presence of pyridine for one hour. The mixture was then diluted with about ten times its volume of ethanol and allowed to stand in the icebox. The solid was recrystallized from ethanol in which it is only slightly soluble. The m. p. of the pure product was found to be 260° (with decomposition).[3] Yields in both cases were 70%. *Anal.* Calcd. for $C_{20}H_{16}O_4N_2S$: N, 7.37. Found: N, 7.57.

Thanks are due to Dr. T. S. Ma, University of Chicago, for the micro-analyses.

COMMUNICATIONS TO THE EDITOR

STRUCTURE AND ACTIVITY OF SULFANILAMIDES

Sir:

In a recent paper, Kumler and Daniels[1] have suggested that the activity of sulfonamides may be correlated with the contribution of the resonance form,  (I) to the structure of the molecule. To account for the fact that the sulfonamide anion seems to be the active form of the drug, they have postulated that the contribution of the resonance structure with the separation of charge is greater in the anion than in the undissociated molecule. *A priori*, one would be inclined to the contrary conclusion, and we believe the spectral evidence[2] confirms this interpretation.

High intensity ultraviolet absorption spectra are due to transitions from the neutral ground state of the molecule to an ionic excited state.[3] An increase in the number or contribution of ionic resonance structures stabilizes the excited state, *i. e.*, decreases its energy relative to that of the ground state, and hence shifts the maximum of the absorption toward larger wave lengths. Consequently, the fact that the maximum absorption of sulfanilamide in neutral solution is at 2600 Å., whereas that in basic solution is at 2500 Å., indicates that ionic resonance forms contribute *less* to the anion than they do to the undissociated molecule.

The Kumler and Daniels theory also does not explain the low activity of sulfanilylurea and 3-sulfanilamido-1,2,4-triazole. Resonance structures similar to those written for these molecules could be written for N^1-acetylsulfanilamide,  , for sulfadiazine,

 , and for many other active sulfanilamides. It should be observed that Bell and Roblin[4] originally suggested that the *individual anions* in more acidic sulfanilamides such as sulfadiazine, *sulfanilylurea*, and *3-sulfanilamido-1,2,4-triazole* are less active than sulfanilamide anions because of the decrease in negative character of the $-SO_2$ group, but that this effect is counteracted *by a greater number* of anions.[5]

Simple vinylogs of sulfanilamide such as p-$NH_2C_6H_4CH{=}CH{-}SO_2NHR$ have occupied the attention of one of us for some time. These compounds are now of especial interest since the contribution of resonance structures with a coplanar amino group should be appreciable due to the possibility of a contribution from structures of the type  , in addition to those attributed to sulfanilamides by Kumler and Daniels. If, as Kumler and Daniels suggest, the sulfonamide group is significant for activity only insofar as it affects the amino group, these vinylogs should be active. Up to now only one compound of this type has been tested. 2-p-Aminophenylethene-1-sulfonamide (R = H) appears to be practically inactive *in vitro*.

(4) Bell and Roblin, THIS JOURNAL, **64**, 2905 (1942).

(5) Kumler and Daniels attribute the low activity of very acidic sulfanilamides to the impenetrability of the cell wall toward anions, as originally suggested by Cowles, *Yale J. Biol. Med.*, **14**, 599 (1942), rather than to the concentration effects postulated by Bell and Roblin.

NORTHWESTERN UNIVERSITY FREDERICK G. BORDWELL
EVANSTON, ILLINOIS IRVING M. KLOTZ

RECEIVED JANUARY 3, 1944

AN AZEOTROPE IN THE SYSTEM *n*-BUTANE–METHYL BROMIDE

Sir:

In analyzing the products of reactions of mixtures containing butanes, methyl bromide, and aluminum bromide,[1] a successful procedure has been to remove excess methyl bromide from the volatile fraction by reaction with ethanolamine and to determine the paraffin hydrocarbons remaining by low temperature micro-fractionation. In one such experiment, where there was poor contact between the halide and amine, the distillation showed no *n*-butane (b. p. −0.6°), but did give a methyl bromide flat (b. p. 3.5°[2]), and in addition a puzzling fraction boiling at approximately −5° (atm. pressure).

The only possibilities for this −5° fraction would be unsaturates (butadiene, b. p. −4.8°; isobutene, b. p. −6.6°; butene-1, b. p. −6.1°) and methylamine (b. p. −6.5°), although the former are very unlikely because they all are polymerized by and form stable complexes with aluminum bromide, and the latter could come only from decomposition of the ethanolamine, which is extremely improbable.

The distillate was shaken with 96% sulfuric acid at room temperature for two days and refractionated. It showed the same distillation characteristics as before, with the exception of a slight diminution of the methyl bromide fraction, which was to be expected.

Sulfuric acid will absorb unsaturates and amines readily, and these possibilities are therefore eliminated. The only hypothesis that will fit the facts is that *n*-butane and methyl bromide form a minimum boiling mixture. Indeed, when the product reacted with excess fresh ethanolamine and was refractionated, the flat at −5° disappeared and the expected *n*-butane fraction appeared, in accord with the hypothesis.

To determine the properties of the azeotrope, a synthetic mixture of 49.1 mole % of *n*-butane and 50.9 mole % of methyl bromide was prepared and fractionated in a Podbielniak micro-precision type R column[3] with 3.0 mm. unpacked inner bore, manually operated, the pressure being regulated at 760 mm. (cor.). The distillation curve is shown below. Each mm. of distillate corresponds to 1.85×10^{-4} mole at 26°, the temperature of the vapor receiving bulb in this case, and the thermocouple-galvanometer system gives a deflection of almost exactly 2 per deg. (R, $t < 0°$; L, $t > 0°$) in the range −15 to 15°.

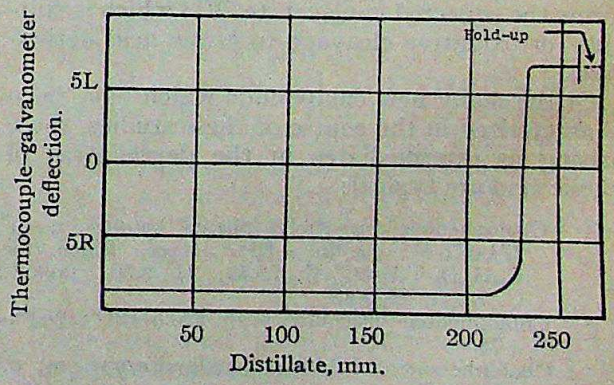

Fig. 1.

From the distillation plot, it is apparent that the azeotrope boils at −4.4°. A material balance suffices to fix its composition at 58.1 ± 0.5 mole % *n*-butane.

A detailed study of the vapor–liquid equilibrium in the above system is now in progress.

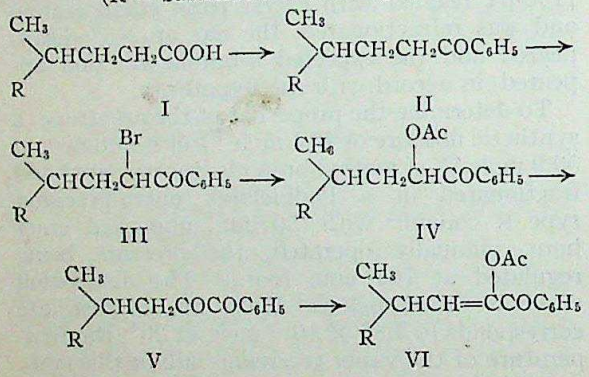
A NEW METHOD FOR THE DEGRADATION OF BILE ACID DERIVATIVES

Sir:

I wish to report in outline form a promising new procedure for degrading the characteristic γ-substituted *n*-valeric acid side chain (I) of the bile acids and their derivatives in the preparation of suitable starting materials for steroid hormone partial syntheses.

The excellent method of Gilman and Nelson[1] when applied to the acid chloride of I provides the phenyl ketone (II) in 70 to 75% yield if diphenylcadmium is used. Bromination of the ketone yields a mixture of isomeric 23-bromo compounds (III) which upon acetolysis forms the corresponding 23-acetoxy derivatives (IV). The latter, after hydrolysis to the α-ketols, can be oxidized

(R = Substituted steroid ring system)



with copper sulfate in aqueous pyridine to the α-diketone (V) in 65 to 70% over-all yield from the monoketone. Acetylation of the diketone then forms the expected enolacetate (VI) which is suitable for oxidative cleavage to *bisnor*-acid derivatives.

Of the many new compounds which have been characterized in the course of these studies, those arising as intermediates in the degradation of cholic acid are typical:

(II) Cholophenone (*nor*-cholyl phenyl ketone), m. p. 174–176.5°; $[\alpha]^{20}D$ +26°.[2] *Anal.* Calcd. for $C_{30}H_{44}O_4 \cdot {}^1/_2H_2O$: C, 75.43; H, 9.50. Found: C, 75.35; H, 9.48.
Cholophenone triacetate, m. p. 120.3–121°; $[\alpha]^{20}D$ +79°
Cholophenone 2,4-dinitrophenylhydrazone, m. p. 221–222.5°
Cholophenone oxime, m. p. 214–217° dec.

(III) 23(β)[3]-Bromo-cholophenone triacetate, m. p. 108.5–111.5°; $[\alpha]^{20}D$ +95°. *Anal.* Calcd. for $C_{36}H_{49}O_7Br \cdot H_2O$: C, 62.51; H, 7.43. Found: C, 62.86; H, 7.19. Calcd. for $C_{36}H_{49}O_7Br$: C, 64.18; H, 7.33. Found: (sintered *in vacuo*), C, 64.05; H, 7.35.

(IV) 23(α)[3]-Acetoxy-cholophenone triacetate, m. p. 180–182°; $[\alpha]^{20}D$ −10°. *Anal.* Calcd. for $C_{33}H_{52}O_9 \cdot {}^1/_2H_2O$: C, 68.96; H, 8.07. Found: C, 69.15; H, 8.09.

(V) *bisnor*-Cholyl benzoyl ketone triacetate, m. p. 166–169° (after drying, 161.5–166°); $[\alpha]^{20}D$ +92°. *Anal.* Calcd. for $C_{36}H_{48}O_8$: C, 71.02; H, 7.95. Found: C, 70.92; H, 7.88.

bisnor-Cholyl benzoyl ketone 7,12-diacetate, m. p. 201–203.5°; $[\alpha]^{20}D$ +80°. *Anal.* Calcd. for $C_{34}H_{46}O_7$: C, 72.05; H, 8.18. Found: C, 72.16; H, 8.34.

2-*bisnor*-Cholyl-3-phenyl-quinoxaline triacetate, m. p. 217–218.5°.

Work now in progress indicates that the application of this degradation scheme to substituted *nor*-bile acids will result in the formation of pregnane-20-one derivatives in much higher yields than heretofore obtainable.

DESTRUCTION OF RIBOFLAVIN IN MILK BY SUNLIGHT[1]

Sir:

The phenomenon of photochemical destruction of riboflavin has been adequately demonstrated by György and coworkers[2] and Roscoe,[3] and more recently by Williams and Cheldelin.[4] The latter workers demonstrated that as much as 26% of the riboflavin of milk was destroyed by light when the milk was exposed for as short a time as five minutes at 100°. These findings suggested that in all probability appreciable amounts of riboflavin would be lost in milk bottled in the standard type retail glass milk bottle when exposed to sunlight at ordinary temperatures.

Experiments were conducted from mid-morning until mid-afternoon on sunny days. Fresh milk obtained the same day was bottled in pint milk bottles with the usual type cap and exposed to direct sunlight on an open porch. Riboflavin concentrations were determined fluorometrically with the Coleman electronic photometer (Model 12), using essentially the technic of Hand[5] except that 10 cc.

Table I

Destruction of Riboflavin in Milk by Sunlight

Series	Original riboflavin content, γ/cc.	Riboflavin content after 1 hr. exposure, γ/cc.	Destruction %
I	1.86	1.13	39
	1.51	0.97	36
II	1.98	1.13	43
	2.29	1.40	39
	2.29	1.60	30
III	0.83	0.38	54
	1.94	1.30	33
IV	2.43	1.65	32
	2.60	1.90	27

of acetone was added to 5 cc. of well-mixed whole milk to obtain the filtrate. The results of four studies conducted on separate days are summarized in Table I. All samples were from different cows. Atmospheric temperatures at which the samples were exposed were never less than 60°F. nor higher than 72°F.

The mean loss of riboflavin in sixty minutes was 0.69 γ. The standard error of this loss based on the variation in loss from series to series was 0.055 γ. Observed losses of riboflavin at exposure intervals of 30, 90, 120 and 210 minutes were, respectively, 28, 50, 66 and 72%.

Control samples of milks used in the study showed no loss of riboflavin when stored in the dark at room temperature for twenty-four hours, nor did any loss occur when they were stored in a refrigerator for seven days. In order to determine whether an initial exposure to sunlight would stimulate a more rapid decrease when samples were subsequently placed in the dark under refrigeration, three samples (1.54 γ/cc.) were placed in the refrigerator after one-half, one, three and five hours of exposure. After forty-eight hours, the additional loss which had taken place was extremely small, averaging 0.016 γ, and in no case exceeding 0.07 γ.

It is evident that the destruction of riboflavin in milk by sunlight proceeds at a very rapid rate, even at ordinary temperatures.

THE LINKAGE OF CORPUSCULAR PROTEIN MOLECULES. I. A FIBROUS MODIFICATION OF INSULIN

Sir:

When 1.5 to 2.0% solutions of insulin hydrochloride (Lilly, amorphous) at *p*H 2.0 to 2.5 are heated for thirty minutes at 100°, thixotropic gels are formed which exhibit static double refraction.[1,2] Dilution to 0.5% produces a viscous solution showing intense flow double refraction.

Electron micrographs of this material reveal the presence of uniform fibrils several microns in length, having uniform widths of approximately 200 Å. (an asymmetry well above 100).

Insulin gels, containing 2% protein, have been frozen and thawed many times in a solid carbon dioxide-alcohol mixture. During this treatment the viscosity gradually decreases to low values. Flow double refraction replaces static double refraction and after 10 cycles even the former decreases greatly in magnitude. A second heat treatment produces a thixotropic gel showing static double refraction. This indicates that segments of fibrils produced by the freezing-thawing treatment unite in a directional manner.

After standing for twenty-four to forty-eight hours at *p*H 11.0–11.5 and 0°, a dispersion of insulin fibrils loses its characteristic double refraction and viscosity. The solution thus produced resembles an equivalent solution of native insulin so far as the methods mentioned have demonstrated.[3] Protein may be recovered after such a "reversal" and dissolved to form a 2% solution at *p*H 2.0. Heat treatment again produces a thixotropic gel showing static double refraction. This cycle has been repeated several times.

Prolonged heating of insulin in acid solution or at reactions well below *p*H 2.0 produces sphaerocrystalline aggregations of insulin fibrils termed the "heat precipitate of insulin" by du Vigneaud, Geiling and Eddy.[4] These authors have shown that this material, dissolved in dilute alkali and immediately acidified, exhibits 80% of the biological activity of the original insulin. Since the heat precipitate of insulin is now shown to consist of aggregations of insulin fibrils, it is considered that insulin fibrils show such activity after reversal by alkali whether or not they have formed the "heat precipitate."

Insulin fibrils are considered to be constructed of corpuscular molecules which have been deformed only slightly in the process. Jensen[5] has suggested that the insulin molecules present in the heat precipitate are linked by covalent bonds. Unpublished chemical evidence shows that insulin fibrils may be formed after the sulfur has been split off by alkali and after ammonia has been liberated by heat. This type of evidence indicates that fibril formation may take place after the removal of those groupings which are expected to take part in covalent bond formation. Therefore it is proposed that insulin molecules are linked mainly through the secondary valence forces resulting from the approximation of nonpolar side chains. Two surface concentrations of these chains on opposite portions of the insulin molecule would account for the bifunctional nature exhibited in fiber formation.

NEW BOOKS

Optical Crystallography. By ERNEST E. WAHLSTROM, Department of Geology and Mineralogy, University of Colorado, Boulder. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1943. v + 206 pp. 209 figs. 14.5 × 22 cm. Price, $3.00.

This book is a welcome addition to the rather small number of optical crystallographic texts accessible to chemists. The simple, concise presentation of the theory of crystal optics in a form already familiar to mineralogists and petrographers accents the sound physical foundation underlying this subject in a way not as readily achieved in the typical laboratory treatments. Both in the more advanced petrographic manuals and in experimental texts on chemical microscopy the details of microscopic technique tend to obscure the well integrated treatment of the propagation light in crystalline solids upon which the individual methods depend.

After brief chapters on geometric crystallography, physical properties, elementary optics, and the polarizing microscope, the author begins a systematic development of the behavior of light in non-opaque crystals. Isotropic materials are discussed first and after a timely digression to describe fundamental methods of refractive index measurement, the treatment goes on to cover uniaxial and finally biaxial crystals. Extensive use is made of the indicatrix and the related ellipsoidal diagrams in correlating optical phenomena. This treatment is essential to a clear understanding of the relationships of the individual optical constants both among themselves and to the crystal lattice. A commendable feature is the large amount of space (including illustrations) given to the description of interference figures and their use in discovering the principal ellipsoidal axes and in determining optical sign. Much attention is given to off-center interference figures which in practice greatly predominate.

The author confines his treatment to those optical properties of unquestioned value in mineralogical studies and leaves to the chemist the problem of discovering and developing for himself other optical criteria which may assume importance because of the greater variety of chemical compounds at his disposal. It is believed that insufficient emphasis has been placed upon the value of interference figures in locating the principal refractive indices, greater attention having been given the less exact statistical methods based on the selection of high and low interference colors in an aggregate of crystalline particles. While there is evident some tendency toward over-simplification, the simple, direct treatment employed gives this book unquestioned pedagogical value.

W. M. D. BRYANT

The Biochemistry of Malignant Tumors. By KURT STERN, M.D., Formerly Research Associate of University of Vienna, New York, N. Y., and ROBERT WILHELM, M.D., Professor, University of Philippines, Manila. Reference Press, Brooklyn, N. Y. (The Chemical Publishing Co., Inc., 234 King Street, Brooklyn, N. Y.), 1943. xiv + 951 pp. 14.5 × 22.5 cm. Price, $12.00.

The etiology of cancer has commanded the attention of specialists in widely different fields of scientific research, and valuable contributions have already been made by investigators whose background experiences lie outside the boundaries of morphological pathology and clinical medicine. There has been a tendency, unfortunate but probably unavoidable, for investigators of the cancer problem to become segregated into small specialist groups of biochemists, organic chemists, geneticists, endocrinologists, and the like, each following its own highly specialized line of attack. Under these conditions it is not easy to obtain an integrated picture of the progress of cancer research as a whole, or to gain an insight into possible inter-relationships between the findings of the various specialist groups.

The book has yet to be written in which such a complete coördination is attempted, and must probably await further advances in our understanding of the nature of the disease. In "The Biochemistry of Malignant Tumors" Dr. Stern and Dr. Willheim have achieved the lesser, but still formidable, task of coördinating the contributions of the chemist and bio-chemist to this subject, and the range of the material actually covered is much broader than the title suggests. The text was developed from an earlier German monograph, published by the authors in Vienna in 1936. Coöperation between Dr. Stern and Dr. Willheim was unfortunately interrupted in December, 1941, when Dr. Willheim was in Manila, and the greater share of the responsibility for the later stages of the preparation of the book was borne by Dr. Stern.

The book is divided into ten chapters. The first three are concerned with the contributions of inorganic, organic and physical chemistry, and are followed by chapters on enzymes, nutrition and vitamins, metabolism, endocrine glands and their hormones, immunology, biochemical aspects of tumor origin and tumor growth, and, finally, chemical and biological tumor diagnostics. The literature has been covered systematically to the end of 1941; yet, in spite of the considerable amount of detail included, the authors have succeeded in avoiding the tedious style common to many specialist monographs in which a more or less complete literature coverage is attempted. This can be attributed mainly to their plan of omitting authors' names from the text, where possible, but providing extensive references to original publications as footnotes to each page.

Drs. Stern and Willheim make no attempt to advance any particular "cancer theory" of their own. They draw attention to discrepancies between the observations of different workers, where they occur, try to reconcile these, or to suggest factors which may account for the differences. It is somewhat discouraging to observe how frequently some line of attack has yielded promising results in the hands of one group of workers while other investigators obtained contradictory results under apparently comparable circumstances. It would seem there must still be many uncontrolled factors which influence the initiation, growth and degeneration of malignant tumor tissue.

As a result of the war, the number of investigators active in the field of cancer research has been very materially reduced, but it is to be expected that a search for the cause and cure of cancer will become one of the foremost objectives of post-war science. In summarizing the present state of our knowledge of the bio-chemistry of cancer, Dr. Stern and Dr. Willheim have made a real contribution to that post-war objective; their book should be read both by those at present engaged in the study of cancer and by those contemplating taking up such work in the future.

JOURNAL OF THE AMERICAN CHEMICAL SOCIETY

Published monthly by the American Chemical Society at Easton, Penna.

Editorial Office: Chemical Laboratory of Harvard University, 12 Oxford St., Cambridge 38, Mass.

Assistant to the Editor (Proof and Make-up): Allen D. Bliss, Department of Chemistry, Simmons College, 300 The Fenway, Boston 15, Mass.

Business Office: American Chemical Society, 1155 16th St., N.W., Washington 6, D. C.

Advertising Office: American Chemical Society, 332 West 42nd St., New York 18, N. Y.

The American Chemical Society and the Editors of the *Journal of the American Chemical Society* assume no responsibility for the statements and opinions advanced by contributors to THIS JOURNAL.

Remittances and orders for subscriptions and for single copies, notices of changes of address and new professional connections, and claims for missing numbers should be sent to the American Chemical Society, 1155 16th Street, N.W., Washington 6, D. C. Changes of address for the *Journal of the American Chemical Society* must be received on or before the 18th of the preceding month.

Claims for missing numbers will not be allowed (1) if received more than sixty days from date of issue (owing to the hazards of war-time delivery, no claims can be honored from subscribers outside of North America), (2) if loss was due to failure of notice of change of address to be received before the date specified in the preceding paragraph, or (3) if the reason for the claim is "missing from files."

Annual subscription—$8.50 to non-members, $3.00 to members. Postage to countries not in the Pan American Union, $1.50; Canadian postage, $0.50. Single copies—current issues $0.75, back numbers $0.80; special rates to members.

The American Chemical Society also publishes *Chemical Abstracts*, *Industrial and Engineering Chemistry* (Industrial and Analytical Editions), and *Chemical and Engineering News*. Rates on request.

NOTICE TO AUTHORS OF PAPERS

Manuscripts for THIS JOURNAL should be submitted to the Editor ready for publication, typewritten (double space), with 2–3 cm. margins, on a good quality, durable paper, preferably of 8.5″ × 11″ size. In addition to the original typewritten copy, one or more carbon copies should be submitted so that the time required for examination by the Editorial Board may thus be considerably shortened. Care should be taken that all pages in a manuscript, including tables (but not the diagrams) be numbered consecutively. In preparing manuscripts authors are requested to observe, for reasons of economy, the utmost conciseness consistent with clarity of presentation. The manuscripts should be addressed to specialists in their particular field rather than to the general reader. Extensive reviews of the literature cannot be accepted. When well-known or previously published procedures have been followed in the experimental work they should only be designated or referred to.

Form of Presentation.—There should be one or more introductory paragraphs setting forth the occasion, significance and main objectives of the investigation and the method of attack. This should be followed by the experimental results and a discussion of them, either *seriatim* or at their conclusion. Finally, there should be a brief summary of the main achievements of the investigation. Sometimes, particularly when the subject matter is involved and there are many details which, though essential for a successful repetition of the experiments, are unnecessary for the main account of the investigation, these details can with advantage be relegated to an appendix or supplement, just preceding the Summary. In intermediate cases it is often advisable to retain a single, straightforward presentation but to intercalate sections in fine print giving the experimental details of procedure. This has the great advantage of keeping the experimental details close to the more general statements based upon them and yet at the same time permitting the reader if he wishes to pass over this section without inconvenience.

It will be of great assistance to the Editor's Office if the style, arrangement and orthography of the manuscripts are made to conform to the usages of the JOURNAL as exemplified in its recent issues and as set forth in the following paragraphs.

Center headings should be employed sparingly; side headings should be indented and run into the text to which they apply, using period and dash. References to the literature and all footnotes regardless of their nature (except those in tables) should be numbered in one consecutive series, repetition of notes being avoided by using simply the superscript number corresponding to the original reference. They should follow immediately in separate lines the line of text containing the text words to which they refer, and may be set off by short rules above and below. The items in the references to the literature should conform to the uniform usages of the Journal as regards order and punctuation, and to the abbreviations as given by *Chemical Abstracts* in its "List of Periodicals Abstracted." The names of all simple compounds rather than their formulas should be used whenever they occur in the text. Periods of time (unless fractional) should be written in words and quantities of material in Arabic numerals, unless occurring at the beginning of a sentence. Letters used to represent quantities in mathematical expressions should be underscored to indicate that they are to be printed in italics, and Greek or other unusual characters should be written plainly or should be explained by annotations. Simple fractional expressions should be written with a slant line rather than in the conventional manner, so that only a single line of type is required. All subscripts and superscripts should be carefully made and placed (the degree sign ° or a small o should not be used to represent zero). For economy, except in unusual circumstances the abbreviations %, °A., cm., cc., ml., g., Å., m. p., f. p., b. p., cal., kcal., expt. and Fig., should be used rather than the words.

Figures and graphs should be carefully prepared line drawings on plain white drawing paper, blue drawing cloth or coördinate paper printed in blue only. The

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

originals are preferable, but clear, well-prepared photographic prints or photostats are acceptable. Illustrations are most conveniently handled when made in the conventional 8.5″ × 11″ manuscript size; if they are of necessity larger, and therefore liable to damage in mailing, duplicate rough sketches or photographic prints of smaller size should be furnished for dispatch to the Referees. Diagrams should be designed to occupy a single column width and should therefore be tall rather than wide. Particular attention should be given to the correct proportions of the various parts of the figure, especially the experimental points, and if any letters, numbers, or legends must be placed on the diagram to their proportions also. In graphs the frame and actual curves should be ruled and inked more heavily than the coördinate lines, and these latter should not be too close together. Experimental points should always be given and should be indicated not by crosses but by circles or other symbols carefully drawn with drafting instruments. Where feasible it is often helpful to have the diameter of the circles indicate the precision of the measurements. The numbers and legends on coördinate axes are set up in type by the printer; the author, therefore, should place them in pencil outside the axes. The numbers and titles of figures should be placed below the diagrams, or on the back, or collected on a separate sheet. Small photographic prints should be mounted on cardboard and any composite series of photographic prints should be mounted in the order and arrangement desired. Each piece of illustration copy should be marked on the margin or back with the name of the author and brief title of the article (for identification purposes).

Tables.—Tables should not be used indiscriminately as they are much more expensive, line for line, than running text. If reasonably possible, they should be designed to occupy fully a single column (3 inches), which will take 50–75 characters and spaces. Tables occupying the full width can be used, but they are undesirable for the same reasons advanced with regard to page wide figures; their preparation should follow the same principles as for those of single width. Care should be taken to avoid any arrangement which unduly increases the depth of a table, and column heads should be made as small as possible, using abbreviations liberally. Lines of data should not be numbered nor run numbers given unless these numbers are needed for reference in the text. Columns should not be used to contain only one or two entries, nor should the same entry be repeated numerous times consecutively, since these cases may be taken care of more economically in footnotes, or by entries following the title of the table. Data should not be included in one column which are deducible easily by simple arithmetic from data in another column. Tables should be interspersed in the manuscript as near as possible to the places where they are referred to in the text, and need not be placed alone on separate sheets.

Formulas and Equations.—Empirical and structural formulas and mathematical and chemical equations should be arranged to fill adequately the width of a single column. This will often require a continuation of the equation in additional lines, and although this is a disadvantage it is in general preferable to intrusion into the adjoining column. Subscripts and superscripts, especially the latter, should be written with care and the conventional fractional arrangements should not be used in exponents. Organic structural formulas should be arranged to fill the space economically, and arrows should be used horizontally or vertically, not diagonally, wherever possible.

Notes do not differ fundamentally from Articles. They describe fragmentary or less complete studies and hence particular attention must be given to brevity and conciseness of presentation. Summaries are not included. They are collected in a special section near the end of each number of the Journal.

New Compounds.—This department is for brief accounts of new substances which do not appear of sufficient importance to justify separate publication and cannot be described appropriately as part of any other Article or Note. These accounts should report the preparation of the new compound succinctly, yet fully enough so that the operations can be duplicated. Significant properties, formulas and analytical data to establish the identity and purity of the substance should be given. Material appearing in this classification will not be accepted for subsequent publication.

Communications to the Editor are designed to afford prompt, brief, preliminary publication in our Journal of new and significant observations or discoveries. Their total length may in no case exceed 500 words or the equivalent. They will be given as rapid editorial consideration as possible, but at best it will usually be out of the question to include them in a given issue of the Journal if they arrive at the Editor's office later than the 20th of the preceding month. Communications like other contributions should be self-sustaining; that is, they should present experimental or other evidence adequate to establish the *prima facie* credibility of the results or conclusions stated or to permit their appraisal by an expert in the field although because of the 500-word limit a complete presentation cannot usually be expected. These requirements make Communications on many subjects impracticable, particularly those of an involved or theoretical nature.

Communications differ from ordinary Articles or Notes in that their publication does not prevent the re-publication of their subject matter in a later, more complete article in the Journal. In view of this special provision and their expedited publication, it is clear that the contribution made by the Communication should be of special interest or timeliness; mere abstracts of forthcoming articles cannot be accepted. Proof and reprint order will be sent to authors whenever possible, but as this cannot always be done, a memorandum as to the reprints desired should accompany the manuscript.

Microfilm Supplements.—By arrangement with Science Service material supplementary to articles in THIS JOURNAL, such for instance as extensive tables, graphs or calculations, can be distributed at small cost as American Documentation Institute Documents in the form of microfilms with images 25 mm. high on standard 35-mm. film or photoprints 6 × 8 inches legible to the unaided eye. Such material must, however, have been submitted to the Editor of the Journal and must have been approved by him for publication. Attention will then be called to these documents by means of footnotes at appropriate points in the text of the article concerned.

The Acetolysis of Trimethylene-D-sorbitol. 2,4-Methylene-D-sorbitol and 1,3:2,4-Dimethylene-D-sorbitol

BY A. T. NESS, RAYMOND M. HANN AND C. S. HUDSON

Recently[1] we have shown that the limited acetolysis of the trimethylene-D-mannitol of Schulz and Tollens yields a compound to which has been tentatively assigned the structure 1,6-diacetyl-3,4-di-(acetoxymethyl) - 2,5 - methylene - D - mannitol. This structure seems highly probable since the saponification of the acetolysis product yields a 2,5-methylene-D-mannitol, a fact which we take to indicate that the acetal linkages of trimethylene - D - mannitol which are formed through secondary hydroxyl groups are relatively more stable to acetolysis than those formed through primary hydroxyl groups. The acetolysis apparently proceeds with rapid rupture of the acetal linkages at positions one and six and the 3,4-di-(hydroxymethyl) - 2,5 - methylene - D - mannitol which is assumed to be formed is immediately acetylated to produce 1,6-diacetyl-3,4-di-(acetoxymethyl)-2,5-methylene-D-mannitol. In view of the unusual nature of the acetolysis reaction, and particularly since the acetolysis product and the 2,5-methylene-D-mannitol derived from it contain the rare C_5O_2 dioxepane ring as an integral part of their structures, it seemed of interest to study the acetolysis of the known trimethylene-D-sorbitol.[2] In the course of preparation of a supply of this material we isolated from the mother liquor a dimethylene-D-sorbitol, a new substance, which melted at 174–175° and rotated $[\alpha]^{20}D$ −29.6° in water, and the investigation was extended to include the acetolysis and proof of structure of this diacetal.

Considering first the trimethylene-D-sorbitol, it is obvious that its acetal linkages must be formed through four secondary and two primary hydroxyl groups. From our previous experience it was anticipated that upon limited acetolysis it would yield a diacetyl-di-(acetoxymethyl)-monomethylene-D-sorbitol; it was found that the acetolysis of trimethylene-D-sorbitol by an ice-cold 1% sulfuric acid acetylating solution for five minutes gave a 51% yield of a crystalline reaction product (m. p. 111–112°; $[\alpha]^{20}D$ +29.8° in chloroform), the composition of which agreed with that of the expected substance. The compound was saponified by the method of Kunz[3] with the consumption of four molecular equivalents of sodium hydroxide, and the saponification product proved to be a crystalline monomethylene-D-sorbitol (m. p. 163–164°; $[\alpha]^{20}D$ −9.8° in water). Oxidation of this product with sodium periodate (and other glycol-splitting reagents) reduced one molecular equivalent of the oxidant and proved that only a single glycol grouping is present in the monomethylene-D-sorbitol. At this stage of the study the experimental results in the case of trimethylene-D-sorbitol are thus closely parallel with those previously reported for the isomeric trimethylene-D-mannitol. However, the periodate oxidation of the 2,5-methylene-D-mannitol proceeded without the production of acid or formaldehyde, thereby confirming the structure assigned to it, whereas 0.86 of a molecular equivalent of formaldehyde was isolated as the crystalline dimethone derivative from the oxidized solution of the monomethylene-D-sorbitol. One hydroxyl group of the glycol grouping of methylene-D-sorbitol is therefore primary in character and the structure of the acetal cannot be 2,5 but is limited to that of 2,4 or 3,5-methylene-D-sorbitol. A choice between these two possibilities could be readily made; the oxidation of 2,4-methylene-D-sorbitol (III) with glycol-splitting reagents would yield 2,4-methylene-L-xylose, which upon reduction would be converted to 2,4-methylene-xylitol (IV) of *meso* con-

solution, which had changed in rotation $[\alpha]^{20}D$ from an original value of $-9.8°$ (calculated as 2,4-methylene-D-sorbitol) to $-17.6°$ (calculated as 2,4-methylene-pentose), was found to be strongly reducing to Fehling solution; removal of the acids and the solvent left the colorless sirupy oxidation product, which did not crystallize; this sirup was reduced in aqueous solution at 100° for six hours with Raney nickel and hydrogen under a pressure of 133 atmospheres. The crystalline reduction product (m. p. 108–109°), which did not reduce Fehling solution and had the composition of a monomethylene-pentitol, was optically inactive in aqueous solution, from which fact the conclusion was drawn that it is the *meso* 2,4-methylenexylitol rather than the 2,4-methylene-D-arabitol. Exact proof of this conclusion was obtained through the preparation of authentic 2,4-methylene-xylitol from xylitol, as described in the accompanying article[4]; the substances from the two sources are identical. The production of 2,4-methylene-xylitol (IV) from the monomethylenesorbitol limits the structure of the latter to 2,4-methylene-D-sorbitol (III) and this conclusion makes it probable that trimethylene-D-sorbitol is 1,3:2,4:5,6-trimethylene-D-sorbitol (I) (since a 1,5- or 1,6-acetal ring is highly improbable) and that the intermediate product obtained by the acetolysis of trimethylene-D-sorbitol is 1,6-diacetyl-3,5-di-(acetoxymethyl)-2,4-methylene-D-sorbitol (II).

Considering next the dimethylene-D-sorbitol of m. p. 174–175° and rotation $[\alpha]^{20}D$ $-29.6°$ in water, it was found that upon oxidation in dilute

figuration and therefore optically inactive; on the other hand, the oxidation of 3,5-methylene-D-sorbitol would produce 2,4-methylene-D-arabinose, reducible to 2,4-methylene-D-arabitol, the formula of which represents an optically-active system. To decide the question, methylene-D-sorbitol was oxidized by aqueous per-iodic acid; the oxidation was complete in fifteen minutes and the oxidized

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

aqueous solution with sodium periodate, only slightly more than one molecular equivalent of oxidant was consumed, and the yield of crystalline formal-dimethone from the oxidized solution corresponded to 0.98 molecular equivalent of formaldehyde. In further experiments, the other oxidation product, which proved to be an *aldehydo*-dimethylene-pentose monohydrate, crystallized spontaneously from the oxidation mixture; the compound, which rotated $[\alpha]^{20}D$ −33.9° in water and melted at 175–180° after previous sintering at 150°, was converted upon sublimation to the anhydrous dimethylene-pentose, which melted at 189–192° and rotated −38.7° in aqueous solution; it was characterized as the crystalline oxime, a substance which melted with decomposition at 227–228° and showed the unusually high rotations $[\alpha]^{20}D$ −272° in pyridine and −215° in water. The structure of the *aldehydo*-dimethylene-pentose is limited by reason of the genesis of the substance from dimethylene-D-sorbitol to *aldehydo*-2,3,4,5-dimethylene-L-xylose or *aldehydo*-2,3,4,5-dimethylene-D-arabinose. Conclusive proof that it is the former compound was obtained in the following manner: upon reduction with hydrogen and Raney nickel it is converted to a crystalline dimethylene-pentitol melting at 217–219° and rotating $[\alpha]^{20}D$ −25.3° in aqueous solution; this pentitol diacetal is transformed by limited acetolysis to the 1,5-diacetyl-3-acetoxymethyl-2,4-methylene-xylitol (*meso*) (V) that is obtained by the limited acetolysis of the 2,4:3,5-dimethylene-D,L-xylitol which is described in the accompanying communication.[4] This result is definitive proof that the optically active pentitol diacetal ($[\alpha]^{20}D$ −25.3°) is 2,4:3,5-dimethylene-L-xylitol (IX); it follows that the *aldehydo*-dimethylene-pentose and the dimethylene-D-sorbitol from which it is derived must be *aldehydo*-2,4:3,5-dimethylene-L-xylose (VIII) and 1,3:2,4-dimethylene-D-sorbitol (VI), respectively.

The formation of an optically inactive acetolysis product (1,5-diacetyl-3-acetoxymethyl-2,4-methylene-xylitol, *meso* structure (V)) from the optically active 2,4:3,5-dimethylene-L-xylitol (IX) is additional evidence supporting our previously expressed view that the limited acetolysis of methylene sugar alcohol acetals takes place initially through a rupture of the acetal linkage at a primary hydroxyl group; had the acetal rupture of (IX) occurred at any other position than carbon five the acetolysis product would be expected to possess optical rotatory power.

Confirmatory evidence for the assigned structure of 1,3:2,4-dimethylene-D-sorbitol (VI) was also obtained through its acetolysis to form the expected 1,5,6-triacetyl-3-acetoxymethyl-2,4-methylene-D-sorbitol (VII), a compound which is saponified by sodium methylate with the production of the previously isolated 2,4-methylene-D-sorbitol (III).

The fact that 1,3:2,4-dimethylene-D-sorbitol (VI) is obtained from the reaction mixture employed for the preparation of trimethylene-D-sorbitol, suggests that it is a precursor of the latter compound; support for this inference was attained when it was found that upon treatment with formaldehyde and hydrochloric acid the crystalline diacetal was converted in 85% yield into the triacetal; this experimental result also offers further support for the previously expressed view that the triacetal is 1,3:2,4:5,6-trimethylene-D-sorbitol (I). Apparently the rare C_5O_2 dioxepane ring that is present in 1,3:2,5:4,6-trimethylene-D-mannitol is absent from the structure of the isomeric trimethylene-D-sorbitol. The two substances are structural rather than stereoisomers, and in view of this result it seems obvious that the methylene derivatives of the other hexitols should be investigated similarly.

Experimental

I. Substances Derived from Trimethylene-D-sorbitol

1,3:2,4:5,6-Trimethylene-D-sorbitol (I) and 1,3:2,4-Dimethylene-D-sorbitol (VI) from D-Sorbitol, Formaldehyde and Concentrated Hydrochloric Acid.—A solution of 200 g. of D-sorbitol in a mixture of 300 cc. of 37% aqueous formaldehyde and 200 cc. of concentrated hydrochloric acid was heated at 50° for four days; after cooling the reaction mixture to 5° for several hours the trimethylene-D-sorbitol which had crystallized was separated by filtration and the filtrate was again heated at 50° for several days; no further deposition of triacetal occurred and the solution was employed for the isolation of 1,3:2,4-dimethylene-D-sorbitol as described in the following paragraph. The trimethylene-D-sorbitol, which was obtained in a yield of 162 g. (68%), was recrystallized from 20 parts of water or 50% alcohol as long rods which melted at 212–216° and rotated $[\alpha]^{20}D$ −30.8° in chloroform (*c*, 1.2).[5] Schulz and Tollens[3] record a melting point of 206° and rotations $[\alpha]^{20}D$ −30.3° (*c*, 2.58) and −29.3° (*c*, 4.578) in chloroform.

The mother liquor of the triacetal preparation was neutralized with sodium carbonate, the sodium chloride which precipitated was separated by filtration, and the filtrate was concentrated *in vacuo* to dryness; the dry residue was extracted with two 200-cc. portions of hot absolute alcohol and the extract upon cooling deposited 35 g. of fine needles (m. p. 150–168°) which after several recrystallizations from 40 parts of acetone yielded 19.0 g. of pure 1,3:2,4-dimethylene-D-sorbitol melting at 174–175° and rotating $[\alpha]^{20}D$ −29.6° in water (*c*, 1.47). The yield was 8% based on the D-sorbitol used or 26% based on the D-sorbitol which did not form trimethylene-D-sorbitol. The diacetal is soluble in cold water, dioxane, pyridine and acetic acid, in warm methyl and ethyl alcohols and practically insoluble in ether, carbon tetrachloride and chloroform.

Anal. Calcd. for $C_8H_{14}O_6$: C, 46.60; H, 6.84. Found: C, 46.66; H, 6.92.

1,6-Diacetyl-3,5-di-(acetoxymethyl)-2,4-methylene-D-sorbitol (II).—Eighty grams of dried and powdered trimethylene-D-sorbitol was added to a rapidly stirred ice-cold mixture of 175 cc. of acetic anhydride, 75 cc. of glacial acetic acid and 2.5 cc. of concentrated sulfuric acid; solution of the triacetal was rapid and after five minutes the reaction mixture was poured into 3 liters of vigorously stirred ice water. The acetolysis product crystallized and after two hours the crystalline product was separated by

(5) All the crystalline compounds described in the experimental part were recrystallized to constant melting point and specific rotation; *c* is the concentration in grams in 100 cc. of solution; the tube length was 4 dm.; all melting points were determined with the stem of the calibrated thermometer immersed in the rapidly stirred bath.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

filtration, washed with cold water and air dried. The yield was 80 g. (52%). The compound was recrystallized from 12 parts of alcohol as long needles which melted at 111–112° and rotated $[\alpha]^{20}D$ +29.8° in chloroform (*c*, 1.20). It is soluble in acetone, chloroform, benzene, acetic acid and pyridine and practically insoluble in water, ether and cold methyl and ethyl alcohols.

Anal. Calcd. for $C_{17}H_{26}O_{12}$: C, 48.34; H, 6.20; saponification, 0.1452 g. substance requires 13.75 cc. 0.1 *N* NaOH (4 saponifiable groups). Found: C, 48.41; H, 6.10; saponification, 0.1452 g. substance consumed 13.75 cc. 0.1 *N* NaOH.

2,4-Methylene-D-sorbitol (III).—A solution of 10 g. of 1,6 - diacetyl - 3,5 - di - (acetoxymethyl) - 2,4 - methylene-D-sorbitol in 100 cc. of chloroform was cooled in an ice-bath and 10 cc. of 0.2 *N* sodium methylate solution was added; upon standing at 5° for eighteen hours, 4.6 g. (quantitative) of 2,4-methylene-D-sorbitol crystallized from the reaction mixture. The acetal was recrystallized from 20 parts of alcohol in the form of fine needles which melted at 163–164° and rotated $[\alpha]^{20}D$ −9.8° in aqueous solution (*c*, 1.30). It is readily soluble in water, hot methyl and ethyl alcohols and practically insoluble in chloroform, acetone and ether.

Anal. Calcd. for $C_7H_{14}O_6$: C, 43.29; H, 7.27. Found: C, 43.27; H, 7.25.

1,3,5,6-Tetraacetyl-2,4-methylene-D-sorbitol.—A solution of 2.0 g. of 2,4-methylene-D-sorbitol in a mixture of 15 cc. of acetic anhydride and 10 cc. of pyridine was allowed to stand for forty-eight hours at 25° and then poured into ice-water; the precipitated tetraacetyl derivative, which is soluble in chloroform, acetone, acetic acid, pyridine and benzene and practically insoluble in water and cold methyl and ethyl alcohols, was recrystallized from 10 parts of alcohol as prismatic needles melting at 150–151° and rotating $[\alpha]^{20}D$ −1.5° in chloroform (*c*, 1.40). The yield was 3.6 g. (94%).

Anal. Calcd. for $C_{15}H_{22}O_{10}$: C, 49.72; H, 6.12; CH_3CO, 47.5. Found: C, 49.80; H, 6.03; CH_3CO, 47.3.

Lead Tetraacetate Oxidation of 2,4-Methylene-D-sorbitol.—To a solution of 0.1018 g. of 2,4-methylene-D-sorbitol in 15 cc. of glacial acetic acid, 30 cc. (3.32 molecular equivalents) of 0.0581 *M* lead tetraacetate glacial acetic acid solution was added and the volume was adjusted to 50 cc. with glacial acetic acid, all operations being conducted at 25°. Analysis of 5 cc. subsamples at one, three and nineteen hours indicated that 0.67, 1.00 and 1.04 molecular equivalents, respectively, of oxidant had been consumed. The analytical data indicate that 2,4-methylene-D-sorbitol contains a single glycol grouping as a portion of its structure.

Per-iodic Acid Oxidation of 2,4-Methylene-D-sorbitol.—A solution of 1.0036 g. of 2,4-methylene-D-sorbitol in 25 cc. of water was cooled to 5° and 15 cc. (1.79 molecular equivalents) of 0.616 *M* per-iodic acid was added; the solution was allowed to warm to 20° and the volume was adjusted to 50 cc. with water. Analysis of 5 cc. aliquots at twenty, forty and sixty minutes showed that 1.04 molecular equivalents of oxidant had been consumed and no further oxidation was noted after twenty and two hundred sixty hours. After titration, the first three aliquots were combined and poured into 200 cc. of 0.4% dimethone solution; the precipitate of formal-dimethone (m. p. 189–190°) which deposited on keeping the mixture at 5° for eighteen hours, weighed 0.387 g. and represented 85% of that expected from the production of one molecular equivalent of formaldehyde as an oxidation product. The results of the oxidation show that the glycol grouping of 2,4-methylene-D-sorbitol must contain a primary alcohol group since the analytical findings agree with the reaction course $C_5H_9O_4{\cdot}CHOH{\cdot}CH_2OH + HIO_4 = C_5H_9O_4{\cdot}CHO + HCHO + H_2O + HIO_3$. Although the analyses mentioned above show that the oxidation was complete within twenty minutes under the experimental conditions, the specific rotation $[\alpha]^{20}D$ of the solution (calculated on its presumed content of methylene-pentose) showed values of −17.6, −14.5, −6.2, −3.1° and a constant value of −2.6° at the expiration of fifteen and sixty minutes, four, twenty and ninety-two hours, respectively; these changes in rotatory power are presumably due to the change of the *aldehydo* form of the methylene-pentose to the equilibrium mixture of its α and β cyclic forms (probably α- and β-2,4-methylene-L-xylopyranose).

Sodium Periodate Oxidation of 2,4-Methylene-D-sorbitol.—The oxidation of 1.0045 g. of 2,4-methylene-D-sorbitol with 15 cc. (1.65 molecular equivalents) of 0.570 *M* sodium periodate was conducted by the same procedure employed in the per-iodic acid oxidation. The analytical results showed that 1.01, 1.03 and 1.02 molecular equivalents of oxidant had been consumed at the end of twenty, forty and sixty minutes, respectively, and the formal-dimethone recovered was 86% of that expected for the production of one molecular equivalent of formaldehyde. The specific rotation $[\alpha]^{20}D$ of the oxidized solution remained constant at −18.4° for three hours and thereafter showed values of −15.3, −11.9, −4.1, −3.6 and −2.6° at the expiration of nineteen, forty-three, one hundred eighty-seven, two hundred twelve and two hundred eighty-three hours, respectively, the reduced rate of mutarotation in this case being probably due to the lower hydrogen-ion concentration.

2,4-Methylene-xylitol (IV) from 2,4-Methylene-D-sorbitol (III).—A solution of 5.0 g. of 2,4-methylene-D-sorbitol in 50 cc. of water was cooled to 5° and 50 cc. (1.20 molecular equivalents) of 0.616 *M* aqueous per-iodic acid was added; the reaction mixture was allowed to stand at 25° for eighteen hours, cold saturated barium hydroxide solution was added in slight excess, the precipitated barium iodate and periodate were separated by filtration and the filtrate was concentrated *in vacuo* to a dry sirup in the presence of barium carbonate. The sirup was extracted with 50 cc. of warm water and the extract, which was reducing to Fehling solution, was transferred to a bomb and agitated at 100° for six hours with Raney nickel and hydrogen under a pressure of 133 atmospheres. The catalyst was separated by filtration and the filtrate, upon concentration *in vacuo*, deposited a crystalline residue (4.2 g.; quantitative) which was recrystallized from 5 parts of alcohol and yielded 2.9 g. of the 2,4-methylene-xylitol (m. p. 108–109°) which is described in the accompanying communication.[4] The isolation and identification of this methylene-pentitol is a definitive proof that the methylene-D-sorbitol from which it is derived is 2,4-methylene-D-sorbitol.

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.90; H, 7.37. Found: C, 43.82; H, 7.35.

II. Substances Derived from 1,3:2,4-Dimethylene-D-sorbitol

5,6-Diacetyl-1,3:2,4-dimethylene-D-sorbitol.—A solution of 1.0 g. of the previously described 1,3:2,4-dimethylene-D-sorbitol in a mixture of 10 cc. of acetic anhydride and 10 cc. of pyridine was allowed to stand at 25° for seventy-two hours and then poured into 600 cc. of ice water; the solution was extracted with chloroform and the washed and dried extract was concentrated *in vacuo* to a crystalline residue which upon crystallization from 10 parts of alcohol formed plates melting at 135–136° and rotating $[\alpha]^{20}D$ −12.8° in chloroform (*c*, 1.08). The compound is soluble in acetone, benzene, chloroform, acetic acid and ethyl acetate and insoluble in water. The yield was 1.2 g. (86%).

Anal. Calcd. for $C_{12}H_{18}O_6$: C, 49.65; H, 6.25; CH_3CO, 29.7. Found: C, 49.60; H, 6.27; CH_3CO, 29.8.

5,6-Dibenzoyl-1,3:2,4-dimethylene-D-sorbitol.—The dibenzoate was obtained by the action of benzoyl chloride on 1,3:2,4-dimethylene-D-sorbitol in pyridine solution. The yield was 2.1 g. (quantitative). The compound deposited from its solution in 10 parts of alcohol in the form of needles melting at 134–135° and rotating $[\alpha]^{20}D$ −54.8° in chloroform (*c*, 1.08); it is soluble in pyridine, acetic acid, acetone and ethyl acetate and insoluble in water.

Anal. Calcd. for $C_{22}H_{22}O_8$: C, 63.76; H, 5.35; C_6H_5CO, 50.7. Found: C, 63.61; H, 5.37; C_6H_5CO, 50.8.

Sodium Periodate Oxidation of 1,3:2,4-Dimethylene-D-sorbitol (VI).—A solution of 1.0619 g. of 1,3:2,4-dimethyl-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

ene-D-sorbitol in 20 cc. of water was cooled to 5° and 25 cc. (2.10 molecular equivalents) of 0.432 *M* aqueous sodium periodate was added; the mixture was allowed to warm to 25° and the volume was adjusted to 50 cc. with water. Analysis of 5-cc. aliquots at the expiration of twenty minutes, two and twenty hours indicated that 1.00, 1.03 and 1.04 molecular equivalents, respectively, of sodium periodate had been reduced. After titration, the first two aliquots were poured into 200 cc. of 0.4% dimethone solution and the mixture, upon preservation at 5° for forty-eight hours, deposited 0.2124 g. of formal-dimethone, which is 98% of that expected if one molecular equivalent of formaldehyde was produced as a product of the oxidation. These analyses prove that the dimethylene-D-sorbitol contains a terminal glycol grouping as a part of its structure. They indicate that the dimethylene-acetal was oxidized with the formation of formaldehyde and an *aldehydo*-dimethylene-pentose. Support for this assumption was obtained when it was noted that the specific rotation, $[\alpha]^{20}D$ −37.1° (calculated as *aldehydo*-dimethylene-pentose), of the oxidized solution did not change in value even on standing for one-hundred twenty hours, an observation which would be expected only in the absence of a ring form of the sugar (compare the rotation changes of the oxidized solution of 2,4-methylene-D-sorbitol which presumably contains 2,4-methylene-L-xylose, a sugar capable of existing in α and β cyclic forms).

aldehydo-2,4:3,5-Dimethylene-L-xylose Monohydrate from 1,3:2,4-Dimethylene-D-sorbitol (VI).—A solution of 5.0 g. of 1,3:2,4-dimethylene-D-sorbitol in 50 cc. of water was cooled to 5° and 75 cc. (1.3 molecular equivalents) of 0.432 *M* aqueous sodium periodate was added. Within thirty minutes small needles started to deposit in the solution and after the mixture had been allowed to stand in the refrigerator for eighteen hours they were separated by filtration. The yield was 2.6 g. (56%). The product was recrystallized from 10 parts of water as needles which rotated $[\alpha]^{20}D$ −33.9° in aqueous solution (*c*, 0.82) and melted at 175–180° after prior sintering at 150°. The substance is soluble in warm water and acetic acid and practically insoluble in warm methyl and ethyl alcohols, chloroform, acetone and dioxane.

Anal. Calcd. for $C_7H_{10}O_5 \cdot H_2O$: C, 43.75; H, 6.30. Found: C, 43.78; H, 6.34.

aldehydo-2,4:3,5-Dimethylene-L-xylose (VIII).—A sample of 0.5 g. of *aldehydo*-2,4:3,5-dimethylene-L-xylose monohydrate was sublimed in a vacuum at 140–145°; the sublimate of fine needles showed a melting point of 189–192° and a specific rotation $[\alpha]^{20}D$ −38.7° in water (*c*, 0.44); no mutarotation was observed in twenty-four hours.

Anal. Calcd. for $C_7H_{10}O_5$: C, 48.27; H, 5.79. Found: C, 48.02; H, 5.92.

Oxime of *aldehydo*-2,4:3,5-Dimethylene-L-xylose.—A mixture of 1.0 g. *aldehydo*-2,4:3,5-dimethylene-L-xylose monohydrate, 1.0 g. of hydroxylamine hydrochloride, 1.0 g. of fused sodium acetate, 25 cc. of methyl alcohol and 5 cc. of water was refluxed for twenty minutes. Upon standing at 5° for several days the solution deposited 0.8 g. (80%) of product, which upon recrystallization from 100 parts of alcohol yielded small lath-like crystals which melted at 227–228° and rotated $[\alpha]^{20}D$ −272° in pyridine (*c*, 0.50). Because the magnitude of this rotation is unusual for this type of compound, its rotation was also determined in aqueous solution (*c*, 0.31); it was found to be $[\alpha]^{20}D$ −215.0°. The oxime is soluble in pyridine, hot water and hot alcohol and practically insoluble in cold alcohol, acetone and chloroform.

Anal. Calcd. for $C_7H_{11}O_5N$: C, 44.44; H, 5.86; N, 7.40. Found: C, 44.43; H, 5.86; N, 7.45.

2,4:3,5-Dimethylene-L-xylitol (IX) from *aldehydo*-2,4:3,5-Dimethylene-L-xylose Monohydrate.—A solution of 6.0 g. of 2,4:3,5-dimethylene-L-xylose monohydrate in 200 cc. of water was agitated in a bomb at 25° for eighteen hours with Raney nickel and hydrogen at a pressure of 133 atmospheres; the catalyst was separated by filtration and the filtrate was concentrated *in vacuo* to a crystalline mass (5.0 g.; 91%) which was recrystallized from 50 parts of alcohol; the 2,4:3,5-dimethylene-L-xylitol crystallized in needles which melted at 217–219° and rotated $[\alpha]^{20}D$ −25.3° in aqueous solution (*c*, 1.09). The compound is one component of the crystalline 2,4:3,5-dimethylene-D,L-xylitol which is described in the accompanying communication.[4] A more detailed comparison of these two substances is made in that article.

Anal. Calcd. for $C_7H_{12}O_5$: C, 47.72; H, 6.87. Found: C, 47.64; H, 6.83.

1-Acetyl-2,4:3,5-dimethylene-L-xylitol.—This compound was prepared by the acetylation of 2,4:3,5-dimethylene-L-xylitol (1.0 g.) in pyridine solution (10 cc.) by acetic anhydride (10 cc.). The yield was 1.0 g. (83%). It was recrystallized from 12 parts of alcohol in the form of rods which melted at 153–154° and rotated $[\alpha]^{20}D$ +2.8° in chloroform (*c*, 0.96); it is soluble in acetone, ethyl acetate, carbon tetrachloride and acetic acid and practically insoluble in water. A microscopic optical crystallographic examination by Mr. George L. Keenan, of the Food and Drug Administration, Federal Security Agency, showed that in parallel polarized light (crossed nicols) the extinction was parallel and the elongation negative, the refractive indices being $n_\alpha = 1.484$, $n_\beta = 1.504$ and $n_\gamma = 1.524$, all ±0.002.

Anal. Calcd. for $C_9H_{14}O_6$: C, 49.54; H, 6.47; CH_3CO, 19.7. Found: C, 49.58; H, 6.48; CH_3CO, 19.7.

1,5-Diacetyl-3-acetoxymethyl-2,4-methylene-xylitol (V) from 2,4:3,5-Dimethylene-L-xylitol (IX).—A suspension of 1.0 g. of 2,4:3,5-dimethylene-L-xylitol in a mixture of 7.0 cc. of acetic anhydride and 3.0 cc. of glacial acetic acid was cooled to 0° and 10 cc. of an acetylating solution (prepared as described for the acetolysis of trimethylene-D-sorbitol) cooled to 0° was added; the mixture was agitated until solution of the alcohol diacetal was complete (ten minutes) and after a further five minutes it was poured into 400 cc. of ice water. The solution was nearly neutralized by the addition of 35 g. of sodium bicarbonate and extracted with three 50 cc. portions of chloroform; the washed and dried extract was concentrated to a crystalline residue (1.4 g.; 78%; m.p. 138–145°) which was recrystallized from 30 parts of hot water and yielded 0.8 g. of pure 1,5-diacetyl-3-acetoxymethyl-2,4-methylene-xylitol melting at 139–140° and devoid of rotation in aqueous solution (*c*, 0.92). A mixed melting point with the compound prepared by the acetolysis of 2,4:3,5-dimethylene-D,L-xylitol[4] also showed 139–140°, a result which was anticipated since the acetolysis of either the optically active (IX) or racemic form of the diacetal according to the acetolysis mechanism which has been proposed should yield the *meso* 1,5-diacetyl-3-acetoxymethyl-2,4-methylene-xylitol (V).

1,5,6-Triacetyl-3-acetoxymethyl-2,4-methylene-D-sorbitol (VII) from 1,3:2,4-Dimethylene-D-sorbitol (VI).—A solution of 1.0 g. of 1,3:2,4-dimethylene-D-sorbitol in 5 cc. of an ice-cold 1% sulfuric acid acetylating mixture was allowed to stand at 0° for five minutes and then poured into 200 cc. of ice-water; the flocculent precipitate which formed (0.6 g.; 32%) was separated by filtration and recrystallized from 7 parts of alcohol. The compound, which crystallized as fine needles, melted at 94–95° and rotated $[\alpha]^{20}D$ +11.0° in chloroform (*c*, 1.04); it is readily soluble in acetone, ethyl acetate, acetic acid, pyridine and warm methyl and ethyl alcohols and practically insoluble in water.

Anal. Calcd. for $C_{16}H_{24}O_{11}$: C, 48.98; H, 6.16; saponification, 0.1139 g. substance requires 11.61 cc. 0.1 *N* NaOH (4 saponifiable groups). Found: C, 49.05; H, 6.21; saponification, 0.1139 g. substance consumed 11.58 cc. 0.1 *N* NaOH.

2,4-Methylene-D-sorbitol (III) from 1,5,6-Triacetyl-3-acetoxymethyl-2,4-methylene-D-sorbitol (VII).—To an ice-cold solution of 2.0 g. of 1,5,6-triacetyl-3-acetoxymethyl-2,4-methylene-D-sorbitol in 30 cc. of chloroform, 5 cc. of 0.2 *N* sodium methylate solution was added and the reaction mixture was allowed to stand at 5° for seventy-two hours; the precipitate which had deposited was separated by filtration and recrystallized from 20 parts of alcohol; the needles which formed showed a melting point of 163–

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

164° and a specific rotation $[\alpha]^{20}D$ −9.7° in aqueous solution, these data being in agreement with those previously found for the 2,4-methylene-D-sorbitol obtained by the saponification of 1,6-diacetyl-3,5-di-(acetoxymethyl)-2,4-methylene-D-sorbitol (II). A mixed melting point determination with 2,4-methylene-D-sorbitol from this source showed no depression.

1,3:2,4:5,6-Trimethylene-D-sorbitol (I) from 1,3:2,4-Dimethylene-D-sorbitol (VI).—A solution of 1.0 g. of 1,3:2,4-dimethylene-D-sorbitol (VI) in a mixture of 1.0 cc. of concentrated hydrochloric acid and 1.0 cc. of 37% aqueous formaldehyde was warmed to 50°; within thirty minutes crystallization of needles was noted and after forty-eight hours the mixture was cooled to 5°, the needles were separated by filtration, washed with ice-cold 50% alcohol, and dried. The yield was 0.90 g. (85%). The product, after recrystallization from 20 parts of 50% alcohol, showed a melting point of 210–214° and a mixed melting point determination with authentic trimethylene-D-sorbitol showed no depression.

Summary

The condensation of D-sorbitol with formaldehyde under the influence of concentrated hydrochloric acid yields, in addition to the known trimethylene-D-sorbitol of Schulz and Tollens, a new crystalline dimethylene-D-sorbitol. The limited acetolysis of the known trimethylene-D-sorbitol yields a diacetyl-di-(acetoxymethyl)-methylene-hexitol, which upon saponification is transformed into a crystalline methylene-D-sorbitol that can be only 2,4-methylene-D-sorbitol since it is converted by periodate oxidation and subsequent reduction to 2,4-methylene-xylitol of proved structure.

The new dimethylene-D-sorbitol can be only 1,3:2,4-dimethylene-D-sorbitol since upon periodate oxidation it yields an *aldehydo*-2,4:3,5-dimethylene-L-xylose which is successively converted to 2,4:3,5-dimethylene-L-xylitol, 1,5-diacetyl-3-acetoxymethyl-2,4-methylene-xylitol and 2,4-methylene-xylitol by known reactions.

The fact that the limited acetolysis of 2,4:3,5-dimethylene-L-xylitol forms a compound of *meso* structure rather than one possessing optical activity is cited as evidence supporting the previously proposed acetolysis mechanism based on the hypothesis that the acetal linkages of methylene acetals which are formed through primary alcoholic groups are more easily ruptured than those formed through secondary alcoholic groups; this experimental corroboration allows assignment of the structures of 1,6-diacetyl-3,5-di-(acetoxymethyl)-2,4-methylene-D-sorbitol and 1,-5,6-triacetyl-3-(acetoxymethyl)-2,4-methylene-D-sorbitol, respectively, to the acetolysis products of trimethylene-D-sorbitol and 1,3:2,4-dimethylene-D-sorbitol.

In view of the present experimental results, and particularly the conclusive establishment of the presence of the 2,4-acetal linkage, it seems highly probable that the trimethylene-D-sorbitol of Schulz and Tollens is 1,3:2,4:5,6-trimethylene-D-sorbitol, the rare C_5O_2 dioxepane ring that is present in 1,3:2,5:4,6-trimethylene-D-mannitol being absent from the structure of the isomeric trimethylene-D-sorbitol.

2,4:3,5-Dimethylene-D,L-xylitol and 2,4-Methylene-xylitol

BY RAYMOND M. HANN, A. T. NESS AND C. S. HUDSON

In the course of the study of the acetolysis of trimethylene-D-sorbitol that is described in the accompanying article[1] there was obtained by degradative reactions a monomethylene-pentitol (m. p. 108–109°) the structure and configuration of which needed to be established. In configuration it is limited to a monomethylene derivative of xylitol or D-arabitol by reason of its origin. In aqueous solution no optical rotation was detected, which indicated the probability that the compound is a monomethylene-xylitol of *meso* structure since all structures for a monomethylene-D-arabitol represent optically active systems. The direct identification of its constituent pentitol through acid hydrolysis seemed of little attraction because of the experimental difficulties that are often encountered in attempts to hydrolyze methylene cyclic acetals. Accordingly, it was sought to produce the substance by condensing formaldehyde with xylitol, a procedure which, if successful, would establish the identity of its constituent pentitol and might also lead to a less laborious method for obtaining it.

There appears to be no recorded combination of formaldehyde with xylitol, although dibenzylidene[2] and di-isopropylidene xylitols[3] are known. A crystalline dimethylene-xylitol (m. p. 201–202°) was obtained in 91% yield by the reaction of xylitol with 37% aqueous formaldehyde and concentrated hydrochloric acid for two hours at 50°. One of the methylene groups in this dimethylene-xylitol is readily removable, as will be described, and the resulting monomethylene-xylitol proved to be identical with the monomethylene-pentitol (m. p. 108–109°) which was obtained from trimethylene-D-sorbitol. This monomethylene-xylitol does not react with sodium periodate and thus it contains no α-glycol group;

Digitized by Arya Samaj Foundation Chennai and eGangotri

the only possible structure for the acetal is therefore that of 2,4-methylene-xylitol (III). Its optical inactivity is to be ascribed to its *meso* configuration.

Consider next the structure of the dimethylene-xylitol. Obviously the substance contains one free hydroxyl group and it readily formed crystalline mono acetyl, benzoyl, carbanilo and tosyl derivatives. The tosyl-dimethylene-xylitol reacted with a solution of sodium iodide in acetonylacetone to yield a crystalline iodo-dimethylene-xylitol which was reduced by hydrogen and Raney nickel to a desoxy-dimethylene-xylitol; the replacement of the tosyl group by the iodine atom is a strong indication, by the Oldham–Rutherford rule,[4] that it is attached at a terminal carbon atom. Conclusive proof of this inference was obtained when it was found that the desoxy-dimethylene-xylitol is identical with the desoxy-dimethylene-xylitol that is obtained by heating the known 1-desoxy-2,3,4,5-di-isopropylidene-D,L-xylitol[3b] with formaldehyde and concentrated hydrochloric acid. The substance can be only 1-desoxy-2,3,4,5-dimethylene-D, L-xylitol and the diacetal from which it is derived must be a 2,3,4,5-dimethylene-D,L-xylitol. The allocation of the acetal linkages among the four positions in its structure was made through the acetolysis reaction previously applied by us to trimethylene-D-mannitol.[5] Upon limited acetolysis in a one per cent. sulfuric acid mixture at about 0° the 2,3,4,5-dimethylene-D,L-xylitol is converted in 44% yield to a crystalline substance which had the composition of a diacetyl-acetoxymethyl-methylene-xylitol; upon saponification with sodium methylate the latter compound is converted in nearly quantitative yield to the previously mentioned 2,4-methylene-xylitol

(III) (*meso*)
2,4-Methylene-xylitol

(III), originally obtained from trimethylene-D-sorbitol. The 2,3,4,5-dimethylene-D,L-xylitol from which it was formed must be 2,4:3,5-dimethylene-D,L-xylitol (I) and its acetolysis product is in all probability 1,5-diacetyl-3-acetoxymethyl-2,4-methylene-xylitol (II), a *meso* structure.

We express our appreciation to Mr. George L. Keenan of the Food and Drug Administration, Federal Security Agency, for the determination of the optical crystallographic properties of the 2,4:3,5-dimethylene-L- and D,L-xylitols and their acetyl derivatives.

Experimental

2,4:3,5-Dimethylene-D,L-xylitol (I).—A solution of 5.0 g. of crystalline xylitol in a mixture of 5 cc. of concentrated hydrochloric acid and 5 cc. of 37% formaldehyde was allowed to stand at 50° for two hours; the magma which formed when the reaction mixture was cooled to room temperature was thinned with 25 cc. of alcohol and the precipitate (5.1 g.) was separated by filtration; the mother liquor was evaporated by an air current and the residual solid was crystallized from 10 cc. of alcohol to yield an additional 0.2 g. of product, making the total yield 91%. The colorless compound was recrystallized by solution in 3 parts of warm water and the addition of 15 parts of alcohol, and obtained as small thin lath-like crystals with a m. p. of 201–202°.[6] It is soluble in cold pyridine, warm methyl and ethyl alcohols and acetic acid, and insoluble in acetone, chloroform and benzene. At 24° a saturated aqueous solution contains 4.2 g. of the substance in 100 cc. of solution; a saturated aqueous solution of 2,4:3,5-dimethylene-L-xylitol at 24° contains 3.7 g. of the acetal in 100 cc. of solution. Thus the D,L-form is more soluble than the L-form but less than twice its solubility. The substance appears to belong to the class of compounds which have been defined by Kipping and Pope[7] as pseudo racemates. An optical crystallographic comparison of it and the previously described L-form [m. p. 217–219°; $[\alpha]^{20}D$ −25.3° in water] was made by Mr. George L. Keenan who reported as follows:

"In ordinary light (plane polarized) both substances were seen to consist of elongated rods and prisms. The L-form showed prism faces that were straight and parallel, while the D,L-compound showed many of the prisms to be somewhat fibrous and curved. In parallel polarized light (crossed nicols) the extinction was parallel and the sign of elongation negative for both compounds. The n_α, n_β, and n_γ refractive indices were identical in both compounds. However, in the case of the authentic L-compound the prisms are so oriented that the n_α and n_β values are commonly shown, while in the D,L-compound n_α and n_γ are commonly shown. Interference figures were not observed on either compound. As a result of the examination, these compounds are very similar if not identical optically. The most striking feature for differentiation is the difference in orientation. The indices are as follows:

	D,L-Compound	L-Compound
n_α	1.524	1.524
n_β	1.543	1.544
n_γ	1.560	1.558"

The melting point of the D,L-form was depressed upon admixture of a small amount of the L-form and the L-form did not dissolve in a saturated aqueous solution of the D,L-form. Although an exhaustive study was not undertaken, the experiments cited above agree in their indication that

2,4:3,5-dimethylene-D,L-xylitol is a pseudo rather than a true racemate; its crystals are comparable with those from a solution of two isomorphous substances.

Anal. Calcd. for $C_7H_{12}O_6$: C, 47.72; H, 6.87. Found: C, 47.61; H, 6.93.

1-Acetyl-2,4:3,5-dimethylene-D,L-xylitol.—A mixture of 4.4 g. of 2,4:3,5-dimethylene-D,L-xylitol, 0.5 g. of fused sodium acetate and 22.5 cc. of acetic anhydride was heated gently and, following a vigorous exothermic reaction, refluxed for fifteen minutes; upon pouring the cooled reaction mixture into 25 cc. of water, 3.4 g. of the acetate crystallized, and an additional 2.0 g. was obtained by concentration of the acetic acid filtrate, making the yield quantitative. The compound was recrystallized from 20 parts of boiling water in the form of needles which melted at 156–157° and showed no rotation in chloroform solution, (*c*, 0.5). It can also be recrystallized from 10 parts of methyl or ethyl alcohol and is readily soluble in acetone, chloroform and benzene. The compound is a true racemate; a mixed melting point with a small amount of the previously described 1-acetyl-2,4:3,5-dimethylene-L-xylitol (m. p. 153–154°) gave a depressed value of 146–156°; an optical crystallographic examination by Mr. Keenan showed that in parallel polarized light (crossed nicols) the extinction was parallel and the elongation negative, the indices of refraction being $n_\alpha = 1.495$, $n_\beta = 1.514$ and $n_\gamma = 1.539$ (all ±0.002), these values being distinctly different from those of 1-acetyl-2,4:3,5-dimethylene-L-xylitol.[1] The substance is therefore to be classed as a true racemate.

Anal. Calcd. for $C_9H_{14}O_6$: C, 49.54; H, 6.47; CH_3CO, 19.7. Found: C, 49.66; H, 6.47; CH_3CO, 19.5.

1-Benzoyl-2,4:3,5-dimethylene-D,L-xylitol.—This compound was obtained in a yield of 88% (2.8 g.) by the benzoylation of 2,4:3,5-dimethylene-D,L-xylitol (2.0 g.) in pyridine solution with benzoyl chloride. It was recrystallized from 30 parts of alcohol and obtained in the form of fine needles which melted at 164–165°. The substance is soluble in acetone, methyl alcohol, chloroform and ethyl acetate and insoluble in water.

Anal. Calcd. for $C_{14}H_{16}O_6$: C, 60.00; H, 5.75; C_6H_5CO, 37.5. Found: C, 60.35; H, 5.79; C_6H_5CO, 37.2.

1-Carbanilo-2,4:3,5-dimethylene-D,L-xylitol.—This derivative was prepared by a procedure similar to that which Wolfrom and Pletcher[8] have employed for the preparation of the carbanilates of sugar glycosides. A mixture of 2.0 g. of 2,4:3,5-dimethylene-D,L-xylitol, 1.4 cc. of phenyl isocyanate and 20 cc. of pyridine was boiled for two hours under a reflux condenser protected from atmospheric moisture by a drying tube. The carbanilo derivative (1.2 g.) which precipitated from the solution on cooling was recrystallized from 20 parts of acetone as clusters of glistening prisms which melted at 196–197°. An additional 2.0 g. of compound showing the same melting point was obtained by allowing the pyridine to evaporate from the mother liquor and recrystallizing the residue from acetone. The total yield was 94%. The substance is readily soluble in warm methyl and ethyl alcohols, chloroform and dioxane, sparingly soluble in warm water and practically insoluble in cold water and benzene.

Anal. Calcd. for $C_{14}H_{17}O_6N$: C, 56.94; H, 5.80; N, 4.74. Found: C, 56.98; H, 5.64; N, 4.64.

1-Tosyl-2,4:3,5-dimethylene-D,L-xylitol.—A mixture of 1.0 g. of 2,4:3,5-dimethylene-D,L-xylitol, 1.2 g. (1.1 molecular equivalents) of *p*-toluenesulfonyl chloride and 10 cc. of pyridine was agitated at room temperature until the diacetal dissolved (four hours) and the resulting solution was allowed to stand for eighteen hours and then was poured upon crushed ice. The precipitated tosyl derivative (1.7 g., 90%) was recrystallized from 20 parts of alcohol and formed prisms which melted at 145–146°. The compound is readily soluble in cold chloroform and acetone, methyl alcohol, warm benzene and dioxane and insoluble in water.

Anal. Calcd. for $C_{14}H_{18}O_7S$: C, 50.90; H, 5.49; S, 9.70. Found: C, 50.92; H, 5.48; S, 9.58.

1-Iodo-2,4:3,5-dimethylene-D,L-xylitol.—The replacement of the tosyl group of 1-tosyl-2,4:3,5-dimethylene-D,L-xylitol by iodine was incomplete in an experiment in which 5.0 g. of the tosyl derivative, 5.0 g. of sodium iodide and 100 cc. of acetone were heated at 100° for four hours; only about 50% of the sodium *p*-toluenesulfonate which would be expected from the removal of the tosyl group precipitated in the acetone solution and the product, which melted from 119 to 130°, was a mixture of unchanged tosyl derivative and some of the desired 1-iodo-2,4:3,5-dimethylene-D,L-xylitol. A quantitative conversion was attained however by substitution of acetonylacetone (25 cc.) as a solvent[9] and carrying out the reaction at 120° for four hours or by refluxing the reactants in acetic anhydride (25 cc.) for one hour. The 1-iodo-2,4:3,5-dimethylene-D,L-xylitol deposited from its solution in 15 parts of alcohol in the form of needles which melted at 144–145°; a mixed melting point determination with 1-tosyl-2,4:3,5-dimethylene-D,L-xylitol, which melts at 145–146°, gave a value of 117–119°. The iodo derivative is readily soluble in cold acetone and chloroform and in warm methyl and ethyl alcohols and is insoluble in water.

Anal. Calcd. for $C_7H_{11}O_4I$: C, 29.39; H, 3.88; I, 44.36. Found: C, 29.39; H, 3.84; I, 44.28.

1-Desoxy-2,4:3,5-dimethylene-D,L-xylitol from 1-Iodo-2,4:3,5-dimethylene-D,L-xylitol.—To a solution of 3.0 g. of 1-iodo-2,4:3,5-dimethylene-D,L-xylitol in 150 cc. of methyl alcohol, 3 cc. of 20% methyl alcoholic potassium hydroxide solution and 2.0 g. of Raney nickel were added and the reaction mixture was agitated vigorously at 22° while hydrogen under a slight positive pressure was introduced. In thirty minutes 240 cc. (theory, 235 cc., S. T. P.) of hydrogen was taken up and only 5 cc. more was absorbed in a further thirty minutes. The catalyst was removed by filtration and the filtrate was concentrated *in vacuo* to dryness. The solid was extracted with 20 cc. of boiling absolute alcohol and, upon cooling the extract, the desoxy diacetal crystallized in the form of fine needles; the compound, after recrystallization from 15 parts of alcohol, melted at 155–156°, and the value was not altered by further recrystallization; it is readily soluble in acetone, warm methyl alcohol and warm water, and relatively insoluble in cold water. The substance sublimes readily. The yield was 1.3 g. (76%).

Anal. Calcd. for $C_7H_{12}O_4$: C, 52.49; H, 7.55. Found: C, 52.59; H, 7.60.

1-Desoxy-2,4:3,5-dimethylene-D,L-xylitol from 1-Desoxy-2,3,4,5-di-isopropylidene-D,L-xylitol.[3b]—A solution of 1.5 g. of 1-desoxy-2,3,4,5-di-isopropylidene-D,L-xylitol in a mixture of 2 cc. of 37% aqueous formaldehyde and 2 cc. of concentrated hydrochloric acid was allowed to stand for two and one-half hours at 50°; the solution was diluted with 25 cc. of alcohol and concentrated *in vacuo* to a sirupy residue; following the addition of 2.0 g. of barium carbonate, the residue was dried by thes uccessive addition and evaporation of two 25 cc. portions of absolute alcohol and finally extracted with warm absolute alcohol The extract, upon removal of the solvent, deposited fine needles (m. p. 148–152°) which, after one recrystallization from 20 parts of absolute alcohol, melted at 155–156°; a mixed melting point determination with the 1-desoxy-2,4:3,5-dimethylene-D,L-xylitol described in the preceding paragraph also gave 155–156°. The yield was moderate, 0.30 g. (37%), presumably because of the volatile nature of the product.

1,5-Diacetyl-3-acetoxymethyl-2,4-methylene-xylitol (II).—To an ice-cold suspension of 1.0 g. of 2,4:3,5-dimethylene-D,L-xylitol in a mixture of 7 cc. of acetic anhydride and 3 cc. of glacial acetic acid was added 10 cc. of an ice-cold acetylating solution (prepared by adding 2 cc. of concentrated sulfuric acid dropwise to an ice-cold mixture of 70 cc. of acetic anhydride and 30 cc. of acetic acid); the diacetal dissolved and after standing for fifteen minutes at 5° the reaction mixture was poured upon crushed ice.

The crystalline precipitate (0.3 g., m. p. 137°) was separated by filtration and the filtrate was neutralized with sodium bicarbonate and extracted with chloroform; the chloroform was evaporated and the sirupy residue remaining was crystallized from 10 cc. of hot water and yielded a further 0.5 g. of product melting at 137–138° making the yield of 1,5-diacetyl-3-acetoxymethyl-2,4-methylene-xylitol 44%; a residual sirup (0.5 g.) could not be induced to crystallize. The substance is readily soluble in cold methyl and ethyl alcohols, chloroform, acetone and benzene. It deposited from its solution in 30 parts of water as long needles which melted at 138–139°.

Anal. Calcd. for $C_{13}H_{20}O_9$: C, 48.75; H, 6.29; saponification, 0.1117 g. substance requires 10.46 cc. 0.1 *N* NaOH (3 saponifiable groups). Found: C, 48.85; H, 6.34; saponification, 0.1117 g. substance consumed 10.32 cc. 0.1 *N* NaOH.

2,4-Methylene-xylitol (III) from 1,5-Diacetyl-3-acetoxymethyl-2,4-methylene-xylitol (II).—A solution of 1.6 g. of 1,5-diacetyl-3-acetoxymethyl-2,4-methylene-xylitol in 15 cc. of chloroform was cooled to 0° and 1 cc. of 0.1 *N* sodium methylate solution was added. The next day the chloroform was evaporated by an air current and the sirup which remained was dissolved in 2 cc. of warm alcohol; the reaction product (0.7 g., 88%), which crystallized as the solution cooled, was recrystallized from 12 parts of alcohol as elongated prisms which melted at 108–109°. It is readily soluble in water, warm methyl and ethyl alcohols, and dioxane and relatively insoluble in benzene, acetone and chloroform.

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.90; H, 7.37. Found: C, 43.98; H, 7.40.

Triacyl Derivatives of 2,4-Methylene-xylitol (III) (a) **1,3,5-Triacetyl-2,4-methylene-xylitol** was obtained in nearly quantitative yield (1.7 g.) by acetylation of the acetal (1.0 g.) in pyridine solution with acetic anhydride. It was recrystallized from 5 parts of alcohol as long needles which melted at 87–88°. It is readily soluble in acetic acid, acetone, chloroform and ethyl acetate and nearly insoluble in water.

Anal. Calcd. for $C_{12}H_{18}O_8$: C, 49.65; H, 6.25; CH_3CO, 44.5. Found: C, 49.69; H, 6.19; CH_3CO, 44.5.

(b) The **1,3,5-tribenzoyl-2,4-methylene-xylitol** (2.9 g., quantitative) which was obtained by the benzoylation of 1.0 g. of 2,4-methylene-xylitol in pyridine solution by benzoyl chloride (2.5 cc.) was recrystallized from 20 parts of alcohol and obtained in the form of needles which melted at 117–118°. The substance is soluble in cold chloroform, ethyl acetate and acetone, warm methyl and ethyl alcohols and insoluble in water.

Anal. Calcd. for $C_{27}H_{24}O_8$: C, 68.06; H, 5.08; C_6H_5CO, 66.2. Found: C, 68.16; H, 5.25; C_6H_5CO, 66.2.

(c) An ice-cold solution of 2.0 g. of 2,4-methylene-xylitol in 10 cc. of pyridine was mixed with a cold solution of 9.0 g. of *p*-toluenesulfonyl chloride in 15 cc. of pyridine and the mixture was allowed to stand at 20° for forty-eight hours. The **1,3,5,tritosyl-2,4-methylene-xylitol** (7.7 g.) which precipitated upon pouring the mixture upon crushed ice was recrystallized from 20 parts of 1:1 dioxane-alcohol as fine needles which melted at 198–199°. The compound is difficultly soluble in the usual organic solvents.

Anal. Calcd. for $C_{27}H_{30}O_{11}S_3$: C, 51.74; H, 4.83; S, 15.35. Found: C, 51.76; H, 4.89; S, 15.26.

1,5-Dibenzoyl-2,4-methylene-xylitol.—A solution of 1.0 g. of 2,4-methylene-xylitol in 10 cc. of pyridine was cooled in ice and to the stirred solution 1.4 cc. of benzoyl chloride (2 molecular equivalents) was added dropwise. After standing for two hours at 25° the mixture was poured upon crushed ice and the crystalline precipitate (1.3 g., 56%) was recrystallized from 20 parts of alcohol; the small needles so obtained showed a melting point of 139–140°; the substance is soluble in chloroform, pyridine and acetone and insoluble in water. The 1 and 5 positions for the benzoyl groups are assigned because of the well-known preferential benzoylation of primary hydroxyl groups under these experimental conditions; thus D-arabitol yields 1,5-dibenzoyl-D-arabitol,[10] the structure of which has been proved conclusively.

Anal. Calcd. for $C_{20}H_{20}O_7$: C, 64.51; H, 5.41; C_6H_5CO, 56.5. Found: C, 64.72; H, 5.34; C_6H_5CO, 55.9.

Stability of 2,4-Methylene-xylitol (III) against Oxidation by Sodium Periodate.—To a solution of 0.2032 g. of 2,4-methylene-xylitol in 10 cc. of water at 25°, 6.30 cc. of 0.432 *M* sodium periodate was added and the volume was adjusted to 25 cc. with water. Analysis of 5 cc. subsamples at the expiration of one and forty-eight hours showed that none of the sodium periodate had been consumed. The failure of this reagent to oxidize the 2,4-methylene-xylitol indicates that its structure does not include a glycol grouping. The only possible structure for a monoacetal of a pentitol which conforms with this limitation is that of a 2,4-acetal; methylene-xylitol is therefore 2,4-methylene-xylitol.

Summary

The isolation and proof of structure of 2,4:3,5-dimethylene-D,L-xylitol and 2,4-methylene-xylitol are described. The diacetal must be a 2,3,4,5-dimethylene-D,L-xylitol because its monotosyl derivative is converted to an iodo derivative which is reduced by hydrogen and Raney nickel to a desoxy-dimethylene-D,L-xylitol and this desoxy compound is identical with the 1-desoxy-2,3,4,5-dimethylene-D,L-xylitol that is obtained by treating the known 1-desoxy-2,3,4,5-di-isopropylidene-D,L-xylitol with formaldehyde and concentrated hydrochloric acid. The acetal linkages must be at positions 2,4 and 3,5 of the xylitol moiety because the saponification of the acetolysis product of the diacetal, namely, 1,5-diacetyl-3-acetoxymethyl-2,4-methylene-xylitol, yields a monomethylene-xylitol which is not oxidized by glycol-splitting reagents; this fact not only limits its structure to that of 2,4-methylene-xylitol but also proves that the structure of the dimethylene-D,L-xylitol from which it is derived must be that of 2,4:3,5-dimethylene-D,L-xylitol.

The experimental findings confirm and extend the previously published views regarding the limited acetolysis of the methylene acetals of the sugar alcohols.

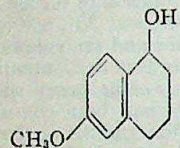
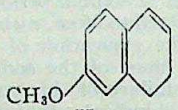
The Dimerization of 6-Methoxy-3,4-dihydronaphthalene

BY R. B. WOODWARD AND R. H. EASTMAN

On dehydration of 6-methoxy-1,2,3,4-tetrahydro-1-naphthol (I) with aqueous hydrobromic acid, Long and Burger[1] obtained a crystalline *substance*, $C_{11}H_{12}O$, m. p. 73–74°, which was formulated as 6-methoxy-3,4-dihydronaphthalene (II). Our interest in II as a possible intermediate in the synthesis of oestrone, or allied substances, prompted us to reinvestigate this reaction.

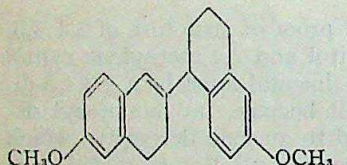


I

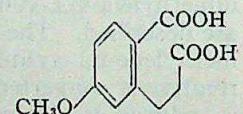


II

In this communication it is shown that the above substance is in fact a dimer of II, *viz.*, 2-(6-methoxy-1,2,3,4-tetrahydro-1-naphthyl)-3,4-dihydro-6-methoxynaphthalene (III).



III



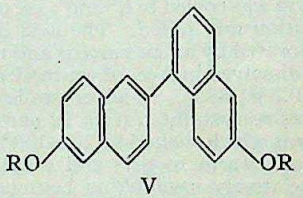
IV

Since neither the dehydration product obtained by the earlier investigators, nor our material, even after a number of recrystallizations, gave concordant analyses for the formula $C_{11}H_{12}O$, we carried out a chromatographic fractionation of the recrystallized substance on alumina. Over 90% of material was recovered, which on one further recrystallization melted at 75.5–77°, and analysis of which left no doubt that the empirical formula of the substance was $(C_{11}H_{12}O)_n$.

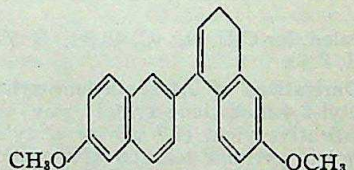
Quantitative titration of the dehydration product with perbenzoic acid indicated one double bond for a molecular weight of 320, and from the oxidation mixture, a crystalline *oxide*, $C_{22}H_{24}O_3$, m. p. 127–128.5°, was obtained. These observations indicated clearly that the original product had the dimeric formula, $C_{22}H_{24}O_2$ (320), and this conclusion was substantiated by direct molecular weight determinations on the material (290, 333) and on the above oxide (322, 326).

Oxidative degradation of the dimer with permanganate led to the isolation, in small quantity, of a dibasic acid, m. p. 201.5–203°, neutralization equivalent 112.6, undoubtedly β-(2-carboxy-4-methoxyphenyl)-propionic acid[2] (IV), and a *dehydro-compound*, $C_{22}H_{22}O_2$, m. p. 107.5–108.5° (VII, *vide infra*). The latter substance was subsequently obtained relatively smoothly and in better yield by the chromic acid oxidation of the dimer. Attempts to obtain products resulting from simple oxidative scission at the (presumable) double bond were unsuccessful.

Dehydrogenation of the dimer with sulfur, or better, catalytically over palladium-charcoal catalyst, gave a *hexadehydro-compound*, $C_{22}H_{18}O_2$, m. p. 91–92°, which was shown by synthesis to be 6,6′-dimethoxy-1,2′-binaphthyl (V, R = CH_3). Condensation of the Grignard reagent

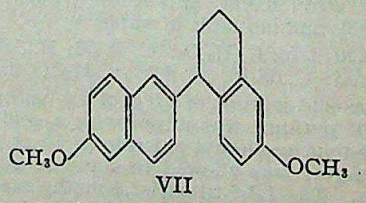


V



VI

from 2-bromo-6-methoxynaphthalene[3] with 6-methoxy-α-tetralone gave directly the dihydrobinaphthyl (VI), m. p. 126°. Catalytic dehydrogenation of VI gave the 6,6′-dimethoxy-1,2′-dinaphthyl (V, R = CH_3), identical in all respects with the hexadehydro compound from the dimer. Further, hydrogenation of the Grignard product (VI) gave a dihydro derivative (VII), which proved to be identical with the de-



VII

hydro compound, m. p. 108°, obtained by direct permanganate or chromic acid oxidation of the dimer.

These observations establish the structure of the dimer as III. The identity of the synthetic binaphthyl with that obtained from the dimer affords conclusive proof of the nature of the carbon skeleton of the latter. The identity of the synthetic substance VII with the dehydro compound from the dimer confirms the skeletal structure,[4]

(1) Long and Burger, *J. Org. Chem.*, **6**, 854 (1941).

(2) The prior preparation of this acid has been reported, without details, by Johnson and Anderson, abstracts of papers presented at the Atlantic City Meeting of the A. C. S., September, 1941, p. 13.

(3) Franzen and Staubel, *J. prakt. Chem.*, **103**, 369 (1922).

(4) Since all of the reactions used in establishing this identity were carried out under mild conditions, this proof of the nature of the carbon skeleton is possibly preferable to that involving the high temperature dehydrogenations. However, the work as a whole demonstrates that no rearrangement takes place during the latter reaction.

and further provides evidence in favor of the $\Delta^{1,2}$-position of the double bond, as opposed to the *a priori* alternatively possible positions, $\Delta^{2,1'}$, $\Delta^{2,3}$, or $\Delta^{1',2'}$. In this light, the failure to obtain products corresponding to simple oxidative fission at the double bond of the dimer is a consequence of the facility with which dihydronaphthalenes pass into the fully aromatic condition. Confirmation of the conjugation of the double bond with one of the aromatic rings is further provided by the absorption spectrum of the dimer (Fig. 1), which is strongly reminiscent of that of the (chromophorically) similarly constituted anethole, $CH_3OC_6H_4CH{=}CHCH_3$,[4a] and markedly different from that of a simple disubstituted anisole.

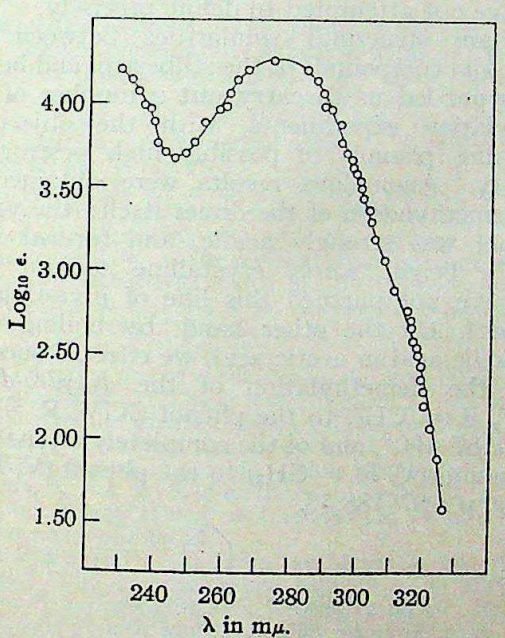

Fig. 1.—Absorption spectrum of 6,6′-dimethoxy-1,2,3,3′,-4,4′-hexahydro-1,2′-binaphthyl in ethanol; $\lambda_{max.}$ = 274 mμ, log ε = 4.25.

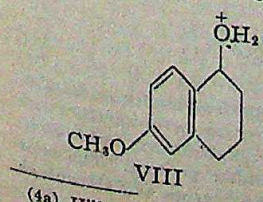
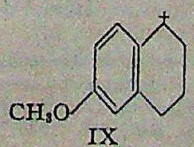
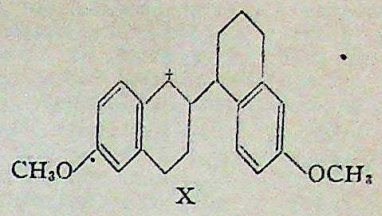
We turn now to a discussion of the mechanism by which the dimer is produced by the action of acid on 6-methoxy-α-tetralol. Loss of water from the conjugate acid (VIII) of the tetralol will give a carbonium ion (IX) (or its equivalent) which may (a) lose a proton with the formation of 6-methoxy-3,4-dihydronaphthalene (II) *and* (b) attack the latter product at the double bond (polarized in the sense $C^{1}{=}\overset{\curvearrowright}{C}^{2}$) to give the dimeric species (X). Loss of a proton from the latter intermediate then gives the dimer of structure



VIII

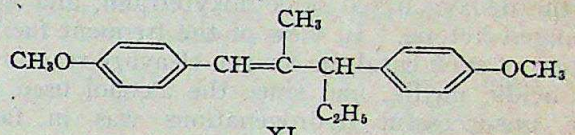


IX



X

III. A similar mechanism may be envisaged for the observed dimerization of anethole, in the presence of acidic reagents, to XI.[5]



XI

For the rest, we are concerned with a number of incidental observations made in the course of our experiments. The attack of perbenzoic acid on the dimer need not *a priori* have given an oxide: not infrequently, ketonic, or other isomeric, products are obtained with this reagent. In order to ascertain the structure of our *compound*, $C_{22}H_{24}O_3$, m. p. 127–128.5° (*vide supra*), we determined the ultraviolet absorption characteristics of the substance (Fig. 2). The spec-

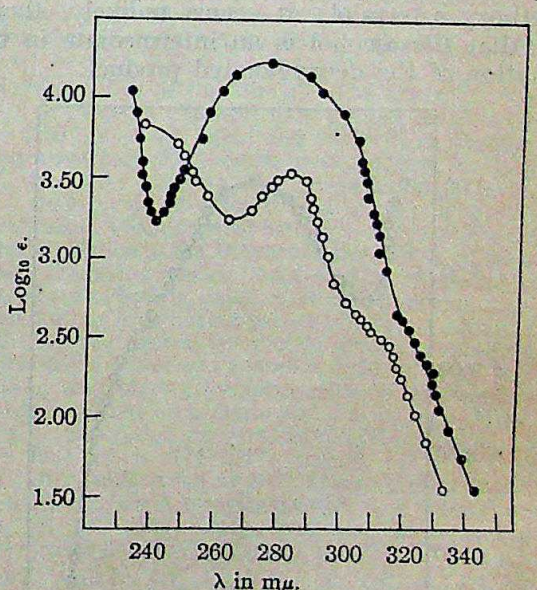


Fig. 2.—Absorption spectra in ethanol: ●, 6-methoxy-α-tetralone; $\lambda_{max.}$ = 276 mμ, log ε = 4.22; ○, 6,6′-dimethoxy-1,2,3,3′,4, 4′-hexahydro-1′, 2′-oxido-1, 2′-binaphthyl; $\lambda_{max.}$ = 283 mμ, log ε = 3.54.

trum shows a considerable resemblance in general form to isosafrole oxide,[6] and differs markedly, on the other hand, from that of 6-methoxy-α-tetralone. The conclusion would seem to be justified that our substance is a true oxide, of the structure XII.

The hydrogenation of 6-methoxy-α-tetralone to the corresponding alcohol (the immediate precursor of the dimer) is subject to variations,

XII

the exact cause of which has not been established. Frequently there were isolated, after the absorption of one mole of hydrogen, equimolar amounts of the deoxygenated 6-methoxytetralin, and unchanged ketone. In view of the frequent facilitation of such catalytic oxygen-cleavage reactions by acidic media, and since the alcohol used in the unsuccessful hydrogenations was in fact slightly acidic, we attempted, usually with success, to avoid this undesirable result by using as solvent ethanol which had been freshly distilled from sodium hydroxide. On the other hand, the reductions by this method proceeded more slowly and, in one case, the reaction would not start at all until a very small quantity of hydrochloric acid was added: it then proceeded rapidly and without untoward result (*i. e.*, no oxygen cleavage). In none of our hydrogenations did we observe concomitant formation of 6-methoxytetralin and 6-methoxy-α-tetralol; it seems unlikely, therefore, that the alcohol is an intermediate in the formation of the deoxygenated product.

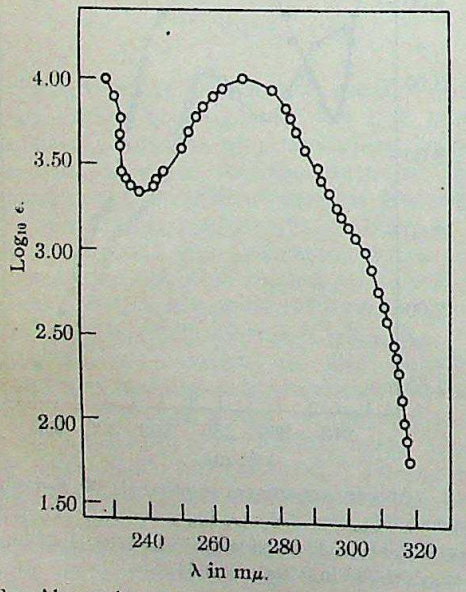

Fig. 3.—Absorption spectrum of 6-methoxy-3,4-dihydronaphthalene in ethanol.

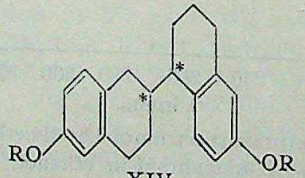
Although 6-methoxy-α-tetralone is now a readily available intermediate[7] the somewhat unpredictable course of the hydrogenations described above led us to investigate a more reliable source of the dimer. Oxidation of 6-methoxytetralin with red lead in acetic acid at room temperature gave a good yield of 6-methoxy-α-tetralol acetate[8] which, like the corresponding alcohol, was smoothly transformed into the dimer (III) by the action of hydrobromic acid.

The alkaline hydrolysis of the above acetate did not proceed smoothly: the main product was a new liquid *substance*, which is formulated as 6-methoxy-3,4-dihydronaphthalene (II) on the basis of analyses, physical properties and, in particular, the absorption spectrum (Fig. 3). In accordance with this view, the compound is transformed by aqueous hydrobromic acid into the dimer (III). The substance also was obtained occasionally during the distillation of 6-methoxy-α-tetralol (prepared by hydrogenation of the corresponding ketone), in consequence of conditions which we have not attempted to define precisely.

Certain structural similarities between the dimer and compounds of the stilbestrol and hexestrol types led us to carry out a number of demethylation experiments, with the object of obtaining phenols of possible high oestrogenic activity. Anomalous results were obtained in the demethylation of the dimer itself; the *yellow* product was strongly acidic, and formed with soda a bright *scarlet* crystalline sodium salt. We have not pursued this line of investigation further.[9] On the other hand, by boiling with hydriodic acid in acetic acid, we effected successfully the demethylation of the *dihydro-dimer* (XIV, R = CH_3) to the phenol (XIV, R = H), m. p. 187–190°, and of the completely aromatized compound (V, R = CH_3) to the phenol (V, R = H), m. p. 187–188.5°.



XIV

We should like to express our appreciation to Parke Davis and Co. for a grant to Harvard University for a Fellowship, which was held by the junior author while carrying out this investigation.

(7) One of us, with R. B. Loftfield, will describe in a subsequent communication, an excellent method for the preparation of the ketone from β-naphthol in 50% yield.

(8) Prior preliminary notice of the successful execution of this reaction has been given, without details, by Johnson and Anderson, *cf.* ref. 2.

(9) These observations suggest that oxidation has taken place at some stage in the reaction with formation of XIII. We may point out in support of this suggestion that the self-condensation of 6-methoxy-α-tetralone by *aqueous* sodium hydroxide (presumably with hydrolysis of the O-methyl groups [*cf.* Peak, Robinson and Walker, *J. Chem. Soc.*, 753 (1936)]) gives a similar product. The most reasonable formulation of the latter is a desmotrope of XIII with an additional hydroxyl at position

Experimental

6-Methoxytetralin, b. p. 129–131° (11 mm.) and **6-methoxy-α-tetralone,** m. p. 77–78°, were prepared from *ar*-(2)-tetralol by methylation and oxidation, following procedures developed in this Laboratory by other workers.[7]

6-Methoxy-1-acetoxy-1,2,3,4-tetrahydronaphthalene.—To 34.2 cc. of 6-methoxytetralin dissolved in 200 cc. of glacial acetic acid and 100 cc. of acetic anhydride, 138 g. of red lead was added in portions with stirring during eight hours. The resultant clear yellow solution was poured into an equal volume of chopped ice, and stirred vigorously to facilitate the separation of a large yellow crystalline precipitate, which was removed at once, washed with a small amount of ice water, and dissolved in ether. After washing, drying and removal of solvent, the residual red oil was distilled *in vacuo*; after *ca.* 5 g. of lower boiling material, 22 g. of the tetralol acetate, b. p. 144–149° (3 mm.), was obtained.

Anal. Calcd. for $C_{13}H_{16}O_3$: C, 70.89; H, 7.33. Found: C, 71.54; H, 6.94.

6-Methoxy-α-tetralol.—This substance was prepared by catalytic hydrogenation of 6-methoxy-α-tetralone. We have carried out this reaction a great many times; in our experience, the results are apt to vary, apparently adventitiously. Often the reduction proceeds directly to 6-methoxytetralin (*cf.* theoretical section). A typical cleavage experiment is reported.

The ketone (20 g.) in 400 cc. of 95% ethanol absorbed one mole of hydrogen in twenty-four hours on shaking over 0.3 g. of platinum oxide catalyst in the presence of 1 cc. of 1 *M* ferrous sulfate. After removal of catalyst and solvent, fractionation *in vacuo* gave 10 g. of 6-methoxytetralin, b. p. 135° (17 mm.), and 9.5 g. of unchanged 6-methoxy-α-tetralone, b. p. 180° (17 mm.), m. p. 76–78°, mixed with an authentic sample, m. p. 76–78°.

The following procedure illustrates the most consistently successful method: The ketone (10 g.) in 200 cc. of 95% ethanol (freshly distilled from sodium hydroxide) absorbed 1.2 moles of hydrogen in seventeen hours on shaking over 0.2 g. of platinum oxide. After removal of catalyst and solvent, 9.1 g. of 6-methoxy-α-tetralol, b. p. 175° (16 mm.), was obtained on fractionation *in vacuo* as a colorless, very viscous oil.

The Dimer (III): (a) From the Alcohol.—6-Methoxytetralol-1 (3.25 g.) was shaken with 32 cc. of 46% (by titration[10]) hydrobromic acid for twelve hours. The resultant solid pinkish-white ball, after recrystallization from ethanol, weighed 1.9 g. and had m. p. 74–75°.

Anal. Calcd. for $(C_{11}H_{12}O)_n$: C, 82.46; H, 7.55. Found: C, 83.33; H, 7.75.[11]

In view of the unsatisfactory analytical figures, the material was chromatographed on Brockmann alumina; the substance was put on with benzene, and eluted first with low-boiling petroleum ether, and then with benzene–petroleum ether (20/80). Fourteen (approximately weight equivalent) fractions were taken. All but three fractions, on evaporation and trituration with methanol, gave white crystalline material, m. p. 75–77°. The eleven fractions together constituted more than 90% of the original material, and were recrystallized from methanol, m. p. 75.5–77°.

Anal. Calcd. for $(C_{11}H_{12}O)_n$: C, 82.46; H, 7.55. Found: C, 82.59; H, 7.62. The other three fractions had melting points 69–74, 71–76, and 65–110°, and were not further investigated. As will be evident from (b, below), the tedious chromatographic separation may be obviated by distillation *in vacuo* of the crude dimer.

(b) From 6-Methoxy-α-tetralol Acetate.—The acetate (*vide supra*) (12.2 g.) was shaken for forty-eight hours with 150 cc. of 46% hydrobromic acid. The resultant viscous red material was taken up in ether, washed with soda, then water, dried, and distilled *in vacuo* after removal of solvent. The very viscous yellow oil (6.0 g., b. p. 233–238° (3 mm.)) obtained, on crystallization from methanol–ethyl acetate, separated in beautiful long needles, m. p. 75.5–76.5° (3.6 g.); recrystallized from ethanol, m. p. 76–77°.

Anal. Calcd. for $(C_{11}H_{12}O)_n$: C, 82.46; H, 7.55. Found: C, 82.65; H, 7.58. The absorption spectrum was taken in absolute ethanol (*vide* Fig. 1). Determination of the molecular weight (Rast). Calcd. for $C_{22}H_{24}O_2$: 320.4. Found: 290 (Tiedcke); 333 (R. H. E.).

Perbenzoic Acid Oxidation of the Dimer.—The purified dimer (2.53 g., 0.0079 mole) dissolved in 200 cc. of chloroform was treated with 1.19 g. of perbenzoic acid in 50 cc. of chloroform. The reaction, which was carried out below 5°, was followed iodimetrically:

Time, hr.	0.0645 *N* $Na_2S_2O_3$/cc. (aliquot), cc.
0	1.07
2	0.27
19	.11
25	.10
26	.10

These figures indicate one double bond for a molecular weight of 320. The reaction mixture, which still possessed oxidizing power, was washed with dilute bisulfite solution, soda, and water; removal of solvent and trituration with methanol–petroleum ether gave 0.8 g. of material, m. p. 124–126°; recrystallized from ethanol, faintly yellow needles, m. p. 127–128.5°.

Anal. Calcd. for $C_{22}H_{24}O_3$: C, 78.54; H, 7.19. Found: C, 78.45; H, 7.69. The absorption spectrum was taken in absolute ethanol (*vide* Fig. 2). Determination of the molecular weight (Rast). Calcd. for $C_{22}H_{24}O_3$: 336.4. Found: 322, 326 (Tiedcke).

Hydrogenation of the Dimer.—The dimer (1.30 g.) in 10 cc. of glacial acetic acid took up 116 cc. of hydrogen (t = 25.5°, p = 680 mm.) and stopped, on shaking 254 minutes over reduced platinum oxide. Calcd. for $C_{22}H_{24}O_2$: mol. wt., 320.4. Found (by hydrogenation): mol. wt. 307. On removal of catalyst and solvent, a viscous oil was obtained which resisted attempts at crystallization.

Demethylation of the Dihydro-dimer.—The oil from the above experiment was dissolved in 5 cc. of glacial acetic acid, heated to boiling, and 5 cc. of 57% hydriodic acid was added drop by drop during twenty minutes. After boiling until a test portion was completely soluble in caustic soda, the reaction mixture was poured into 50 cc. of 1% sodium bisulfite; the resulting flocculent yellow precipitate (1.1 g.) was recrystallized from dilute acetic acid, m. p. 170–176° (0.5 g.). Successive recrystallizations from glacial acetic acid: first, m. p. 174–184°; second, m. p. 177–184°; third [after sublimation at 190° (2 mm.), glass obtained] 177–186°. A fourth recrystallization from *n*-butyl ether, m. p. 181–187°, and, finally, from aqueous alcohol, gave white microcrystalline needles, m. p. 187–190° (0.2 g.).

Anal. Calcd. for $C_{20}H_{22}O_2$: C, 81.59; H, 7.53. Found: C, 81.01; H, 8.08.

Sharp-melting samples of this material were extremely difficult to obtain; the crude material is undoubtedly a mixture of stereoisomers of the formula XIV (R = H), which has two asymmetric carbon atoms (starred). The similar situation in the case of the hydrogenated dimer XIV (R = CH_3) was doubtless responsible for the failure of this material to crystallize.

Oxidation of the Dimer: (a) By Potassium Permanganate.—The dimer (2.3 g.) in 55 cc. of acetone with 2.3 g. of sodium bicarbonate was oxidized with 2.64 g. of potassium permanganate during nine hours at 0°. After standing overnight the precipitated manganese dioxide was removed. The residual red oil after evaporation of the acetone was taken up in acetic acid and precipitated with water. The crystalline material which separated (0.78 g., m. p. 79–81°) was recrystallized (m. p. 83.5–85°) and gave analytical figures indicating partial oxidation (C, 81.55; H, 7.01); the material was then oxidized in 50 cc. of acetic

(10) The use of 46% acid (Long and Burger[1] used 48% material) actually results in a much smoother reaction; a solid product is obtained directly.

(11) Long and Burger[1] found: C, 83.13; H, 7.86.

acid with 0.5 g. of permanganate at room temperature during three hours. The residue after filtration and evaporation *in vacuo* was taken up in ether, washed with soda, water, dried, and decolorized. From the extract, 0.6 g. of a viscous red oil was obtained which on solution in methanol, decolorization, precipitation with water, and two recrystallizations from methanol, gave VII, 0.02 g., clusters of white needles, m. p. 107.5–108.5°. The material was identical in all respects with that obtained by chromic acid oxidation of the dimer (*vide infra*). Mixtures of VII with the dimer had melting points intermediate between those of the pure substances (*cf.*, *e. g.*, the partially oxidized material described above).

The manganese dioxide from the first oxidation (above) was leached with 350 cc. of boiling water. After concentration to half-volume, acidification gave 0.5 g. of a dark gum, which was taken up in soda, decolorized, extracted with ether to remove neutral impurities, and reacidified. The resultant granular yellow solid was crystallized from acetic acid to give pure IV: first, m. p. 201–203°; second, m. p. 201.5–203° (0.10 g. of colorless needles). Neut. equiv. Calcd. for $C_{11}H_{12}O_5$: 112.2. Found: 112.6.

(b) **By Chromic Acid.**—To the dimer (0.90 g.) in 75 cc. of glacial acetic acid, a solution of 0.56 g. of chromium trioxide in 15 cc. of glacial acetic acid and 10 cc. of water was added dropwise with stirring during one hour. After removal of most of the acetic acid *in vacuo*, water was added. The reaction mixture was extracted with ether, which was then washed with soda, water, and dried. The neutral residue after removal of solvent, crystallized from ethanol (0.15 g.), m. p. 107–108.5°. This material (VII), twice recrystallized from ethanol, formed long white needles, m. p. 108–109°.

Anal. Calcd. for $C_{22}H_{22}O_2$: C, 82.95; H, 7.00. Found: C, 83.56; H, 7.14.

Mixed with the material of like melting point from the permanganate oxidation (*vide supra*), m. p. 107.5–109°. The synthesis of this substance is described below.

Dehydrogenation of the Dimer: (a) With Sulfur.—The dimer (1.20 g., 0.0038 mole) mixed intimately with 0.60 g. of sulfur was heated on a metal bath; the hydrogen sulfide evolved was collected in a nitrometer over dilute sulfuric acid previously saturated with the gas. Evolution of gas began at 200°, and heating to 300° during two hours drove off 221 cc. (0.0092 mole) of hydrogen sulfide. The black mass was extracted with hot dilute acetic acid, the extract was evaporated *in vacuo*, the residue was extracted with methanol, from which a gummy solid separated on cooling. On recrystallization from methanol–ethyl acetate, 0.3 g. of V (R = CH_3) was obtained as white needles, m. p. 88–90°. This material was identical with that prepared more smoothly and in better yield by catalytic dehydrogenation (see (b), below).

In a similar experiment, extraction of the initial fusion product with ether left a light yellow residue, which on crystallization from toluene separated in straw-colored needles, m. p. 210–212° (10 mg.). Qualitative tests indicated the presence of sulfur in the material, and it was not further investigated.[12]

(b) **By Catalytic Dehydrogenation.**—The dimer (4.2 g., 0.013 mole) was mixed with 2.6 g. of 10% palladium-charcoal catalyst, and heated in a stream of carbon dioxide at 300° during four hours; the evolved gases (866 cc., 91% of the theoretical quantity for three moles of hydrogen per mole of compound) were collected over 20% sodium hydroxide solution in the usual way. The product was taken up in ether. The residual oil after evaporation of the filtered ethereal solution was distilled *in vacuo*, b. p. 255–260° (3 mm.). Crystallization of the viscous yellow distillate from the minimum quantity of acetic acid gave V (R = CH_3) as beautiful white needles, m. p. 89–90° (1.95 g.). Recrystallized from glacial acetic acid, m. p. 91–92°.

Anal. Calcd. for $C_{22}H_{18}O_2$: C, 84.03; H, 5.77. Found: C, 84.29; H, 5.93.

(12) *Cf.* Hudson and Robinson, *J. Chem. Soc.*, 718 (1941), for a similar result in the sulfur dehydrogenation of a tetralin derivative.

Mixed with the material of like melting point from the sulfur dehydrogenation ((a), above), the m. p. was 88–90°. The synthesis of this compound is described below.

6,6′-Dihydroxy-1,2′-binaphthyl (V, R = H).—To 6,6′-dimethoxy-1,2′-binaphthyl (0.8 g.) in 5 cc. of boiling glacial acetic acid, 5 cc. of 57% hydriodic acid was added dropwise during twenty minutes. The reaction mixture was boiled until a test portion was completely soluble in 5% aqueous sodium hydroxide. On pouring into 50 cc. of 1% sodium bisulfite solution, 0.6 g. of gummy material separated, which was crystallized from the minimum quantity of acetic acid as a purplish microcrystalline powder, m. p. 184–185° (0.4 g.). On recrystallization from acetic acid in the presence of a trace of zinc dust, the substance (V, R = H) separated in small light-yellow needles, m. p. 187–188.5°.

Anal. Calcd. for $C_{20}H_{14}O_2$: C, 83.90; H, 4.93. Found: C, 83.53; H, 5.43.

6-Bromo-β-naphthol was prepared by the elegant method of Franzen and Staubel[3]; from it, however, **6-methoxy-2-bromonaphthalene** was prepared more smoothly and in better yield by catalytic etherification, with methanol and sulfuric acid, than by the dimethyl sulfate–alkali method of those authors. The phenol (46 g.) in 50 cc. of methanol and 10 cc. of concentrated sulfuric acid was heated under reflux overnight. The solid mass of crystalline material was removed, washed in turn with methanol, water, caustic soda, and water, and crystallized from ethanol, white needles (43 g.), m. p. 102–103°. After distillation *in vacuo* (b. p. 160–164° (3 mm.)), m. p. 105–106°.

Condensation of 6-Methoxy-2-naphthylmagnesium Bromide with 6-Methoxy-α-tetralone.—In order to carry out successfully the preparation of the Grignard reagent, it was essential to use freshly distilled bromo compound.

6-Methoxy-2-bromonaphthalene (7.11 g.) in 250 cc. of dry ether was added during eight hours to 0.85 g. of magnesium turnings suspended in a small volume of ether under a current of dry nitrogen at the reflux temperature [ethyl bromide (0.8 cc.) and a crystal of iodine were added to start the reaction]. The solution was concentrated to 100 cc., 75 cc. of dry benzene was added, and the reaction-mixture was boiled for forty-eight hours with stirring. After addition of 6-methoxy-α-tetralone (4.3 g.) in 50 cc. of dry benzene, the solution was heated further for twenty-four hours. Then, with vigorous stirring, 100 cc. of 20% ammonium chloride solution was added; the organic layer was separated, washed, dried (sodium sulfate) and concentrated, finally *in vacuo*. Trituration of the residue with ether and methanol gave 3 g. of a yellowish-white solid, which crystallized from benzene–methanol in white needles, m. p. 127–128°. Twice recrystallized from benzene–methanol, the 6,6′-dimethoxy-3,4-dihydro-1,2′-binaphthyl (VI) separated in needles, m. p. 126°.

Anal. Calcd. for $C_{22}H_{20}O_2$: C, 83.50; H, 6.38. Found: C, 83.26; H, 6.04.

6,6′-Dimethoxy-1,2′-binaphthyl (V, R = CH_3) (by synthesis).—Dehydrogenation over 10% palladium charcoal catalyst (1 g.) of 1.5 g. of the synthetic compound (VI) at 300° gave 90 cc. of hydrogen (80%) at 25° and 760 mm., and, after solution of the organic product in ether, removal of catalyst, and evaporation of solvent, 1.4 g. of crystalline material, m. p. 87–92°. On recrystallization from glacial acetic acid, 6,6′-dimethoxy-1,2′-binaphthyl (V, R = CH_3) separated in white needles, m. p. 91–92°, identical in appearance with the substance obtained by the dehydrogenation of the dimer (*vide supra*), and mixed with that material, m. p. 91–92°.

Synthesis of 6,6′-Dimethoxy-1,2,3,4-tetrahydro-1,2′-binaphthyl (VII).—On hydrogenation of 107 mg. of the Grignard product (VI) (above), in glacial acetic acid over 50 mg. of reduced platinum oxide, 9.8 cc. (110% of the theoretical) of hydrogen was taken up during forty minutes (*p*, 760 mm.; *t*, 25°). After removal of catalyst, the product was precipitated as lustrous white plates (80 mg.), which were crystallized from alcohol, m. p. 106–107°. After two recrystallizations from ligroin, m. p. 107.5–

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

108.5°, mixed with the chromic acid (*or* permanganate) oxidation product of the dimer (*vide supra*), m. p. 107–108°.

6-Methoxy-3,4-dihydronaphthalene.—In the course of the above work, this material was obtained occasionally during distillation of 6-methoxy-α-tetralol, from hydrogenation of 6-methoxy-α-tetralone. The observation that the material in the pot was deep green when the decomposition occurred suggests that the irregularity was caused by the presence of a small amount of chromium salts in the ketone.

6-Methoxy-α-tetralone (9.0 g.) was hydrogenated in the usual way (*vide supra*). During distillation, decomposition occurred, and water appeared in the condenser: Fraction 1; 5.8 g., b. p. 110–118° (3 mm.); Fraction 2: 2.6 g. crystalline solid, m. p. 77–78°, b. p. 130–135° (3 mm.), mixed with 6-methoxy-α-tetralone, m. p. 77–78°. The low-boiling material was redistilled, 3.0 g., b. p. 107–111° (2.5 mm.); d^{30} 1.068; $n^{21}D$ 1.5825; M_R, 50.5. Calcd. for $C_{11}H_{12}O$, 4|⁻, 48.3, $\Delta M_R = 2.2$.

Anal. Calcd. for $C_{11}H_{12}O$: C, 82.46; H, 7.55. Found: C, 81.82; H, 7.53.

The physical constants may be compared with those of 6-methoxy-1,2,3,4-tetrahydronaphthalene [b. p. 105–106° (4 mm.), d^{19} 1.039, $n^{26.5}D$ 1.5441]. The absorption spectrum of the dihydro compound was measured in ethanol (Fig. 3), $\lambda_{max.} = 269$ mμ, $\log \epsilon = 4.00$.

After shaking 2.8 g. of the material with 46% hydrobromic acid for twelve hours, a crystalline solid was obtained, which on crystallization from alcohol separated in lustrous white needles (1.72 g.), m. p. 70–72°. Recrystallized from alcohol, the m. p. was 75°; mixed with the dimer, m. p. 75°.

The dihydro compound also was obtained by the hydrolysis of 6-methoxy-1-acetoxytetralin with alcoholic sodium hydroxide.

Summary

The acid-catalyzed dehydration of 6-methoxy-1,2,3,4-tetrahydro-1-naphthol gives 6,6′-dimethoxy-1,2,3,3′,4,4′-hexahydro-1,2′-binaphthyl.

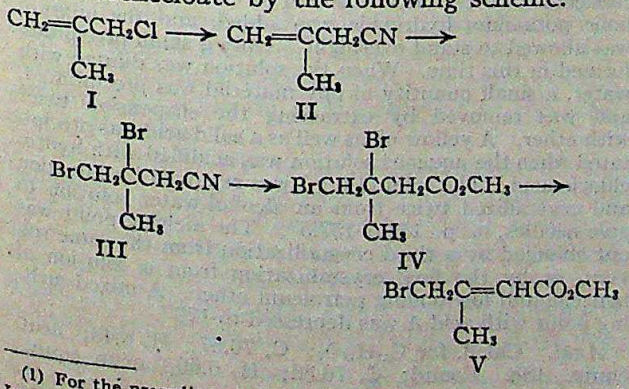
Reformatsky Condensations Involving Vinylogs of Haloacetic Esters. II.[1] Methyl γ-Bromosenecioate

BY REYNOLD C. FUSON AND PHILIP L. SOUTHWICK[2]

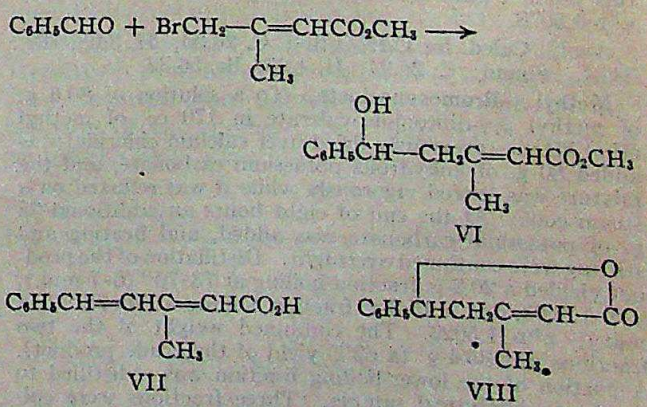
By the use of γ-halocrotonates in the Reformatsky reaction a synthetic route was found to polyene acids.[1] This method has now been extended to a β-methyl-γ-halocrotonate, methyl γ-bromosenecioate (V). The use of this new ester makes possible the extension of a carbon chain by an isoprene unit and thus opens the way for the synthesis of truly carotenoid chains.

After this work had been completed it was discovered that very similar results had been obtained by Ziegler, Schumann and Winkelmann.[3] One of the chief differences between our work and that of the German writers lies in the method of synthesis of the bromoester (V). The direct bromination of the senecioic ester[4] appears to be more convenient than our method which involved the conversion of methallyl chloride into methyl γ-bromosenecioate by the following scheme.



It was found that attempts to purify the ester obtained by this method were attended by very serious losses. For this reason the ester was used in a somewhat impure condition.

To determine whether the methyl γ-bromosenecioate could be condensed with carbonyl compounds by the Reformatsky method, a test run was made with benzaldehyde. The results were similar to those of Ziegler, Schumann and Winkelmann. The isolation and purification of the products presented difficulties. During the distillation and hydrolysis of the expected hydroxy ester (VI), decomposition occurred giving rise to a mixture of compounds. Chief of these were two isomeric unsaturated acids, evidently *cis–trans* forms of β-styrylcrotonic acid (VII). It is not clear which of these isomers corresponds to the product (m. p. 157°) described by Ziegler, Schumann and Winkelmann.



A third product isomeric with the two acids appeared to be the corresponding lactone (VIII).

Experimental

Methallyl Cyanide.—The method of Tamele, Ott, Marple and Hearne[5] was used. From 422 g. of commercial cuprous cyanide and 418 g. of methallyl chloride there was obtained 285 g. (76%) of a water-white liquid boiling at 134.5–136.5°; $n^{20}D$ 1.4180.

Anal. Calcd. for C_5H_7N: C, 74.03; H, 8.70. Found: C, 74.28; H, 8.97.

In another run using 456 g. of cuprous cyanide and an initial 454 g. of methallyl chloride, more methallyl chloride was added until it no longer continued to react, as evidenced by vigorous refluxing of the mixture. An additional 160 cc. was required. By this means 349 g. of methallyl cyanide was obtained (an 86% yield based on the cuprous cyanide).

β,γ-Dibromoisovaleronitrile.—A solution of 200 g. of bromine in 200 cc. of dry chloroform was added dropwise to a stirred solution of 100 g. of methallyl cyanide in 400 cc. of dry chloroform. The mixture was cooled in a water-bath during the addition. When the solution ceased to absorb bromine, shortly before all of it had been added, the addition was stopped.

Removal of the solvent at temperatures not above 60° left 297 g. of crude dibromo nitrile. A portion of the heavy, yellow oil was distilled twice at reduced pressure. Distillation was accompanied by the evolution of hydrogen bromide, even when conducted at relatively low pressures. The product was a colorless oil, b. p. 89° (2–3 mm.), $n^{20}D$ 1.5308.

Anal. Calcd. for $C_5H_7NBr_2$: C, 24.92; H, 2.93; N, 5.81; Br, 66.33. Found: C, 25.62; H, 3.32; N, 6.33; Br, 65.79.

γ-Bromosenecionitrile.—Eighty-nine grams of the crude dibromonitrile was dissolved in 200 cc. of methyl ethyl ketone, and 92 g. of anhydrous potassium carbonate was added. The mixture was refluxed on a steam cone and stirred overnight. The product was a nearly colorless, lachrymatory liquid, boiling at 84° (8 mm.); $n^{20}D$ 1.5175. The yield was nearly 50%.

Anal. Calcd. for C_5H_5NBr: C, 37.55; H, 3.78; N, 8.75; Br, 49.94. Found: C, 38.09, 37.90; H, 3.98, 3.96; N, 8.76; Br, 49.37.

Methyl β,γ-Dibromoisovalerate.—To 200 g. of crude β,γ-dibromoisovaleronitrile was added a solution of 250 cc. of concentrated sulfuric acid in 400 cc. of methanol, and the mixture was stirred vigorously at the reflux temperature. More methanol was added from time to time to replace that which escaped from the condenser. Heating and stirring were discontinued after nine hours, and the mixture was allowed to stand overnight.

The crude product (124 g.), together with 20 g. of a similar crude product from a trial run, was distilled at reduced pressure through a carborundum-packed column. The major fraction, a colorless liquid boiling at 80–83° (2–3 mm.), weighed 104 g. Redistillation of a portion of this product gave a sample boiling at 84–85° (3 mm.); $n^{20}D$ 1.5078.

Anal. Calcd. for $C_6H_{10}O_2Br_2$: C, 26.30; H, 3.68; Br, 58.34. Found: C, 26.94; H, 4.25; Br, 56.32.

Methyl γ-Bromosenecioate.—To a solution of 80.6 g. of methyl β,γ-dibromoisovalerate in 170 cc. of methyl ethyl ketone (previously dried over calcium chloride) was added 80 g. of anhydrous potassium carbonate, and the mixture was stirred vigorously while it was refluxed on a steam cone. At the end of eight hours an additional 25 g. of potassium carbonate was added, and heating and stirring were continued overnight. Distillation of the product yielded a 20.2-g. fraction boiling at 73–76° (6–7 mm.); $n^{20}D$ 1.5003, and a 15.2-g. fraction boiling at 76–78° (6–7 mm.); $n^{20}D$ 1.5023. The combined weight of the two fractions was 35.4 g. (a 62% yield of the crude product). A portion of the lower-boiling fraction was redistilled to obtain an analytical sample. Three fractions were collected, the first boiling at 63° (3 mm.); $n^{20}D$ 1.5002, the second at 63–66° (3 mm.), and the third at 66° (3 mm.); $n^{20}D$ 1.5010. A Kjeldahl determination showed the presence of 0.1% of nitrogen in the first fraction, from which the following analytical results were obtained:

Anal. Calcd. for $C_6H_9O_2Br$: C, 37.33; H, 4.70; Br, 41.40. Found: C, 38.26; H, 5.13; Br, 39.28.

The remainder of the crude product was redistilled at a higher pressure. A large part of it boiled at 98–100° (24 mm.), although the last distillate from the higher-boiling crude fraction came over at 107°. The compound was highly lachrymatory.

Condensation of Methyl γ-Bromosenecioate with Benzaldehyde.—The procedure was similar to that described by Ziegler, Schumann and Winkelmann. A mixture of 24.6 g. of methyl γ-bromosenecioate, 16 g. of purified benzaldehyde, 25 cc. of dry benzene and 6 cc. of dry ether was placed in the dropping funnel, and 10.5 g. of 20-mesh granulated zinc (freshly cleaned with hydrochloric acid and dried with absolute alcohol and dry ether) was placed in the flask.

Approximately one-tenth of the mixture was run into the flask, and a crystal of iodine was added. When the flask was warmed over a low flame, the reaction began almost immediately. Stirring was then begun, and the mixture was added rapidly enough to maintain gentle refluxing of the solvents. The addition required about twenty-five minutes. Stirring was continued, and the mixture was maintained at the reflux temperature over a low flame for an additional two and one-half hours. Distillation of the product at a pressure of 2–3 mm. yielded a 3-g. fraction boiling at 146–148°, a 2.6-g. fraction at 148–152°, and a 9.2-g. fraction at 152–176°.

β-Styrylcrotonic Acid (Form A).—When 1 g. of the fraction boiling at 146–148° (2–3 mm.) was dissolved in 10 cc. of saturated alcoholic potassium hydroxide solution, a voluminous precipitate formed in a few minutes. The mixture was allowed to stand overnight, then diluted with water, and acidified. The precipitated acid was crystallized successively from benzene, alcohol and water, and benzene. White needles, melting at 158.5–159.5°, were obtained.

Anal. Calcd. for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43; neut. equiv., 188. Found: C, 76.76; H, 6.56; neut. equiv., 190.

This acid is probably identical with the high-melting form reported by Kuhn and Hoffer.[6]

β-Styrylcrotonic Acid (Form B).—The high-boiling fraction from the condensation (b. p. 152–176° (2–3 mm.)) was redistilled in the presence of a few crystals of iodine[7] in the hope of dehydrating the hydroxy ester which it was believed to contain. No water distilled from the mixture, however. A fore-run boiling at 146–155° (2–3 mm.) and a 3.9-g. fraction boiling at 172–178° (2–3 mm.) were collected. To the latter fraction 50 cc. of saturated alcoholic potassium hydroxide was added, and the mixture was allowed to stand overnight. Only a small precipitate formed in this time. When the solution was diluted with water, a small quantity of oily material was precipitated, and was removed by extracting the suspension twice with ether. A yellow oil as well as a solid acid was precipitated when the aqueous solution was acidified with hydrochloric acid. The solid (1.5 g.) was removed by filtration and crystallized twice from an alcohol-water solution to give needles, m. p. 156.5–157.5°. The melting point was not changed by a third crystallization from the same solvent, or by the final crystallization from a solution of benzene and low-boiling petroleum ether. A mixed melting point with acid A was depressed to 120°.

Anal. Calcd. for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43; neut. equiv., 188. Found: C, 76.36; H, 6.66; neut. equiv., 190.

Lactone of β-Styrylcrotonic Acid (IX).—After acid B had been removed by filtration, as described above, the oil

which was precipitated at the same time was extracted from the filtrate with ether. The ethereal extract evaporated to leave a residual oil and several large crystals. The crystals dissolved when the mixture was stirred with 10% potassium carbonate solution, but the oil did not, and was removed from the suspension by ether extraction. Acidification of the bicarbonate solution precipitated an additional 0.3 g. of acid, and evaporation of the ether extract left 0.8 g. of an oil which solidified completely after standing for two days. This material melted at 55–57°, and crystallized in the form of needles or plates from mixtures of ether and low-boiling petroleum ether. After two crystallizations from these solvents it melted at 61–62°.

Anal. Calcd. for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43. Found: C, 76.46; H, 6.66.

The compound dissolved slowly in cold aqueous potassium hydroxide solution and could be recovered by acidification of this solution. It dissolved more rapidly in saturated alcoholic potassium hydroxide solution and was not precipitated by dilution of the solution with water. When the diluted solution was acidified with hydrochloric acid a solid product, m. p. 155–157°, was precipitated. This compound was found by the mixed melting point method to be identical with acid B. It seems probable that the compound melting at 61–62° is the lactone of δ-hydroxy-β-methyl-δ-phenyl-α-pentenoic acid.

β-Styrylcrotonic Acid (Form A) from Benzalacetone and Ethyl Bromoacetate.—The procedure employed was essentially that of Kohler and Heritage.[8] These investigators, however, distilled the hydroxy ester which they obtained and subsequently dehydrated it by heating with hydrochloric acid, whereas in the present instance it was more convenient to dehydrate the crude ester directly by distillation in the presence of a few crystals of iodine. To the product obtained from the Reformatsky condensation of 61 g. of benzalacetone with 70 g. of ethyl bromoacetate, 0.1 g. of iodine was added and distillation was carried out under reduced pressure. After the water had been removed, three fractions were collected; a 14.5-g. fraction at 141–145° (2 mm.), a 20-g. fraction at 145–147° (2 mm.) and a 3-g. fraction at 147–149° (2 mm.).

To 1 g. of the middle fraction was added 25 cc. of saturated alcoholic potassium hydroxide solution, and the mixture, in which a precipitate quickly formed, was allowed to stand for two days. The precipitate dissolved when the solution was diluted with water, and a crude acid, m. p. 120–140°, was precipitated when the solution was acidified with hydrochloric acid. White needles melting at 158–159° were obtained after three crystallizations from benzene. No depression of the melting point was observed when this product was mixed with acid A from condensation of benzaldehyde with methyl γ-bromosenecioate.

The melting point reported by Kohler and Heritage[8] was 153°. von Auwers and Müller,[9] using the same method, obtained a product melting at 156–157°. Kuhn and Hoffer reported a melting point of 160°. It seems probable that all the samples made by this method are identical, and different from form B.

URBANA, ILLINOIS RECEIVED JANUARY 20, 1944

Summary

A method has been developed for the preparation of methyl γ-bromosenecioate from methallyl chloride.

Methyl γ-bromosenecioate has been condensed with benzaldehyde to yield two forms of β-styrylcrotonic acid and a third compound thought to be the lactone corresponding to the expected hydroxy acid.

1,2-Addition of Methylmagnesium Iodide to Mesityl Ketones

BY REYNOLD C. FUSON, M. D. ARMSTRONG, WM. E. WALLACE[1] AND J. WAYNE KNEISLEY[2]

The carbonyl group of simple mesityl ketones has been known to react additively only with hydrogen. In particular, normal or 1,2 addition of a Grignard reagent has never been observed.[3] Recently mesityl *t*-butyl diketone (I) was found to undergo 1,2 addition of methylmagnesium iodide to each of the carbonyl groups.[4] Also the conversion of certain mesitoic esters to ketones by the action of Grignard reagents[5] may be explained by assuming 1,2 addition of the reagent to the ester carbonyl group.

These results led to a reëxamination of the behavior of simple mesityl ketones toward the Grignard reagent. The most favorable structure appeared to be that in which the mesitoyl radical was joined to the smallest possible group that possessed no *alpha* hydrogen atom. Among aliphatic radicals *t*-butyl was the logical choice. However, pivalylmesitylene (II) could not be induced to react with methylmagnesium iodide.[4] In the aromatic series benzoylmesitylene (III) appeared to offer the best chance of realizing 1,2 addition.

$MesCOCOC(CH_3)_3$ (I) $\qquad$ $MesCOC(CH_3)_3$ (II)

When benzoylmesitylene was treated with methylmagnesium iodide it was converted in 64% yield to 1-mesityl-1-phenylethylene (V), the dehydration product of the carbinol (IV) that would have resulted from 1,2 addition. The direct production of the olefin rather than the carbinol is similar to results obtained by others.[6]

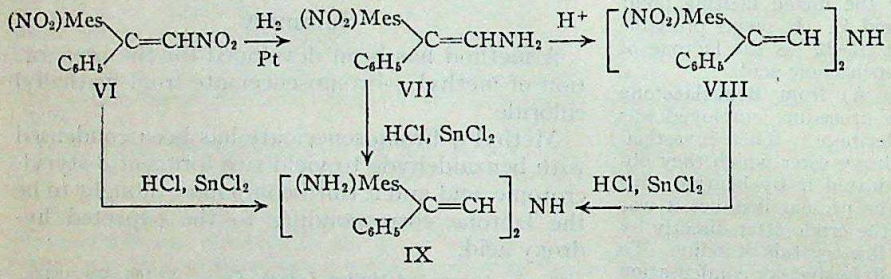
The structure of the olefin was established by an independent synthesis. 1-Mesityl-1-phenylethylene was formed in 15% yield by the condensation of mesitylmagnesium bromide with acetophenone. The experimental conditions were similar to those which were employed with the benzoylmesitylene and the product was the ethylene rather than the carbinol.[7]

Since the olefin was a liquid, it was desirable to compare the two samples by reference to a solid derivative. Such a derivative was prepared by nitration according to the procedure used by Anschütz and Romig to nitrate 1,1-diphenylethylene.[8]

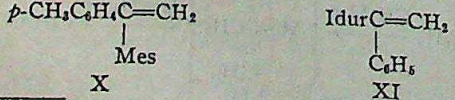
The nitro derivative, 2-(3-nitromesityl)-2-phenyl-1-nitroethylene (VI), was very much like known nitroölefins. The reduction products are shown in the following outline.



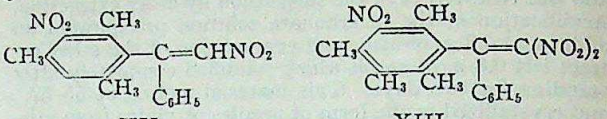
The nitroamine (VII) has been written as a vinylamine rather than as an imine because of the analogy with 2,2-dimesitylvinyl alcohol.[9] It was neutral and could not be hydrolyzed to the corresponding aldehyde and thus appeared to differ in type from the corresponding derivative of 1,1-diphenylethylene.[10]

It did resemble 2,2-diphenylvinylamine,[11] however, in the ease with which it lost ammonia in the presence of acids to yield the corresponding divinylamine (VIII). Reduction with stannous chloride in ethanolic hydrochloric acid converted VI, VII and VIII to the aminodivinylamine, IX. The divinylamines are similar to 2,2,2′,2′-tetraphenyldivinylamine, described by Lipp[12] and by Krabbe and Schmidt.[11]

p-Toluylmesitylene and benzoylisodurene reacted with methylmagnesium iodide in a manner similar to that observed with benzoylmesitylene. The products were 1-mesityl-1-(*p*-tolyl) ethylene (X) and 1-isoduryl-1-phenylethylene (XI), respectively. The latter also was prepared by condensing acetophenone with isodurylmagnesium bromide. The 1-mesityl-1-*p*-tolylethylene (X),



obtained only in impure form, yielded a dinitro derivative (XII) analogous to VI. 1-Isoduryl-1-phenylethylene, by a slightly different procedure, gave a trinitro derivative (XIII).



The new olefins immediately decolorized a solution of permanganate and were attacked by chromic acid. They decolorized a solution of bromine in carbon tetrachloride with the evolution of a small amount of hydrogen bromide.

Experimental

Benzoylisodurene.—This ketone was made by condensing 134 g. of isodurene with 140 g. of benzoyl chloride by the Friedel–Crafts method. The ketone was purified by fractionation *in vacuo;* b. p. 159–164° (4 mm.); m. p. 60–61°; yield 78%.

Anal.[13] Calcd. for $C_{17}H_{18}O$: C, 85.67; H, 7.61. Found: C, 85.98; H, 7.57.

Benzoylmesitylene and Methylmagnesium Iodide.—A solution of 30 g. of benzoylmesitylene, prepared according to the directions of Montagne,[14] in 50 cc. of dry ether was added slowly to a solution of methylmagnesium iodide, prepared from 30 g. of methyl iodide, 5.4 g. of magnesium and 75 cc. of dry ether. After the addition was completed, a little benzene was added and ether was allowed to evaporate until the temperature of the vapors was 60°. The reaction mixture was then stirred under reflux for sixteen hours. The contents of the flask were decomposed and the organic layer was separated. After the solution had been washed with water and dried, the solvent was removed by evaporation. The resulting oil was distilled *in vacuo*. The fraction which came over at 129–134° (3 mm.) was collected; yield 19 g. (64%); $n^{20}D$ 1.5812. Redistillation yielded the pure olefin; b. p. 120° (3 mm.); $n^{20}D$ 1.5835; d_{20}^{20} 1.0003.

Anal. Calcd. for $C_{17}H_{18}$: C, 91.84; H, 8.16; *MR*, 74.2. Found: C, 91.57; H, 8.19; *MR*, 74.4.

1-Mesityl-1-phenylethylene was obtained also by the condensation of acetophenone with mesitylmagnesium bromide. To a mesitylmagnesium bromide solution, prepared from 41 g. of bromomesitylene and 6.5 g. of magnesium in 100 cc. of dry ether, a solution of 20 g. of acetophenone in 25 cc. of dry ether was added at such a rate that the ether refluxed vigorously. When the addition was completed the reaction mixture was refluxed for one hour, cooled in an ice-bath and decomposed with cold, dilute hydrochloric acid. The ether layer was treated in the usual manner and the viscous, yellow oil which was isolated was distilled *in vacuo*. The forefraction contained 12 g. of mesitylene and 12 g. of acetophenone. The main fraction was redistilled *in vacuo* until the index of refraction remained constant; this required four distillations; yield 3 g.; b. p. 117–120° (4 mm.); $n^{20}D$ 1.5831; d_{20}^{20} 1.0004. The olefin was a light yellow oil which decolorized neutral permanganate immediately and reacted with bromine with the evolution of hydrogen bromide.

Reactions of 1-Mesityl-1-phenylethylene.—A solution of the olefin rapidly decolorized a solution of potassium

permanganate in the cold. It absorbed bromine from a bromine solution in carbon tetrachloride; the evolution of hydrogen bromide was detected.

A small amount of platinum oxide was added to a solution of 0.73 g. of the olefin in 40 cc. of 95% ethanol, and the solution was shaken for several hours with hydrogen at one atmosphere. One mole of hydrogen was absorbed.

The 1-mesityl-1-phenylethane boiled at 154–155° (4 mm.); $n^{23}D$ 1.5621.[15]

Anal. Calcd. for $C_{17}H_{20}$: C, 91.01; H, 8.99. Found: C, 90.64; H, 9.11.

The isomeric hydrocarbon 1-mesityl-2-phenylethane is a solid melting at 39–39°.[16]

2-(3-Nitromesityl)-2-phenyl-1-nitroethylene (VI).—A mixture of 6.5 g. of fuming nitric acid, 4 cc. of glacial acetic acid and 4 cc. of acetic anhydride was added dropwise, with stirring, over a period of one hour to an ice-cold solution of 8 g. of 1-mesityl-1-phenylethylene in 5.5 cc. of acetic anhydride. Yellow crystals appeared during the addition of the nitrating mixture. The crude dinitro derivative was collected on a filter; yield 7 g. It crystallized from ethanol in yellow plates melting at 144–145°.

Anal. Calcd. for $C_{17}H_{16}N_2O_4$: C, 65.37; H, 5.16; N, 8.97; mol. wt., 312. Found: C, 65.23; H, 5.36; N, 8.89; mol. wt. (cryoscopic in benzophenone), 306.

2-(3-Nitromesityl)-2-phenylvinylamine (VII).—A mixture of 5 g. of 2-(3-nitromesityl)-2-phenyl-1-nitroethylene (VI), 100 cc. of ethyl acetate and 0.1 g. of platinum oxide catalyst was shaken in an atmosphere of hydrogen. Hydrogen was absorbed rapidly. After thirty minutes the mixture was filtered to remove the catalyst and the solvent was evaporated by a stream of air. The orange residue was recrystallized from ethanol; m. p. 100–101°; yield 4 g.

Anal. Calcd. for $C_{17}H_{18}N_2O_2$: C, 72.32; H, 6.43; N, 9.92; mol. wt., 280. Found: C, 72.42; H, 6.30; N, 10.03; mol. wt. (cryoscopic in benzophenone), 290.

The **acetyl derivative** was formed by heating a mixture of the amine (VII) (1 g.) with acetic anhydride (5 cc.) under reflux for fifteen minutes. It separated from ethanol in pale yellow crystals; m. p. 199–200°.

Anal. Calcd. for $C_{19}H_{20}N_2O_3$: C, 70.35; H, 6.23; N, 8.64. Found: C, 70.45; H, 6.24; N, 8.67.

The **benzoyl derivative** was produced by shaking 0.5 g. of the amine (VII) with 1 cc. of benzoyl chloride and 5 cc. of 10% sodium hydroxide for ten minutes. The mixture was poured into water and the product was purified by recrystallization from ethanol. It formed pale yellow crystals melting at 143–144°.

Anal. Calcd. for $C_{24}H_{22}N_2O_3$: C, 74.59; H, 5.74; N, 7.25. Found: C, 74.60; H, 5.96; N, 7.19.

2,2′-Di-(3-aminomesityl)-2,2′-diphenylvinylamine (IX).—A mixture of 5 g. of 2-phenyl-2-(3-nitromesityl)-1-nitroethylene (VI), 250 cc. of absolute ethanol, 25 g. of hydrated stannous chloride and 25 cc. of concentrated hydrochloric acid was heated gradually at first and finally under reflux, for six hours. The product was the divinylamine, IX. It was recrystallized from 95% ethanol. It rapidly turned blue when allowed to stand in the air. In the pure state it had a light cream color; m. p. 184–186°.

Anal. Calcd. for $C_{34}H_{37}N_3$: C, 83.73; H, 7.65; N, 8.62; mol. wt., 488. Found: C, 83.86; H, 7.65, 7.50; N, 8.78; mol. wt. (cryoscopic in benzophenone), 489.

The divinylamine (IX) was obtained also by the reduction of the nitro amine (VII). A mixture of 2 g. of the amine, 100 cc. of absolute ethanol, 8 g. of hydrated stannous chloride and 10 cc. of concentrated hydrochloric acid was heated for eight hours under reflux. The amine was isolated in the usual manner; m. p. 184–186°.

The divinylamine was produced also by reduction of 2,2′-di-(3-nitromesityl)-2,2′-diphenyldivinylamine (VIII). The procedure was similar to that just described for reducing the mononitro amine (VII); m. p. 184–186°.

(15) This compound was prepared by Dr. Norman Rabjohn.

(16) Fuson, Denton and Best, *J. Org. Chem.*, **8**, 64 (1943).

2,2′-Di-(3-nitromesityl)-2,2′-diphenyldivinylamine (XIII).—When 5 g. of 2-(3-nitromesityl)-2-phenylvinylamine (VII) was dissolved in 95% ethanol and 10 cc. of 6 *N* hydrochloric acid was added, the divinylamine (VIII) separated from the solution as a yellow solid. It was recrystallized from glacial acetic acid; m. p. 235–236°.

Anal. Calcd. for $C_{34}H_{33}N_3O_4$: C, 74.56; H, 6.07; N, 7.67; mol. wt., 548. Found: C, 74.75; H, 6.16; N, 7.77; mol. wt. (cryoscopic in benzophenone), 582.

Treatment of this amine with a hot mixture of concentrated hydrochloric acid and glacial acetic acid produced no change.

1-Isoduryl-1-phenylethylene.—The condensation of benzoylisodurene with methylmagnesium iodide, carried out in the manner described for that of the mesityl analog, produced 1-isoduryl-1-phenylethylene as a yellow oil boiling at 152–154° (3 mm.); $n^{20}D$ 1.5872; d_4^{20} 1.000; yield 42%.

Anal. Calcd. for $C_{18}H_{20}$: C, 91.47; H, 8.53; *MR*, 77.7. Found: C, 91.31; H, 8.35; *MR*, 79.2.

The same compound was obtained, in 10% yield, by the condensation of acetophenone with isodurylmagnesium bromide; b. p. 156–157° (4 mm.); $n^{20}D$ 1.5864. This olefin decolorized an acetone solution of potassium permanganate. It was readily attacked by chromic acid in acetic acid.

A by-product of the reaction between methylmagnesium iodide and benzoylisodurene was a red-orange solid. After repeated recrystallization from absolute ethanol, it melted at 191–192.5°. The yield in grams was about the same as that of the olefin.

Anal. Calcd. for $C_{34}H_{38}O_2$: C, 85.31; H, 8.00; mol. wt., 478. Found: C, 85.80; H, 8.17; mol. wt. (ebullioscopic in chloroform), 457.

This compound did not reduce neutral potassium permanganate solution; it reacted slowly with bromine in carbon tetrachloride, with the evolution of hydrogen bromide. It was treated with acetyl chloride, but no derivative could be isolated.

Three grams of the olefin was treated with hydrogen at 50° and 2000 lb. pressure in the presence of Raney nickel. The product, 1-isoduryl-1-phenylethane, boiled at 160° (5 mm.); $n^{20}D$ 1.5695; d_4^{20} 0.990; m. p. 54.5–55°.

Anal. Calcd. for $C_{18}H_{22}$: C, 90.69; H, 9.31; *MR*, 78.4. Found: C, 90.78; H, 9.54; *MR*, 78.9.

2-(3-Nitroisoduryl)-2-phenyl-1,1-dinitroethylene (X).—1-Isoduryl-1-phenylethylene was nitrated in a manner similar to that described for mesitylphenylethylene except that the nitration mixture was allowed to stand for two days at room temperature. The trinitro derivative separated from ethanol in pale yellow crystals; m. p. 193–194°.

Anal. Calcd. for $C_{18}H_{17}N_3O_6$: C, 58.22; H, 4.62; N, 11.29. Found: C, 58.00; H, 4.84; N, 11.15.

1-Mesityl-1-(*p*-tolyl)-ethylene.—To prepare this olefin methylmagnesium iodide was condensed with *p*-toluylmesitylene by a procedure similar to that used to make the corresponding mesitylphenylethylene. The product was difficult to purify, being contaminated in all probability with the ketone. Nitration, however, produced a satisfactory sample of the dinitro derivative (IX).

2-(3-Nitromesityl)-2-*p*-tolyl-1-nitroethylene (IX).—This compound was prepared from 1-mesityl-1-*p*-tolylethylene by a procedure similar to that described for the phenyl derivative. The gummy residue solidified only after several weeks. It separated from ethanol in yellow crystals; m. p. 174–175°.

Anal. Calcd. for $C_{18}H_{18}N_2O_4$: C, 66.24; H, 5.56; N, 8.59. Found: C, 65.88; H, 5.47; N, 8.75.

Summary

It has been shown that methylmagnesium iodide condenses in the 1,2 manner with benzoylmesitylene, benzoylisodurene and *p*-toluylmesitylene.

The product in each case is not the expected carbinol, but the olefin that would be formed from it by dehydration. The yields of 1-mesityl-1-phenylethylene and of 1-isoduryl-1-phenylethylene were 64 and 42%, respectively.

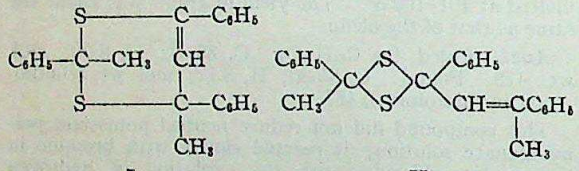
The Synthesis of 2,4-Diarylthiophenes[1]

BY E. CAMPAIGNE

Baumann and Fromm,[2] while investigating thioacetophenone, reported the isolation of a compound, $C_{24}H_{22}S_2$, in good yield from the alcoholic mother liquors of the thioacetophenone preparation. Pyrolysis of this disulfide gave 2,4-diphenylthiophene but no yield was reported. On the basis of analysis and the formation of 2,4-diphenylthiophene, two possible structures were assigned to this compound, which they called "Anhydroacetophenone disulfide"

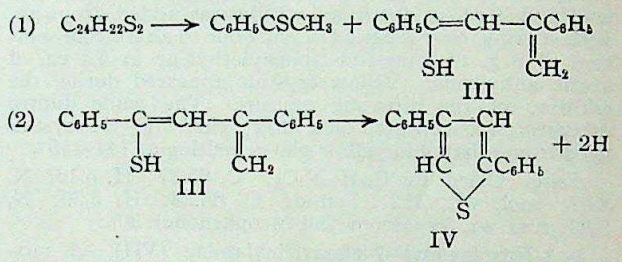


I II

Structure I was assumed to be the most probable, since dithioacetophenone had never been isolated.

The synthesis of 2,4-diarylthiophenes has been reviewed by Bogert and Herrera.[3] These compounds are usually prepared by the reaction of phenylethylene or its derivatives with sulfur. This type of reaction gives a possibility of three different isomers, and consequently the yields have been extremely low. Bogert and Herrera[3] reported that by fusing acetophenone anil with sulfur, 2,4-diphenylthiophene was obtained in 28% yield. No 2,5-diphenylthiophene was found. These authors suggest that the formation of thioacetophenone as an intermediate accounts for the higher yield and lack of formation of 2,5-diphenylthiophene. However, Baumann and Fromm[2] reported the isolation of both 2,4- and 2,5-diphenylthiophene from the pyrolysis of thioacetophenone.

It seemed most probable that if either structure, (I) or (II), of "Anhydroacetophenone disulfide" given by Baumann and Fromm[2] were correct, highest yields of pure compounds could be obtained through this intermediate, since only 2,4-diarylthiophene, (IV), could be formed, according to the equations



III IV

The hypothetical compound III forms 2,4-diphenylthiophene by the loss of two atoms of hydrogen. In the pyrolysis of "Anhydroacetophenone disulfide" apparently acetophenone acts as the hydrogen acceptor, since in addition to the diarylthiophene, styrene and hydrogen sulfide were isolated.[2]

Several experiments were conducted to determine the yield of 2,4-diphenylthiophene from "Anhydroacetophenone disulfide." Pyrolysis of the material at 180° gave a tarry residue from which it was only possible to obtain sufficient pure 2,4-diphenylthiophene for identification. Refluxing the compound for several hours in boiling xylene caused a color change from colorless to deep purple. This would be expected, since the compound is unstable above its melting point, decomposing to give the highly colored thioketone monomers. No diarylthiophene could be isolated from this reaction, but the oily residue contained unsaturated carbon linkages. Apparently the reaction represented by the second equation does not take place readily. When this mixture was treated with copper chromite catalyst, IV was obtained in 83% yield. This reaction might be expected, since this catalyst has been used in the dehydrogenation of alcohols.[4]

A similar experiment with the "Anhydrodisulfide," V, prepared from *p*-methoxypropiophenone gave a 66% yield of 2,4-di-*p*-anisyl-3,5-dimethylthiophene, VI. This reaction was shown to proceed in two steps, as indicated by equations 1 and 2, as follows: the "Anhydrodisulfide" V, was refluxed in xylene, causing decomposition to an unsaturated oil. No thiophene derivative was formed by this treatment. However, when this residual oil was refluxed in alcohol with copper chromite, the dianisylthiophene, VI, was formed in good yield. "Anhydro-*p*-methoxypropiophenone disulfide," V, was not changed by re-

fluxing in alcohol alone, or with copper chromite. Therefore, it seems probable that the first step in the reaction is not influenced by copper chromite, but only occurs at high temperatures, near the melting point of the "anhydro-disulfide." The temperature necessary to initiate the second step is dependent on the efficiency of the hydrogen acceptor, because at the temperature of refluxing alcohol copper chromite is active, while it was necessary to heat the compound above 180° for thioacetophenone to be active.

Since compound VI theoretically has no active hydrogens, the usual derivatives were not formed. However, the compound was sufficiently stable, so that the ether linkages could be hydrolyzed to give a di-*p*-hydroxy compound, which was acetylated to the diacetate. In addition to analysis of its derivatives, the identity of the new compound was further clarified by comparison of its ultraviolet absorption curve with that of IV, 2,4-diphenylthiophene. The absorption curves were taken in methanol solutions, using a Hilger Model E-498 spectrograph and a Spekker Photometer. The solutions were approximately 5×10^{-5} molar, and the cell thickness was 1 cm. The molar extinction coefficient, E, is plotted against the wave length in Fig. 1. It is apparent that the new compound VI, Curve II, and 2,4-diphenylthiophene, IV, Curve I, are very similar in structure, since both show maximum absorption at 250, 265 and 280 millimicrons.

Experimental

Preparation of "Anhydroacetophenone Disulfide."—Forty grams of acetophenone was dissolved in 300 ml. of absolute alcohol, and cooled to 0° in an ice–salt bath. Dry hydrogen chloride was passed in for a few minutes, until the rate of gas influx could be regulated, and then hydrogen sulfide also was passed in at a slow rate. Approximately 140 g. of dry hydrogen chloride (the amount calculated to saturate the alcohol) was passed into the solution over a period of six hours. During this time the reaction flask was kept in the ice–salt bath. When all the hydrogen chloride was used, the bath was allowed to come to room temperature while hydrogen sulfide was passed continuously into the flask for eight hours longer. About three hours after starting white crystals began to form in the flask, and a purple resin precipitated. After fourteen hours, the gas-inlet tubes were removed, and the flask was stored in the refrigerator overnight. The white crystals were stirred up and filtered from the mother liquor, leaving the purple resin of thioacetophenone in the flask. The crystals of "Anhydroacetophenone disulfide" were washed once with alcohol and dried. The crude product melted from 106–109°. The yield was 23.5 g. or 57% of theoretical. After two recrystallizations from acetone, the product was obtained in white hexagonal bars, m. p. 107–108° cor.

Anal.[5] Calcd. for $C_{24}H_{22}S_2$: C, 77.00; H, 5.88; S, 17.11. Found: C, 77.04; H, 5.64; S, 17.09.

Reaction of "Anhydroacetophenone Disulfide" with Copper Chromite.—The copper chromite catalyst was prepared according to the directions of Lazier and Arnold.[6] It was finely ground in a mortar before use. Three grams of the sulfur compound was dissolved in 35 ml. of dry xylene, and 10 g. of the copper chromite powder was added. The mixture was brought to reflux and stirred. No hydrogen sulfide was evolved during the course of three hours. At the end of this time the mixture was cooled and filtered. The residual catalyst was washed thoroughly with xylene, and the combined washings and filtrate distilled under water-pump vacuum to remove xylene. The brown residue solidified on cooling. It was dissolved in about 80 ml. of boiling methanol, and treated with norite. Upon cooling, white flaky crystals deposited. These were recrystallized from methanol, and dried. The melting point was 120.6–121.5° cor. The yield was 1.58 g., 83% of theoretical.

Anal. Calcd. for $C_{16}H_{12}S$: C, 81.31; H, 5.08; S, 13.56. Found: C, 81.24; H, 4.89; S, 13.53.

This compound has a reactive hydrogen at position 5, and readily forms a picrate in bright red needles, m. p. 133.1–133.6° cor. Fromm and Fantl[7] give the melting point of the picrate of 2,4-diphenylthiophene as 133–134°. It also gives the 5-chloromercuri- derivative with alcoholic mercuric chloride, white needles, m. p. 222–223° corresponding to the 5-chloromercuri-2,4-diphenylthiophene obtained by Bogert and Herrera.[3]

Preparation of "Anhydro-*p*-methoxypropiophenone Disulfide."—Twenty grams of *p*-methoxypropiophenone, b. p. 124–128° (4 mm.), (from anisole and propionic anhydride with aluminum chloride[8]) was dissolved in 120 ml. of absolute alcohol, and hydrogen chloride and hydrogen sulfide passed in at 0° as in the previous preparation. Approximately 50 g. of dry hydrogen chloride was used. The reaction was allowed to continue for twelve hours. The solution became deep red in color, due to *p*-methoxythiopropiophenone. As the reaction proceeded, white needle-like crystals precipitated. After storing in the refrigerator overnight, the precipitate was filtered off. The red color had faded to a faint pink by this time. The precipitate was recrystallized from a mixture of equal parts
